Machinery.

Engineering Edition.

Index to Vol. XI.

September, 1904, to August, 1905.

1905.

The Industrial Press.
66 WEST BROADWAY,
NEW YORK.

Index to Volume XI.

Acetylene Gas as an Explosive ... 531
Acid for Etching High Speed Steel. (H. & W., 57) ... 656
Acid Hardening Bath. "I. W. Antano" ... 655
Acme Taps in Sets ... 268
Adams-Farwell Automobile ... 131
Adams, John D.
- Elliptical Chuck ... 413
- Three-Piece Ellipsograph Again ... 491
- Three-Piece Ellipsograph 151
- Link Motion for Rotating a Shaft 180 Degrees ... 214
- One-Turn Clutch ... 598

Adding Attachment for the Typewriter ... 371
Adjustable Boring Tool. F. A. Hobbs ... 551
Advertising Scheme, An. R. Earl Weinland ... 547
Advice to Apprentices. John Mark May ... 434
Aeroplane and Flying Machine, The ... 88
Air Compressor with Minimum Clearance Space ... 481
Air-lubricated Journal ... 52
Air Pump, Westinghouse Compound ... 640
Albespeyre Tunnel, The Ventilator of the. Dr. Alfred Gradenwitz ... 32
Alcohol as a Source of Power 641
Alcohol Motor in France, The 318
Allen, Leicester.
- Some Faults of Indexing ... 353

Allis-Chalmers Shops, Spherical Boring and Turning in the ... 574
Alloy of Aluminum, Copper, and Manganese ... 577
Aluminum for Bedplates and Other Castings ... 222
Aluminum, Fusing and Molding of ... 107
Aluminum Patterns, Soldering ... 627
Alternators of the N. Y. Subway, Engine-driven ... 533
Aluminum, Making Castings in ... 35
Aluminum, Soldering. R. Earl Weinland ... 494
Aluminum, Something about. Earl N. Percy ... 413
Amalgam for Stopping Leaks, Blowholes, etc. O. M. Becker ... 655
American Blower Co.'s New Engine, The ... 309
American Industries, German View of ... 370
American Machine Exports to Germany ... 403
Ammonal ... 20
Ammonia on Iron, Effect of. 390
Angle Bars, Method of Bending ... 34
"Angle of Pressure" of Spur Gears ... 331
Angle of V-Tool to Plane Notches, etc. (H. & W., 52) ... 606
Angles from a Table of Tangents, To lay out ... 220
Anisometric Projection. Robt. Grimshaw ... 492
"Antano, I. W."
- To Bronze Yellow Brass ... 605
- Acid Hardening Bath ... 655

Anvil Block, Improved. J. H. DeGroodt ... 379
Application of Motors to Machine Tools ... 372
Apprentice, A Successful ... 99
Apprentices, Advice to. John Mark May ... 434
Apprenticeship Question, The. Prof. John E. Sweet ... 52
Armature, Rewinding of ... 486
Armstrong Bros.' Shops, Making Inserted Cutters in 631
Arras, C. C.
- Prick Punch with Interchangeable Scriber Points 604

Arthur, James.
- A Five Minute Repeater Clock ... 339
- Friction of Sliding Keyways ... 218
- "Standard" Nose Threads for Lathe Spindles ... 95

Artisans—5th Annual Session, Summer School for .. 475
Asbestos, Applying. James A. Pratt ... 604
Ash, Harry.
- Coloring Steel ... 391
- To Mottle Casehardened Pieces ... 331

Ashley, Carroll.
- An Experiment with Gas. 381
- A Leather Medal ... 150

A. S. M. E. Annual Meeting of the ... 236
A. S. M. E., June Meeting of the ... 545
A. S. M. E., Scranton Meeting of the ... 593
Automatic Gear Cutting Machine, An ... 578
Automatic Prick Punch with Adjustment. Otis D. Storer 381
Automatic Twist Drill Grinding Machine ... 511
Auto-meter for Automobiles. 139
Auto-meter, The Warner ... 362
Automobile Record, A High-speed ... 311
Automobiles, Auto-meter for 139
Automobiles, Experiments with ... 258
Automobile Show, The ... 320
"Autopyrophon," The ... 203

Babbitt Crossheads, To. J. V. N. Cheney ... 442
Babbitt Metal or Lead from Exploding, To Prevent. R. B. Casey ... 605
Bachmann, H. J.:
- Wire Straightener ... 151
- Cement for Sticking Leather Fillet on Brass Patterns ... 331
- A System of Drill Jigs for Rough Castings ... 209
- Regarding Accuracy of Jigs ... 330
- Punch and Die Adjustable to Cut Sectors of Various Lengths ... 387
- Milling and Drilling Jig .. 595

Balancing Arrangement for the Rams of Boring Mills ... 202
Balancing Balls, Alleged Method for ... 445
Balancing Centrifugal Pumps 586
Balancing High-Speed Gasoline Engine ... 498
Balancing High-Speed Machinery, Notes upon ... 183
Balancing Moving Parts ... 524
Ball and Roller Bearings, Carrying Capacity of. (How and Why 11) ... 107
Ball-bearing Rifle Gun ... 32
Ball Bearings ... 329
Ball Cases on Internal Bearings, Method for Burnishing ... 384
Ball, M. H.:
- Prick Punch Holder ... 160
- A Finishing Boring Bar for Bronze ... 654

Ball Reamer, Simple ... 104
Band Brake Design, More Notes on. C. F. Blake ... 344
Bandsaw in the Machine Shop, The ... 85
Bandsaws, Cold-soldering .. 202
Bardons & Oliver Lathe, A Large ... 13
Bar Holder, Facing. B. M. Weller ... 269
Barnard, Wm. N.:
- Strength of Beams with Ribbed Sections, a Paradox ... 176

Barney:
- Catching Threads and Gaging the Depth ... 152

Barnitt, Correction in Name 475
Bath Universal Grinding Machine, New ... 360
Baxter, Jr., William:
- Variable Speed Motors ... 26 120, 171, 246, 348, 399, 513

Beale, Oscar J.:
- To Copper Brass for Laying Out Work ... 605

"Beams and Planes Eccentrically Loaded." E. E. Graham ... 175
Beams and Planes with Several Supports. E. E. Graham ... 29
- John S. Myers ... 30
- "C. F. Blake" ... 68

Beams, Graphical Solution for ... 214
Beams with Ribbed Sections, Strength of — A Paradox. Wm. N. Barnard ... 176
Becker, O. M.:
- To Mend Broken Oil Stones 442
- Amalgam for Stopping Leaks, Blowholes, etc. . 655

Bedplates and Other Castings, Aluminum for ... 222
Bell, A. R.:
- Iron and Its Early Manufacture in England ... 185

Bells, Old Formula for ... 421
Bells, The Designing and Making of. F. P. Lotz ... 295
Belt, Improved Method of Allowing for a Slack ... 371
Belting ... 537
Belts, Lacing ... 276
Bench Vise, Quick-action ... 83
Bending Angle Bars, Method of ... 34
Bending Angles and Structural Shapes. Frank B. Kleinhans ... 306
Bending Cast Iron Pipe ... 94
Bending Dies, Some Hints on 273
Bending Fixtures for Two Operations, Set of ... 325
Bending Stresses in Wire Ropes ... 426
Benjamin, C. H.:
- The Bursting Strength of Wooden Pulleys ... 613

Bevel Curve, Solution of the. Charles Clonkey ... 93
Bicycle Ball Stopped a Train, How a ... 582
Bierbach, A. F.:
- Lubricating Soap for Wire Drawing, Screw Cutting and Working Metals ... 444

Bierbaum, C. H.:
- Oil Grooves and the Fitting up of Bearings ... 459

Binder Pulleys versus a Keeper Belt ... 390
Birnstock, W. W.:
- Filler for Defective Castings ... 331

Birrell, Edwin M.:
- Pattern Shop of the U. S. Naval Gun Factory ... 241

Blacken Brass for Templet Work and Other Purposes, To. P. H. Oto ... 495
Blacken Brasswork for Instruments, To. Jos. M. Stabel ... 655
Blacking Brass. F. H. Jackson ... 444
Black Marks on Graduated Surfaces, To Make. F. H. Jackson ... 655
Black Powder, Report on by Chief Mason of Bureau of Ordnance ... 472
Blackwell's Island Bridge, N. Y., Pins Used in the New ... 530
Blake, C. F.:
- More Notes on Band Brake Design ... 344
- Beams and Planes with Several Supports ... 68

Blake (W. H.) Condenser, The ... 500b
Blanking and Forming Dies. V. H. Marcellus ... 649
Bliss Press with Special Feed 644
Bluing from Tempered Steel, To Remove. F. H. Jackson 605
Bluing Small Brass and Steel Articles by Immersion, For. L. E. Muncy ... 605
Blue-prints ... 54
Bluff that Went," "A. "A. P. Press" ... 601
Bog Fuel, The Possibilities of 256
Boiler Explosion ... 657
Boiler, Large Water Space Watertube ... 263
Boiler Plate Ever Rolled, Largest ... 257
Boiler Shell Chart ... 68
Boiler Tube, A Spirally Corrugated ... 86
Borax, Process for Pulverizing. Albert D. Knavel ... 444
Boring and Turning a Cast Iron Bushing in Halves, Method of ... 275
Boring Bar for Chasing Threads ... 153
Boring Bar Holder ... 159
Boring Bar, Radial Attachment for. D. Lindsay ... 330
Boring Brasses, Fixture for. Philadelphia ... 159
Boring, Facing and Turning Small Spur Gears, Appliances for. "Jaymac" ... 650
Boring Mill, A Ridgway 10-16 Foot, The First Tool Produced ... 407
Boring Rotary Pump Casing, Tool for. L. Myers ... 440
Boring Taper Holes in Lathe Tail Spindles. E. H. Fish .. 651
Boring Tool, Adjustable. F. A. Hobbs ... 551
Bornholt, O. C.:
- Bushings for Drilling and Reaming Jigs ... 491

"Boston Tool" for Model Work ... 277
Bouvier Governor for Water Turbines. Dr. Alfred Gradenwitz ... 523
Boy Electricians ... 267
Brains are His Own, A Man's 422
Brass Railings, Cost of Polishing ... 297
Brass, Silver Paste for. J. S. Gordon ... 391
Brass Wire in Brazing, The Use of. F. H. Jackson .. 605
Brasswork for Instruments, To Blacken. J. M. Stabel 655
Brass Work, Frosting. F. H. Jackson ... 495
Bridge Building since 1880 .. 86
Bridge Over St. Lawrence River, Steel ... 585
Bridge, The Zambesi River .. 144
Bristol:
- Loose Pulleys ... 490

Bristol, F. B. (Obituary) ... 184
British Industrial Methods, Reorganization of ... 294
British Patent Laws, Stricter 140
Bronze, A Finishing Boring Bar for. M. H. Ball ... 654
Bronzes, Characteristics of .. 312
Bronze Yellow Brass, To. I. W. Antano ... 605
Brooks, Wm. H.:
- A Handy Tool for Locating and Aligning Shafting and Machinery ... 76

Bruised Threads, To Straighten ... 389
Brooks, W. J.:
- Flexible Curves for Draftsmen ... 497

Brutsche, A. J.:
- Method of Boring and Turning Cast Iron Bushing in Halves ... 275

Buchet, E. J.:
- How the Pillow-block Seat of a Large Engine was Planed Out with a Small Planer ... 218
- Modern Work with Ancient Tools ... 649

Buffing Wheels, Exhausting Arrangement for ... 475
Building Construction, Steel Cage ... 640
Bullard 36-inch Vertical Turret Lathe ... 367
Bullard Machine Co., Method of Finishing Gears at ... 16
Burbank, L. S.:
- Table of Spur Gear Teeth Giving Diametral Pitch 212
- Mixture for Making a Porous Casting Air and Water Tight ... 444

Burnishing Ball Cases on Internal Bearings, Method for 384
Burns, Charles E.:
- Improvised Vertical Milling Machine ... 323

Bursting of Four-foot Flywheels, The ... 261
Bursting Strength of Wooden Pulleys, The. C. H. Benjamin ... 613
Bushings for Drilling and Reaming Jigs. O. C. Bornholt ... 491

Calculating Charts ... 425
Calipering the Fit of a Screw Thread. H. E. Wood ... 275
Camera, A Sketching. Warren E. Willis ... 326
Camming Screw Machines for Thread Cutting. G. H. 388
Cam, The Davis Self-Locking 44
Carborundum Wheels. Ezra F. Landis ... 102
Car Inspectors are Beaten, How ... 40
Carnegie Engineering Building, Plans for the ... 137
Carpet Tack, New ... 33
Carriage Stop for Lathe. J. A. Webster ... 383
Carrying Capacity of Ball and Roller Bearings (How and Why 11) ... 107
Calcium Reduced by Electrolysis ... 533
Car Wheel Press, Handy Water Connection for. A. E. Mitchell ... 443
Car Wheels, Rolled Steel ... 427
Casehardening ... 642
Case-hardening Cast Iron. A. 605
Casehardening Preparation, Formula for. James P. Hayes ... 391
Casey, R. B.:
- Mixture for Plugging Holes in Cast Iron ... 495
- To Recut Old Files ... 391
- How a Triple Worm was Cut ... 220
- To Prevent Babbitt Metal or Lead from Exploding 605

Cast Iron Bushing in Halves, Method of Boring and Turning. A. J. Brutsche .. 275
Castings in Aluminum, Making ... 35
Cast Iron Sinks ... 158
Cast-Iron Spring Piston Ring, Proportions for a (H. & W. 38) ... 445
Cast Iron, to Harden—To Keep Water from Freezing or Souring. W. T. Sears. 444
Catching Threads and Gaging the Depth. Barney ... 152
Catgut ... 638
Cement for Holes and Cracks in Castings. C. E. Mink .. 605
Cement for Metals. H. S. Gladfelter ... 655
Cement for Iron. David Melville ... 605
Cement for Slicking Leather Fillet on Brass Patterns. H. J. Bachmann ... 331
Cement for Steam Pipes, Permanent Iron. J. H. Taylor 495
Cement, Novel Use of ... 648
"Center-Pressure" Stop Valve 434
Centrifugal Pumps, Balancing 586

Centrifugal Pumps for Elevator Service, Multi-Stage 583
Chain Drive in a Rubber Mill 136
Chain, Manufacture of 318
Change Gear Device, Proposed. E. H. Fish 48
Change Gears for Diametral Pitch Worm Teeth. John T. Giddings 153
Changes of Lead Due to Hardening, Lathe Gearing Compensation for. Hans Dahlstrand 436
Chart for Hollow and Solid Shafts 148
Charts, Calculating 425
Charts for Forming Tools, Geo. D. Hayden 103
"Charts for Forming Tools," Error in 130
Charts in Designing. John S. Myers:
(1) 9
(2) Thickness of Cylinders 90
(3) Helical Springs 145
Chasing Threads, Boring Bar for. D. Lindsay 153
Checking a Drawing. Julian F. Page 382
Cheney, J. V. N.:
To Babbitt Crossheads 442
To Heat the Tips of Small Tools 391
Chern, A. R.:
Device for Preventing wear of Shaper Tools 98
Chimney, A 182-foot Concrete 311
Chimney, How to Fall Down a 389
Chimneys Built from a Derrick 139
Chuck, An Expansion. J. M. Stabel 549
Chuck, Elliptical. John D. Adams 413
Chuck for Holding End Mills. L. E. Muncy 105
Chucking Fixture. P. A. R. 654
Chuck Jaws, To True Universal. J. E. Manlerre 214
Chuck Plates, Patterns for. E. H. Fish 51
Chucks, Time-saving, A. Mertes 95
Circuit Breaker with Solenoid Attachment. Herbert S. Gladfelter 597
Civilized, Though Savage 389
Clamp Coupling in Cement Mills, The Advantage of the. H. A. Houghton 214

A REVIEW OF STEAM TURBINE PATENTS.—1.

Up to 1904 there were over 300 steam turbine patents taken out in the United States and over 100 in England. These patents, in connection with the many that have been issued by the governments of France, Germany, Belgium and other countries, show that a great many inventors have directed their attention to the development of the steam turbine, and we also know that their efforts began at a very early date.

In fact, it is said that the first steam engine was a turbine. In Hero's "Spiritalia," a book on pneumatics issued in the second or third century, is a description of the whirling eolipile consisting of a small hollow sphere mounted on trunnions, one of which is hollow for the admission of steam. The sphere is caused to rotate by the reaction of steam flowing from two diametrically opposite nozzles having bent mouth pieces. This is frequently spoken of as the beginning of the reaction turbine; and to Branca, who issued a work entitled "The Machine," published at Rome in 1629, is given credit for the first impulse wheel. This volume contains an illustration of an eolipile, in the form of a negro's head, placed over a fire. A blast of steam proceeds from the mouth and impinges against the blades of a large wheel which it was proposed to connect by means of cog wheels with a crude stamping mill for pulverizing drugs. These very early efforts could have been nothing more than visionary schemes, but they are scarcely less impracticable than many of the later inventions to be found in the pages of the patent records. Comparatively few of the steam turbine inventions embody even the first elements of success, probably because most of those who have directed their attention to the subject have failed to understand either what was required or what means must be taken to accomplish good results.

When steam flows through a nozzle from a high to a low pressure, it issues with a velocity so enormous that it is difficult to comprehend its magnitude. The new Springfield rifle adopted by the United States Army gives an initial velocity to its bullet of 2,300 feet per second, or over 26 miles a minute. This is almost exactly the velocity with which steam of 50 pounds gage pressure would issue from a nozzle of the best shape when discharging into the atmosphere. With pressures of 100 or more pounds the velocity of the steam would be between 3,000 and 4,000 feet per second or at a speed of 35 or 40 miles per minute. The problem of converting this velocity into the rotary motion of a turbine wheel is not an easy one to solve, since the wheel must not only run with reasonable quietness and without danger of bursting, or of heating its bearings, but its speed must also be moderate enough to enable the power of the machine to be utilized in doing useful work.

In the successful turbine three main objects must be attained: 1st, as much of the potential energy of the steam as possible should be converted into kinetic energy, or the energy of motion; 2d, the wheel should be capable of utilizing the energy of the steam in an efficient manner; and 3d, the apparatus must run at a moderate speed at the point where it delivers its power.

To accomplish these results the best attainable workmanship and material are required, and this is one reason why the steam turbine has not proved successful until recent years. It is only recently that the quality of materials and workmanship have been such as to make the turbine possible.

In selecting from among the great number of turbine patents those that appear to have useful features we have had in mind the requirements stated above, and have not selected inventions unless they seem to embody at least one feature that would contribute toward a practical and operative machine.

Real and Pichon, 1827.

This machine operates by impulse and is one of the earliest attempts to produce a wheel to run at moderate speed and at the same time utilize a large percentage of the energy of the steam by the principle of compounding. Certain of the details of the original patent drawing are somewhat obscure, but in preparing the illustration, it has been made to correspond with the text as nearly as possible. The cylinder *A* contains a succession of disks, *B*, which divide the cylinder into compartments. The shaft *F* is turned with a series of steps,

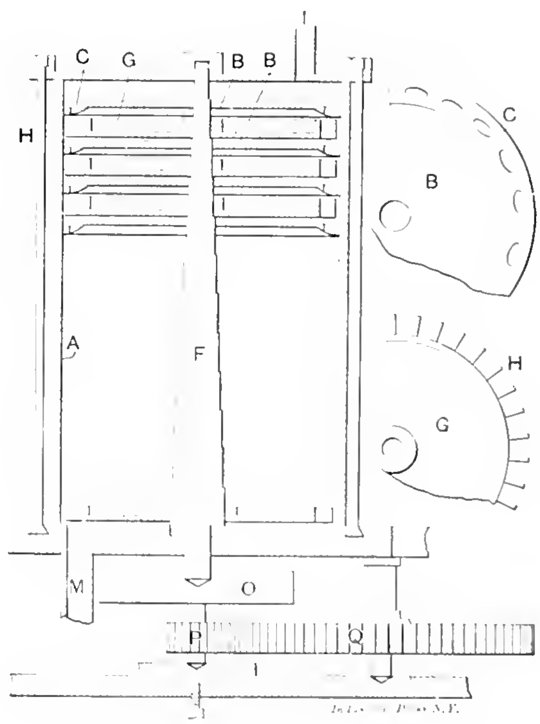

Fig. 1 Real and Pichon Compound Turbine.

upon each of which is carried a turbine wheel *G*, having short radial blades, *H*, around its periphery. Steam is admitted from the boiler through the pipe *I* at the top into the first compartment and flows in the form of jets through a series of openings, *C*, against the blades of the first wheel which runs in the second compartment. The steam next passes through a second series of holes in the second disk and impinges against the second wheel and so on to the bottom of the cylinder, where the steam exhausts through the pipe *M*. The shaft and wheels are carried by a step bearing and power is supposed to be transmitted through the gears *P* and *Q*. The openings, *C*, in the circumference of the disks, *B*, are bored obliquely, so the steam will impinge as directly as possible against the faces of the blades. With this plan the pressure will drop only a few pounds from chamber to chamber, giving the steam a comparatively low velocity of flow. This is substantially the plan used in the Rateau turbine except that in the latter the blades of the wheels are curved, so that the steam acts more efficiently.

In writing this review we have drawn on the historical material in the valuable series "Roues et Turbines a Vapeur," by Sosnowski, published in the August, September, October and November, 1896, numbers of the "Bulletin de la Société d'Encouragement pour l'Industrie Nationale," Paris. We have also been materially assisted by the list of English turbine patents in Neilson's treatise, "The Steam Turbine;" and by information kindly supplied by Mr. Robert A. McKee, mechanical engineer steam turbine department, Allis-Chalmers Co., and by the firm of H. Bollinckx, Bruxelles, Belgium.

Avery Turbine, 1831.

The first steam turbine patent to be issued in the United States was to Foster & Avery for a reaction wheel of the Hero type. Strangely enough, this is one of the few turbine inventions that has been developed and put into actual use, and probably it is the only steam turbine used in commercial work in this country until a considerably later date. There were several of these machines in operation in 1835, at least one of which was used to drive a saw mill at Syracuse, N. Y. In 1901 Prof. John E. Sweet contributed a description to the Transactions of the American Society of Mechanical Engineers, accompanying it by a sketch made from an original drawing of the Avery wheel, reproduced in Fig. 2.

The arm is made, with the exception of the end pieces and knife blades, of two pieces of iron brazed together from end to end at the edges. The openings at the ends of the arms for the steam jets were 1/8 by 1/4 inch. The speed of the tips of the arms was, of course, enormous. Mr. Avery states in his notebook that the speed of the arms of a 7-foot wheel placed upon a locomotive in 1836, which was put upon a railroad near Newark, N. J., and ended its life in a ditch, was

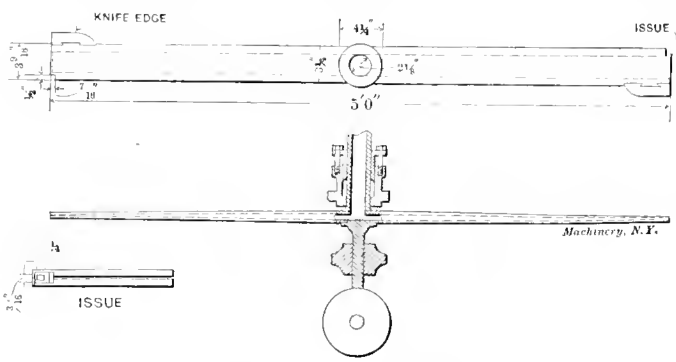

Fig. 2. Avery Reaction Wheel.

at one time 14½ miles a minute at the periphery. A difficulty met with was the end pressure on the hollow shaft, which was overcome by running the end of the shaft against the edge of a wheel set at right angles. The trouble in setting up the packing around the hollow shaft became a serious matter. It was also found that the knife edges at the end of each arm were cut away by the steam and required frequent renewal. The noise also was very objectionable. The economy was about the same as that of the common slide valve engine of that date.

Pelletan, 1838.

This invention is worthy of attention because it is an early attempt to utilize steam mixed with some other gas of greater specific gravity in order to reduce the velocity of flow of the steam and so permit a slower rotation of the turbine wheel. The Pelletan turbine is of the impulse inward-flow type. Steam enters through a valve similar to an injector, so arranged that the steam jet draws in the other gas and combines with it in the nozzle, which directs the jet against the vanes of the wheel. There have been many subsequent attempts to utilize this principle, both by the combination of some other gas with steam, and the combination of some liquid with steam; but none have been successful.

Leroy, 1838.

In commenting on Avery's invention Prof. John E. Sweet said that he had long had the conviction (previous to De Laval's invention) that expanding nozzles applied to the Avery turbine in place of the plain orifices used, would give the benefit of expansion and produce superior results. This would be the case were it not that the speed of a reaction wheel, at best extremely high, would be quickened by using nozzles that would increase the velocity of the escaping steam.

Leroy is perhaps the first on record with this idea of the application of the expanding nozzle. He was a prolific inventor and had definite notions about many features now employed in turbines. Figs. 3, 4 and 5 show three styles of rotating arms that he proposed to use for reaction wheels. The nozzle at N is clearly a diverging nozzle, as are also the orifices in Fig. 5. It is uncertain, however, whether he fully understood the principle of the diverging nozzle, because he states in one place that a nozzle in the form of a tube, Fig. 4, will produce a higher steam velocity than a funnel-shaped opening. While this might be true if the funnel flared too much, as seems to be the case, it goes to show that he did not understand the diverging nozzle at all.

Leroy was one of the first to propose a compound turbine. He shows two illustrations of machines—one a reaction and

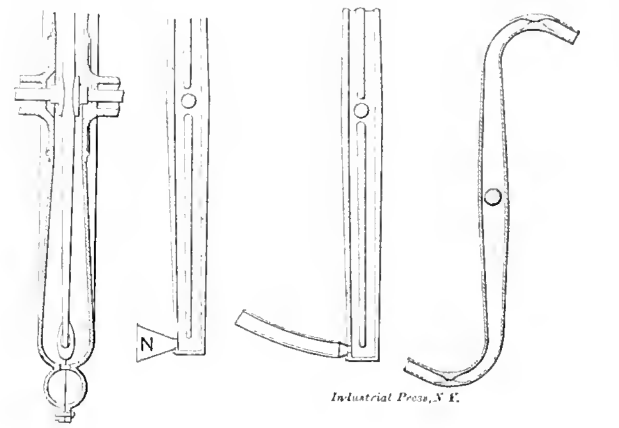

Fig. 3. Fig. 4. Fig. 5.
Le Roy's Reaction Wheels

one an impulse turbine, in which each wheel is encased in a separate chamber. In the reaction turbine steam enters the hollow arms of the first wheel through a trunnion at the center and escapes through openings in the periphery into the first chamber. It is then conducted by a pipe to the second wheel in a similar manner, where it finally escapes into the second chamber, and so on. His compound impulse turbine is entirely similar in principle to the Real and Pichon turbine except that instead of a succession of openings for the steam around the periphery the steam is conducted to each wheel by a single pipe. His drawings of the compound turbine are unpractical, because he makes no provision for the increasing volume of the steam as it expands. The drawings show passages of the same area near the exhaust end of the turbine as at the inlet end.

Pilbrow, 1842.

The inventions of Pilbrow were numerous. He experimented on the flow of steam and determined that for economical results the peripheral velocity of the wheel must be very high, and accordingly devised various arrangements for com-

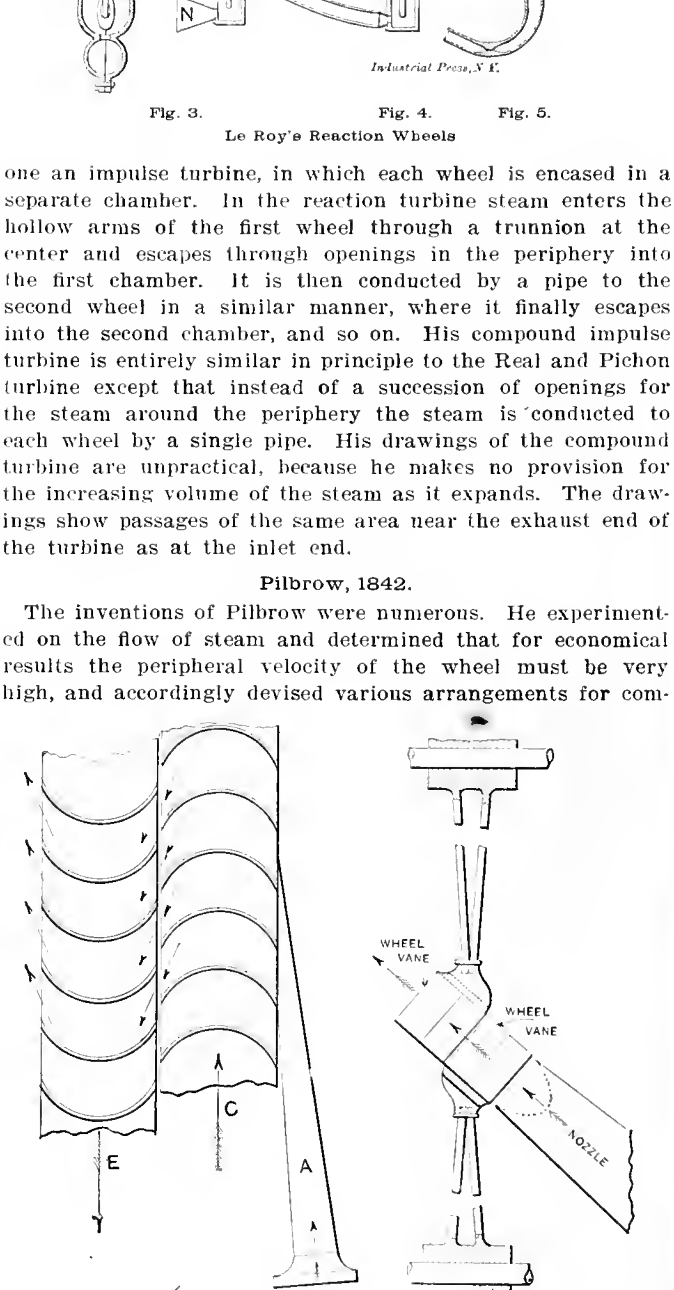

Fig. 6. Fig. 7.
Pilbrow's: Wheels Rotate in Opposite Directions.

pounding with a view to reducing the velocity to a practical rate. In all his compound turbines, however, he adopted the plan of running two or more wheels in opposite directions without stationary guide vanes, as shown in Fig. 6. Here steam enters through the nozzle, A, impinging against the blades of wheel C, which rotates in the direction of the arrow.

The steam then passes through this wheel and discharges against the blades of a second wheel, *E*, rotating in the opposite direction. Fig. 8 shows how he proposed to carry the idea still further by using several wheels, the alternate wheels rotating in opposite directions. Still another construction that he proposed is indicated in Fig. 7, where the two wheels rotate on parallel shafts, as shown, and have inclined vanes so located that steam from the nozzle will flow through the vanes of both wheels in the direction of the arrows. The buckets are curved, as in Fig. 6, and the wheels, of course,

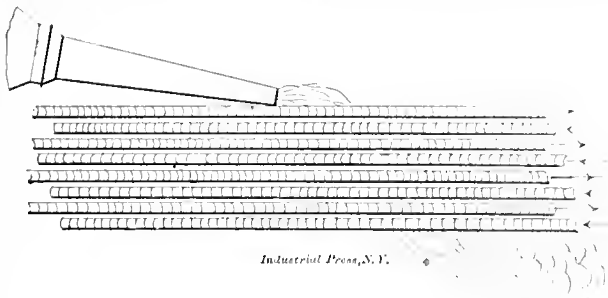

Fig. 8. Pilbrow's Multi-wheel Turbine.

rotate in opposite directions. Another modification of the design shown in Fig. 7 consisted in having several parallel rows of vanes for each wheel, which interlock with those of its mating wheel on the plan of a dovetail. With this construction the steam flowed through the vanes in a direction parallel with the axes of the two wheels. He proposed to couple the two wheels with a parallel rod, so they would keep together.

Pilbrow also proposed a reversing turbine consisting of two wheels inclosed in a casing, and two nozzles, one for each wheel. The nozzles pointed in opposite directions and the wheels would rotate in either direction, according to which nozzle was used.

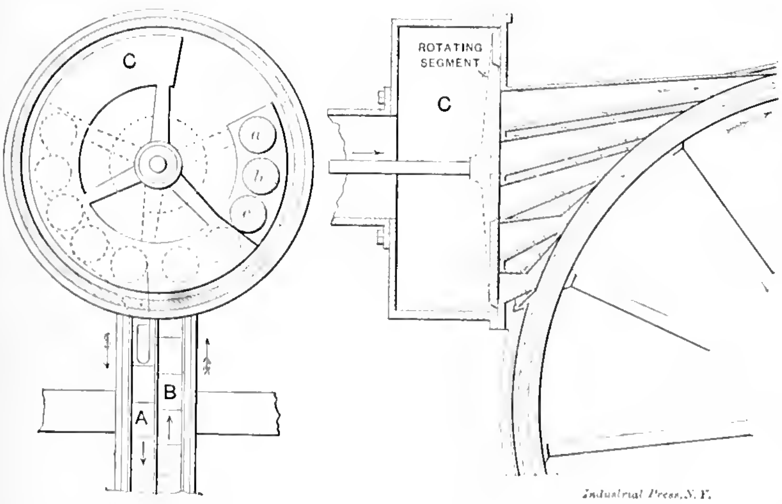

Fig. 9 Pilbrow's Reversing with Valve for Controlling Nozzles

Another interesting invention of Pilbrow is illustrated in Fig. 9. This is a reversing turbine arranged with a number of nozzles that can be shut off or opened successively by means of a rotary valve. The plan of using several nozzles which are brought into or out of action by valves, as used in the De Laval and Curtis turbines, probably here has its introduction, and the invention is of value on this account. Steam enters the chamber, *C*, in which is located a rotating segment that covers or uncovers the nozzle openings, *a*, *b*, *c*, etc. At *A* is the wheel with vanes pointing in one direction and at *B* one with vanes in the opposite direction. Half the nozzles connecting with chamber *C* direct the flow of steam against wheel *A* and the other half against wheel *B*. By rotating the segment, steam can be admitted to either wheel, causing the turbine to revolve in either direction, as desired; and also the amount of steam admitted can be adapted to the power required. A rotating valve of this description is not to be advocated as a durable construction.

Von Rathen, 1847.

Tho specifications of the patent of von Rathen are noteworthy only in that expansion cones or nozzles are a feature. His turbine is of the reaction type, no different in principle from Leroy's; and like Leroy's, the nozzles are not proportioned at all correctly for good results. He shows sketches of several different shapes of nozzles, some with conical and some with curved walls. He also designed a turbine to rotate in either direction by using a double set of nozzles pointing in opposite directions, with arrangements for conveying the steam through either set, as desired. In the reaction wheel

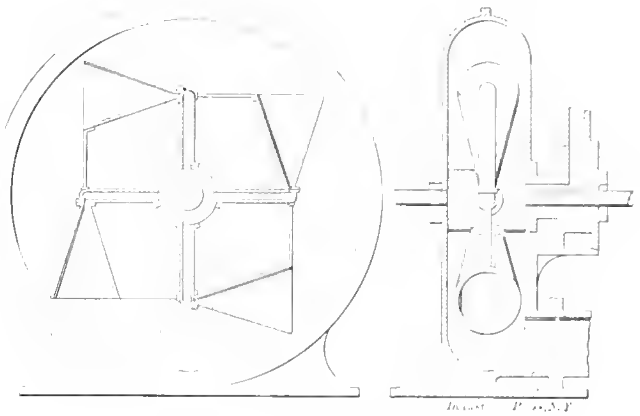

Fig. 10 Von Rathen Reaction Wheel

shown in Fig. 10 steam enters on one side at the center, flows outward through the radial arms and then discharges through the conical mouthpieces.

Wilson, 1848.

The inventions of Wilson rank among the two or three most important early steam turbine patents. His designs are the forerunners of the present Parsons type. He devised several compound reaction turbines in which the steam flowed through alternating sets of stationary and rotating rings of blades, expanding gradually during its passage through the apparatus. Fig. 11 is a sketch of his most valuable invention. Steam enters at the left, passes through the turbine in a longitudinal direction and exhausts at the outlet at the right. The vanes, *a*, *b*, and *c*, are attached to the drum, *D*, and rotate with it, while *d*, *e* and *f* are stationary guide vanes. The depth of the vanes increases from inlet to outlet, allowing for gradual expansion of the steam. This is really the Parsons turbine reduced to its simplest elements.

Another type—the radial flow wheel—is shown in Fig. 12. Here there are alternating stationary and moving vanes, and the steam flows outwardly through them, at the same time expanding to a lower pressure.

In Fig. 13 is still another type in which there is a single rotating ring of blades marked *B*. The steam is expanded and utilized upon this one ring of blades several times in succession by following a tortuous course back and forth through this ring *B*. Steam enters at *A*, passes through the moving blades to the chamber *C*, then returns through the guide vanes in this chamber to the chamber *D*; again it passes through the guide vanes to the wheel and into chamber *E*,

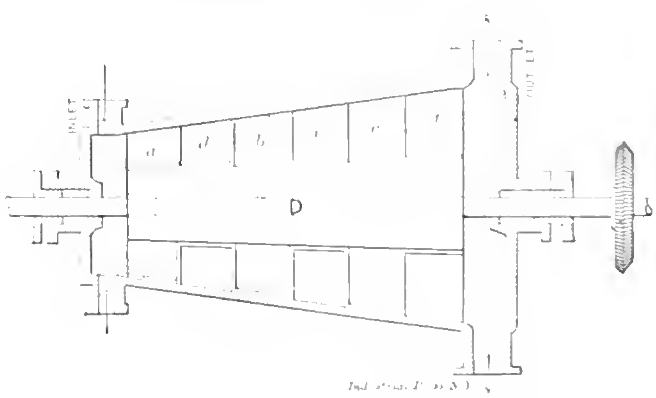

Fig 11 Wilson's Compound Turbine

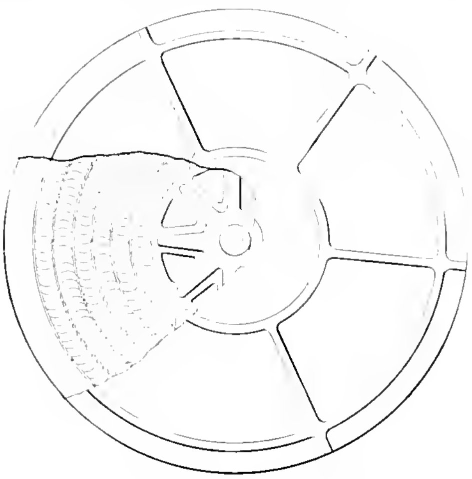
then to chamber *F*, and so on. These successive chambers increase in size to allow for the increase in the volume of the steam as it progresses through the wheel, until finally it has

passed around the whole circumference and exhausts at the outlet *G*. This plan of allowing steam to act at different points in succession on a single rotating ring of blades, has since been worked out in various other ways, as subsequent patent specifications show.

Delonchant, 1853.

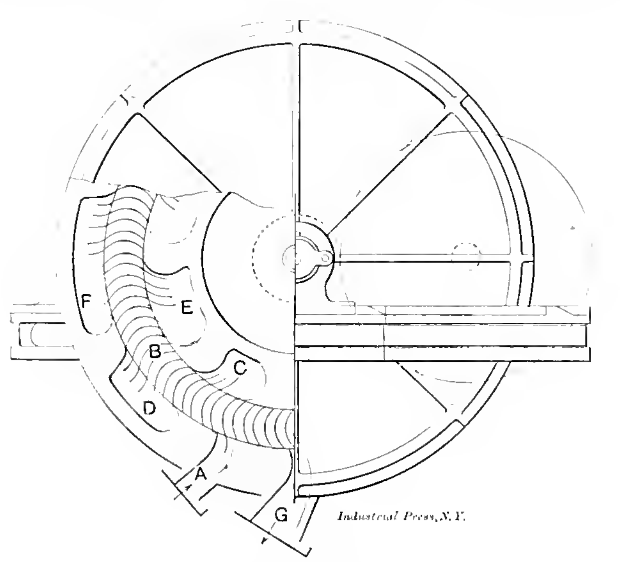
The speed reduction problem was attacked by Delonchant in the same way that it was later by De Laval; that is, instead of compounding he proposed to allow his turbine to run at



Industrial Press, N. Y.

Fig. 12. Wilson's Compound Radial-flow Turbine.

high speed and then used reduction gearing, in the form of the familiar "grindstone bearing." The arbor, *B*, of the wheel, Fig. 14, was supported on the circumference of anti-friction wheels, *C*. In explanation he says: "By the employment of these wheels instead of ordinary bearings, not only the rubbing of the first axes will be replaced by rolling friction but power will also be transmitted to the following parts, without gearing." In the illustration *A* is the rotating wheel; *B*, the arbor and at the center is a steam chest, *D D*, indi-



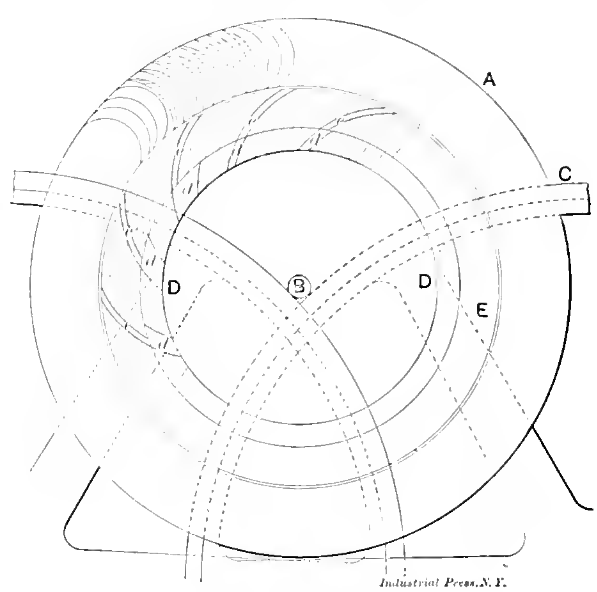
Industrial Press, N. Y.

Fig. 13 Another Type of Wilson Turbine.

cated in outline only. Steam passes from the steam chest through the passages *d d d*; and *E* is a ring having passages *e e e*, used in regulating the amount of steam flowing through the wheel. The passages, *d d d*, are so disposed that by rotating ring *E* the passage *e e e* through the ring will be successively cut off from the steam supply, or else opened to the supply. By moving 1-12 of a turn one passage is closed; another one-twelfth closes a second passage, and so on.

Tournaire, 1853.

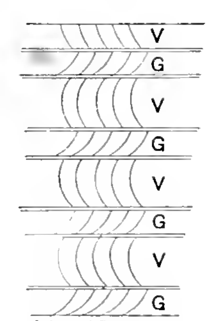
In this year Tournaire presented to the Academie des Sciences a paper discussing the merits of compound turbines both of the impulse and reaction types. There is a copious extract from this paper in the Bulletin de la Societe d'Encouragement pour l'Industrie Nationale for September, 1896, and the facts explained by him as essential to a successful turbine are so in accordance with modern practice as to place him among the leading inventors. He says: "To overcome the difficulties of high velocities the vapor or gas should be made to lose its pressure in a continuous and gradual manner, or by successive fractions, by causing it to react several times upon the floats of turbines conveniently situated. Since the differences of pressure are considerable it is not difficult to recognize the necessity for a large number of successive turbines in order to sufficiently annul the velocity of the fluid jet. In spite of the multiplicity of parts the device must be simple in its action and susceptible of great exactness in construction." Tournaire believed he fulfilled these condi-



Industrial Press, N. Y.

Fig. 14. Delonchant.

tions by means of a machine composed of several wheels, shafts rotating on the same axis and driving the wheel which was to transmit the motion, by means of pinions. A plan of the buckets and vanes is given in Fig. 15, where *G G G* are the rotating elements and *V V V* the stationary elements. He describes the construction of the turbine in detail, but these structural features are of little interest at the present time. It is to be noted, however, that he appreciated fully the necessity for expansion. He says: "As the vapor will expand in proportion as it passes from the wheel buckets and directing rings, it is necessary that the passages between them become larger and larger." He also suggests losses from leakage, saying: "A part of the fluid escaping between the spaces which it is necessary to leave between the fixed and movable parts, will exert no action upon the turbine, nor will it be guided by the directing buckets. Shocks and eddies will be produced at the entrance and exits of the buckets." Again, "The friction which the narrowness of the channel will render considerable will absorb an appreciable part of the theoretical work." As to the structural features he suggests among other things, that "the cogs of the pinions which will turn with great rapidity, should work very evenly without shocks and jolts," and proposes the use of helicoidal gears. His turbine, as well as some of the others already described, is a vertical turbine rotating on a vertical axis.



Industrial Press, N. Y.

Fig. 15. Plan of Vanes in Tournaire's Turbine.

Girard, 1855.

Three years later a turbine was patented having features that are of very doubtful utility but nevertheless of interest. Steam enters pipe *C*, Fig. 16, and flows upward through the curved annular passage, *D D*, where it enters the rotating wheel near the center. Girard in his invention endeavored to do away entirely with the stationary guide vanes and so eliminate the friction of steam against them. Accordingly the steam, starting at the center of the wheel, flows upward in a radial direction and impinges against curved rotary vanes at *a*. These vanes increase in width, allowing the steam

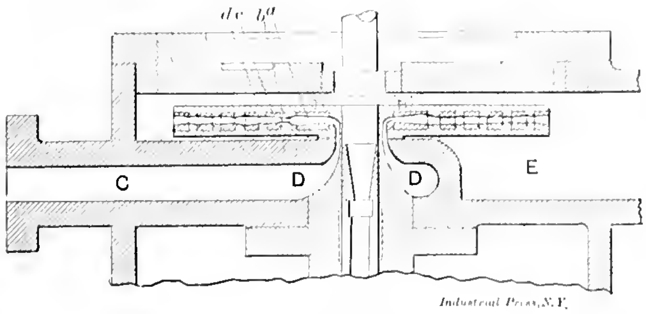


Fig. 16. Girard Turbine.

to expand somewhat until it enters an annular chamber, *b*, which is a part of the rotating wheel but which contains no vanes. The supposition is that steam will come to rest in this chamber, then flow radially outward again through guide vanes at *c*, coming to rest at *d*. The error in this arrangement is evidently in supposing that the steam will come to rest. Instead the steam would flow continuously through the various passages and the wheel would not absorb any more energy than if simply discharged through orifices on the circumference, as in a Barker's mill. This patent is mentioned because it is possible for a radial outward-flow wheel to be constructed without guide vanes, the steam entering the moving passages in radial directions; but the wheel would be quite inefficient.

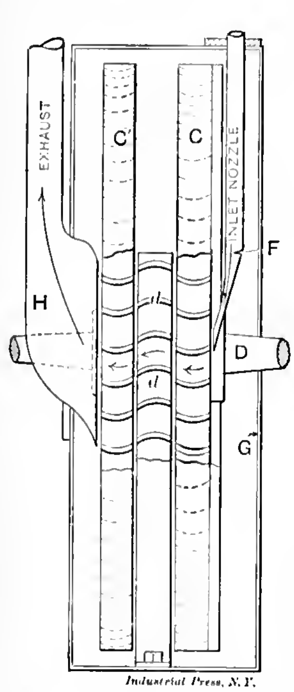

Fig. 17. Hartman's Compound Impulse Turbine.

John and Ezra Hartman, 1858.

Standing in importance with the inventions of Wilson and Tournaire are the English and American patents of the Hartman brothers, from the drawings of which Fig. 17 is made. The patent relates to a "mode of obtaining motive power by causing steam or air to impinge upon a series of chambers with curved bottoms ranged around a wheel at or near the periphery thereof; and second, the general construction and arrangement of machinery or apparatus for obtaining motive power." Fig. 17 shows the most important modification of the patent, of which

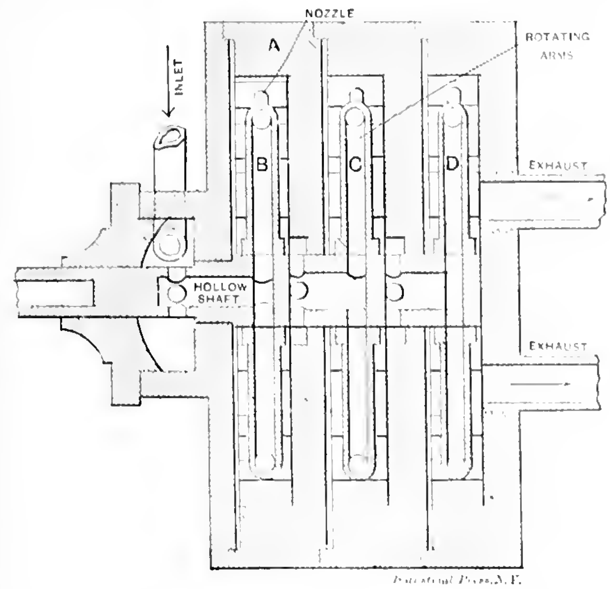

Fig. 18 Monson's Compound Reaction Wheel.

the following is the inventor's description: "This represents a detail of the third modification wherein we propose to employ two wheels, *C C'*, both wheels being fast on one shaft, *D*. A space is left between the contiguous faces of these wheels for the reception of four or more returning chambers, *d d*, the bottoms of which are curved in a direction opposite to that of the bottoms of the chambers in the wheels. These chambers in other respects are precisely similar to those in the wheels and are fitted to a rim which is bolted or otherwise secured to the interior of the casing, *G*. The jet pipe, *F*, is at one side of the wheel and the discharge pipe, *H*, on the opposite side of the second wheel.

The jet pipe on being first introduced impinges against the curved bottoms of the chambers in the wheel *C*, and is thence diverted against the fixed chambers, *d d*, whence it is again diverted on to the curved bottoms of the chambers in the second wheel, *C'*, and finally passes off by the escape pipe, *H*.

Charles Monson, 1862.

We have already illustrated types of simple reaction wheels but a search of the patent records shows that several inventors have attempted to improve on this arrangement and produce a turbine which will run at slower speed, by having a succession of simple reaction wheels, each one in separate chamber and arranged so that steam issuing from a wheel into its chamber will then pass through to the next wheel, and so on. This in substance is the design of Monson's turbine, shown in Fig. 18. The leading specification of his patent is as follows: "A repeating rotary engine constructed in a manner so as to operate substantially as described; namely, of two or more sets of curved arms, *B*, *C*, *D*, or their mechanical equivalents; a series of two or more tight chambers or passages, *A*, and a shaft or its equivalent divided into separate chambers and provided with induction and escape passages." The course followed by the steam will be evident from the engraving.

* * *

A PROCESS FOR COPYING PRINTED PICTURES.

JOSEPH C RILEY.

The so-called "metallic" paper used for steam-engine indicator cards is familiar to all mechanical engineers. It has a smooth surface, chemically prepared so that black lines can be drawn upon it with pencils made of brass, copper, silver, aluminum, or any of the softer metals. When used on the indicator, it receives the faint line drawn by a brass point at one end of the pencil arm, and its special advantage over ordinary paper is that the metallic pencil slides over its surface with very little friction, and keeps its point much longer than a graphite pencil.

Another property, not generally known, is possessed by this paper, and may possibly render it of great value for a purpose quite different from that for which it is now manufactured. It can be used as a transfer paper for copying engravings or sketches, or in fact anything printed or written in ink or drawn in pencil. If a sheet of it is laid face downward upon a printed picture, and then rubbed hard upon the back with a blunt pointed instrument, such as the rounded end of a pocket-knife handle or a smooth piece of ivory, a copy of the original picture will be transferred to the indicator paper. The copy is produced by removal of ink from the print, but the amount removed, although enough to make fairly dark lines, is so small that the original is left practically uninjured and nearly as dark as before. Firm pressure of the tool is necessary, but pressure alone will not effect the transfer; abrasion of the ink surface is necessary, and it is secured by the very slight slipping of one sheet over the other, caused by local stretching of the paper under the point of the rubbing tool. Any more than minute, local slipping must of course be prevented, or a blurred copy will result. The transfer paper should be protected by a thin piece of cardboard laid over it, and the two should be held tightly under the thumb and forefinger of the left hand while the tool is rubbed all over the cardboard, from side to side and top to bottom. Less than a minute is sufficient time for transferring a cut from two to two-and-one-half inches square; larger ones require longer time and the exercise of care to prevent stretching and consequent distortion, the difficulties becoming so great that the process seems at present limited to pictures not over four inches square. A corner of the transfer paper may be turned up for examination at any time.

Line drawings printed from relief plates, or pictures with

sharp contrast of black and white without any half-tones, give the best copies. Very few half-tones can be transferred satisfactorily; almost all give streaked, indistinct copies and many of the results are worthless. This process is not recommended for copying half-tones.

The transfer taken off as described is a *reverse* of the original print, "a view of the opposite hand," as draftsmen say, and any lettering on it will read backward. If the question of right and left is not important, this reversal will seldom be objectionable, for it is easy to read backward what few letters generally occur. However, if desired, the paper may be held up to the light and examined from the back, or placed before a mirror and viewed by means of its reflected image, when the true relations of right and left will be seen. Moreover, if sufficiently important, an exact counterpart of the original may be taken from the reversed copy by laying another sheet face downward upon it and rubbing on the back of the fresh sheet just as was done in making the reversed copy. The impression thus produced will be fainter than the first, but almost always it can be made dark enough to show a distinct outline which may afterward be retouched with a lead pencil.

Fig. 1 shows a reversed copy transferred from a picture in a steam-engine catalogue. The original is in black ink on plate paper and measures 2¾ by 4 inches. It is reproduced in the columns of MACHINERY by printing from a half-tone plate, photographically prepared, and the lines do not appear so clear as in the original. However, the reader is assured that the copy in question is clear in detail and about half as dark as the original picture from which it was taken; and that, furthermore, not enough ink was removed from the original to cause any perceptible change in appearance.

Fig. 2 shows a reversed copy, and Fig. 4 the true copy made from it in the manner described. The second is but little fainter than the first, and both possess a certain artistic softness and quality of line not found even in the original.

Fig. 3. was transferred from a tracing made with Higgins' indelible drawing ink. The copy was made in about forty seconds, and is both dark and clear.

Fig. 5 and Fig. 6, which was produced from it, are transfers of handwriting in Carter's Koal Black ink which had been dry more than two months. This process offers a quick means of obtaining facsimiles of signatures without injuring the documents to which they are attached. It will doubtless be appreciated by collectors of historic autographs—perhaps also by persons of another, not strictly legitimate vocation.

For indicator cards, the paper is prepared by coating one surface with a suitable compound, usually zinc oxide mixed with a little starch and enough glue to make it adhere. After drying, it is passed between calender rolls under great pressure. The various brands manufactured for the trade, though perhaps equally good for indicator diagrams, are not equally well suited for copying. A paper supplied by the Crosby Steam Gage & Valve Co. was used for the cuts illustrating this article. Its surface appears to have just the quality required for transferring ink and preserving clear lines, but the body of the paper is a little softer than it should be, and, unless care is taken, it is likely to stretch when copies over two inches square are attempted. If paper of firmer texture could be prepared with the same surface finish, probably much larger copies could be produced.

Other kinds of paper, notably the heavy plate papers used for some of the best trade catalogues possess this transfer property to a slight degree, though they will not receive marks from a metallic pencil. The latter feature would seem to recommend them for transfer purposes, making them less likely to become soiled by contact with metallic objects, but so far no kind has been found which will remove enough ink to give copies anywhere near as dark as the indicator paper.

In choosing pictures for illustration, the writer selected those which could be copied with best results. Fairly good transfers can be made from almost any common printer's ink, but some inks copy much better than others, and some yield only the faintest impressions. The length of time since a picture was printed does not seem to determine its copying quality. Some very old prints can be copied better than new ones; in fact, it was by accidental transfer to an indicator card from a book nearly a hundred years old that the peculiar property of this "metallic" paper was discovered.

The reader has probably noticed in examining old books, that reversed impressions of engravings are often found on the fly leaves or tissue sheets which face them. This is probably due to chemical action between the ink and the paper; it is not the result of a physical transfer, for usually the ink was dry before the book was bound, and since that time it has not been subjected either to friction or to great pressure.

How many draftsmen and engineers have often wanted private copies, however faint or imperfect, of small details which were too complicated to remember, and which would require too long to trace; how often persons reading in any branch of science would like to make copies of pictures or diagrams from books which they cannot buy, or which are too cumbersome to have at hand when wanted. A ready means of supplying such demands with exact copies of the originals, however intricate, is afforded in this frictional transfer process. For small copies the results are already very satisfactory, and it is believed that by improvement the process can be made of value for work of a much more pretentious character.

Since the above was written, it has been found that much better copies can be made by following the directions below, instead of those already given. Lay the metallic transfer paper, *face up*, upon at least a dozen sheets of blank paper, and lay the print *face down* upon it. On the back of the print, place a sheet of heavy paper, or thin cardboard, and run the rubbing tool over this protecting sheet. In this manner it is comparatively easy to prevent slipping, and prints eight or ten inches on a side may be copied satisfactorily.

* * *

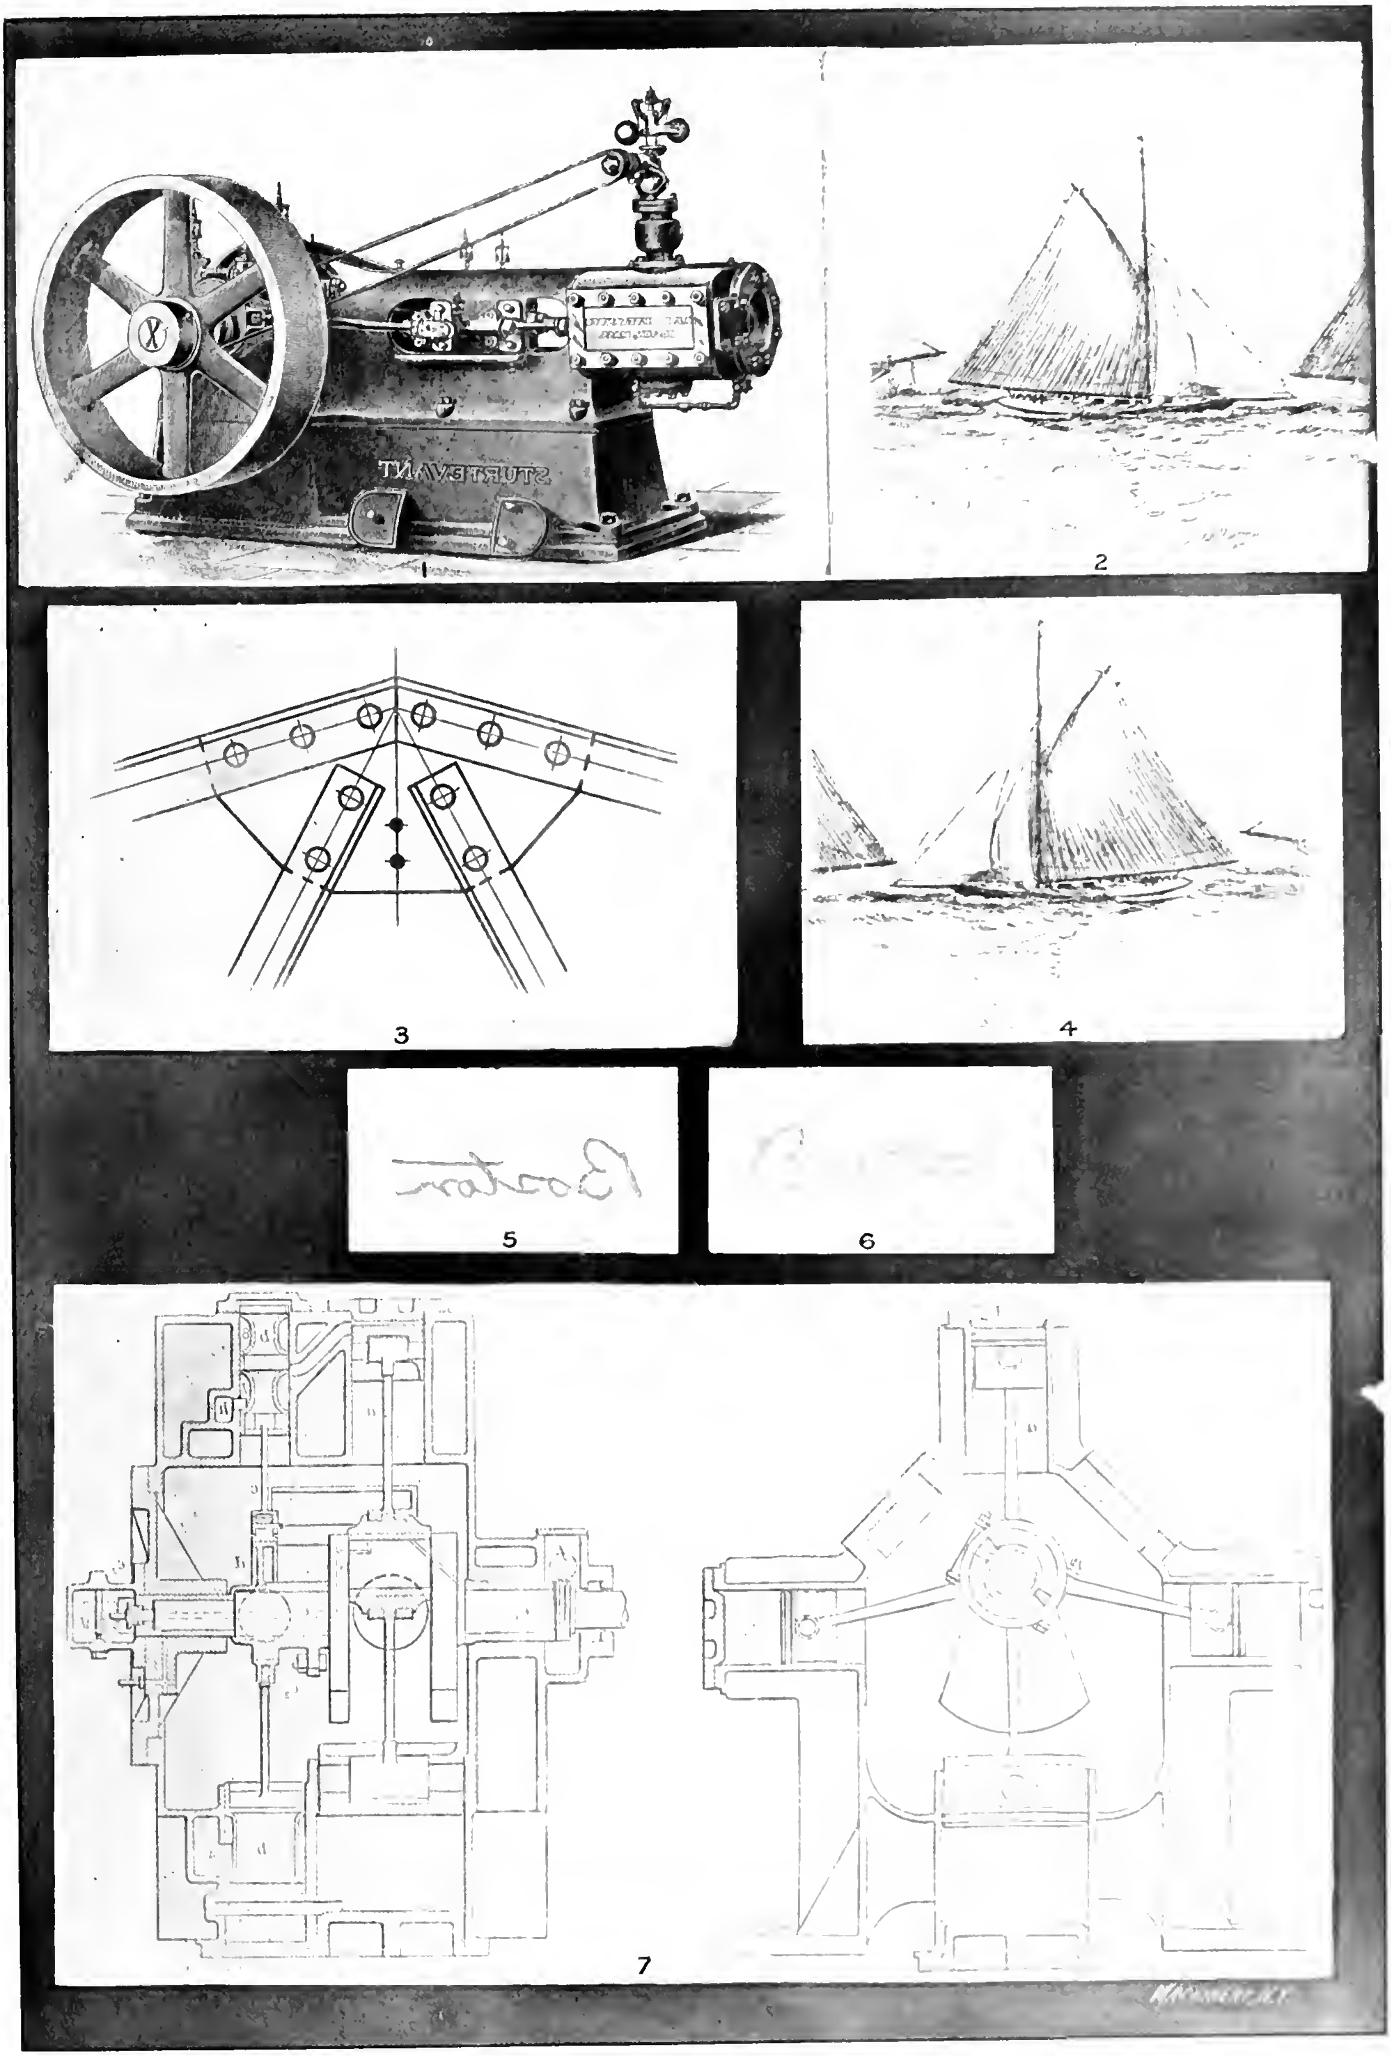
ESSEN AND THE KRUPP WORKS.*

In spite of its fame and its situation on one of the main highways of Europe, Essen is little known. "There is nothing to see except the works. In 1811, when the first smelting furnace for casting steel was set up by Peter Friedrich Krupp, the population of Essen was under 4,000. In 1901 it was 183,500, out of which the Krupp contingent numbered about 84,000. At the same date there were more workmen's dwellings built by the firm than there had been inhabitants when it was founded. Now, this and a great deal more is essentially the work of one man, and it is unparalleled in the history of industry. It must not be supposed, however, that the Krupp family created Essen out of the wilderness, as some places have been created by industrial enterprise. The place is ancient and has a history. In the Middle Ages it was a walled city; the shape of the central quarter, the narrow and winding streets, and the names of the four gates survive as reminders of the past, but no other vestiges remain. For centuries also Essen was famous for the manufacture of firearms. The command of running water and of coal, which is mentioned in connection with Essen as early as 1317, accounts for the development of these industries. They appear, however, to have declined gradually during the eighteenth century, when the town fell into a decayed condition. Modern Essen may be said to date from the evacuation of the French in 1813, which almost coincides with the original foundation of the Krupp works and marks the beginning of a new era.

The Krupp Family.

Peter Freidrich Krupp was born in 1787 and went as a youth into some iron works at Sterkrade, which came into the possession of his grandmother in 1800. These works had been started in 1780 and were among the earliest in the district; they still give their name to the large iron and steel business known as the Gutehoffnungshütte of Oberhausen. Here young Krupp worked at the invention of a process for casting steel and committed the reprehensible imprudence of marrying at 21. He went to Essen, where some iron works that had been built for the abbess in 1790 were at this time acquired by the firm, which also became the owners of the Sterkrade works. This connection may have been the reason of Krupp's settling in Essen, but at any rate he soon set up for himself, and at the age of 23 he purchased a small forge worked by water power, where he devoted his time to secret

*Abstract of article in Consular Report No. 2009, taken from the London Times.



Half-tone Reproduction of Impressions on Metallic Paper, taken from Printed Engravings. Reproduction Full Size. See "A Process for Copying Printed Pictures."

experiments in smelting steel in small crucibles. To this day the casting of crucible steel is the great specialty of the Essen works. A son, Alfred, was born to the young couple in 1812, when Friedrich Krupp was 25. Want of means compelled him to enter into partnership at this time, and in 1815 the firm announced that they were prepared to accept orders for cast steel; but as no orders came the partnership was dissolved and he was left to struggle on alone. This he did for some years, but with difficulty, until in 1826 he fell ill and died, leaving a widow and four children. Alfred, the eldest, was then 14, and on his shoulders fell the burden of carrying on the business. His father had intrusted the secret to him and taught him the trade. Alfred left school at once and took his place in the shop, where he worked at the furnace and the forge harder than his own handful of journeymen, and for years made no more than sufficed to pay their modest wages. "For my own toil and pains at such an early age," he said afterward, "I had no reward but the consciousness of doing my duty."

Few schoolboys have entered on the struggle for life with such a laborious inheritance and fewer have emerged so victoriously after so long a probation. For twenty-five years the fate of the concern hung in the balance, and success became assured only after the London Exhibition of 1851. Four years previously the first gun, a 3-pounder of cast steel, had been finished. Thenceforward the story is one of rapid and almost continual progress. In 1853 the manufacture of weldless steel tires was begun. Ten years later the first workman's colony was built, and not long after Herr Krupp found himself in a position to obtain command of raw materials, and so placed the business in a self-sufficing and impregnable position by the purchase of iron mines and blast furnaces, presently followed by coal mines. He died in 1887, having been for sixty years the head and for forty years the sole proprietor of the works, which then passed to his only son, the late Friedrich Alfred Krupp. They have been greatly extended since by the addition of other works and mines and, in 1902, the Germania shipbuilding yard at Kiel, but are still, with all their branches and appendages, the sole property of the family. They are managed by a board of directors. On April 1, 1902, the total number of persons employed at the various works was 43,083, representing, with their families, a population of about 150,000. The numbers were thus distributed:

Steel works at Essen	24,536
Gruson works at Buckau	2,773
Shipbuilding yard at Kiel	3,987
Coal mines	6,159
Blast furnaces, proving ground, etc.	5,628
Total	43,083

The old-fashioned little house of five rooms in which Alfred Krupp's parents lived and worked and brought up their children, hard by the original forge, still stands at the entrance to the works, and a tablet on the door refers, modestly enough, to the privations, efforts, and anxieties which attended the founding of the business and overshadowed its career for many years. The contrast between the small, struggling beginning and the immense eventual achievement stands embodied before one's eyes with a dramatic significance which cannot fail to impress; but if one inquires the origin of other manufacturing concerns one finds that with rare exceptions—and those of recent date—they were started in much the same manner, went through similar early struggles, and survived by virtue of the same qualities.

The Town

The English town which most naturally suggests itself for comparison with Essen is Sheffield; and there are many points of resemblance between them. Both lie on the same hilly sort of ground that goes with the presence of coal; both have narrow, old-fashioned, irregular streets; both have charming country on their outskirts, though in this the advantage lies with Sheffield; and both manufacture the same things on the same scale. On the other hand, Sheffield is more than twice as big, it is a much older manufacturing place, and has a greater variety of manufactures. The ancient cutlery industry, file cutting, and electroplating give it a special character which is lacking to Essen. Take them as they stand, however, for what the comparison may be worth, and it must be admitted that the German has rather the best of it. The site of the Krupp works on the lower side of Essen, in and out out of the town, is curiously like that of the great Sheffield works—at Cammell's, Brown's, Firth's, and Vickers and Maxim's—which lie all together in a similar position, and probably occupy even more ground between them. They certainly make more smoke, or it hangs more persistently about. Sheffield is the grimiest of all our manufacturing towns, with the possible exception of Gateshead, and a large part of it is generally wrapped in a pall which neither London nor Manchester can equal. America alone, with her genius for surpassing everything, easily beats it. Compared with the inferno of Pittsburg and the lesser, but still more grimy and squalid, hells up the Monongahela Valley—Homestead, Braddock, and the rest—Sheffield is clean and Essen a pleasure resort, in spite of the fifty or sixty tall Krupp chimneys that flank it on one side and various other factories, with sundry coalpits, on the other.

The Industries.

Apart from Krupp's the industries of Essen are not extensive. There is one considerable iron works which makes a specialty of boilers, a chemical factory, breweries, and several coalpits. The town lies over the coal bed and the mines run underneath it. The great Rhine-Westphalian Coal Syndicate —probably the most important industrial combination in Germany—has its headquarters at Essen. The products of the Krupp works are very varied. Their firm is chiefly associated with war material, but they minister no less to innumerable peaceful purposes. All kinds of finished and half-finished material for railways, ships, engines, tools, mills, and other industrial appliances are turned out in large and small quantities. The war department turns out guns of all sorts, of which 39,876 had been delivered up to the end of 1901, projectiles, fuses and ammunition, rifle barrels, and armor. The manufacture of offensive and defensive material is a lucrative game of see-saw, in which the governments of the world are pawns in the manufacturer's hands. It is like the burglar and the safe. The scientific possibilities are infinite, and the experts have only to turn their attention to each in turn and their customers must follow. A more powerful gun, a more vicious projectile, or a new ammunition, and the old defenses are obsolete. The governments hasten to provide themselves with the latest instruments of destruction. Then the metallurgical chemist brings a new hardening process or a new alloy on the scene and produces armor which defies the latest weapons; and again everybody must have it, or questions are asked in Parliament. Thus it happens that the Essener-Hof—that most exclusive of hotels, which stands hard by the works and is reserved for distinguished customers—never lacks guests from all parts of the world. They are the emissaries of their governments, watching the execution of orders. There is not much fear that any of the great powers will outstrip the rest to an alarming extent. These matters are, of course, profound trade secrets; but somehow or other Essen knows pretty well what is going on at Elswick and Sheffield, which return the compliment, and all three have made up their minds about the merits and defects of the new French gun before it has been delivered.

* * *

Many young draftsmen who are desirous of learning to letter drawings neatly, would undoubtedly appreciate, for practice, a stipple paper with rows of dots in slight relief. The upright rows should make an angle of 60 degrees to the horizontal, the tops, of course, being inclined to the right. The spacing of the rows of raised dots should be about 1-128 inch each way, the distance of 1-128 inch forming the unit for proportioning the letters. Thus if lettering in the familiar *Engineering News* style, the body of lower-case letters would be made, say, 8 spaces high and the total height would be 12 spaces in descriptive legends. The proper slant of the letters would be naturally formed by the pencil point following the inclined rows of dots, and horizontal lines in the same way. A few weeks practice on such paper would do much to cultivate the proper stroke and sense in proportion that is often sadly lacking with draftsmen when it comes to neat lettering

CHARTS IN DESIGNING.

JOHN S. MYERS.

John S. Myers.

Charts which are used for recording data or for assisting the designer in proportioning his work or in making calculations, may be classified, according to the purpose for which they are intended, under two general heads, *i. e.*, Record Charts and Calculating Charts.

To the first class belong cards from all recording devices and diagrams of any kind laid out from known values, such as graphical representations of results of tests. Such charts may constitute a record pure and simple; they may be for the purpose of better showing the existing relations of the quantities involved, for ascertaining mean, intermediate or proportional values, or they may be developed with a view to discovering losses, irregularities, errors, etc.

The following development of one of a series of tests on the power required to drive rivets is a fair illustration of the applicability of record charts:

Experiment* on ¾-inch rivets, holes punched 13-16 inch at top, about ⅞ inch at bottom, 1 8-20 inch grip, about 1½ inch projection of shank before driving. The rivets were driven on an Allen riveter, the frame having been previously calibrated as a spring balance by measuring the deflection in thousandths of an inch with a micrometer, for known loads suspended from the die. Chart No. 1 shows the calibration of the frame.

In chart No. 2 the full curved line represents graphically the results of experiment as tabulated. The dotted curve represents allowances for efficiency and inequalities in length of the rivet, plotted with a view to determining the energy required for a power driven machine. In this test the mean average pressure during period of driving was 40,925 pounds. The distance passed over under this mean pressure was 29-64 inch.

$$\frac{40{,}925 \times 29}{64 \times 12} = 1{,}545 \text{ ft. lbs. of energy.}$$

With allowances as per dotted line $= \dfrac{38{,}000 \times 1.25}{12} = 3{,}960$ ft. lbs. If exerted every 3 sec. the H. P. to drive alone $= \dfrac{3{,}960 \times 60}{33{,}000 \times 3} = 2.4$. Of course allowances would have to be made for other losses and for extra stroke.

The uses which have developed for charts have become as numerous as the different branches of industry with which they are associated. Their construction, when taken up in detail, is even more varied than their uses. Cold figures never convey to the mind as clear a conception of relative values as a graphical representation, and in the case of experiments the tabulated data often brings to view points when charted, which would not otherwise be noted.

Frequently a record chart is used to interpolate between known values, obtaining unknown ones, as was the calibration of the riveter frame in the foregoing example.

Similar to the last mentioned class of charts, but closely allied to Calculating Charts, belong stress diagrams and all kindred matter in the art of graphostatics so much used in the determination of stresses in framed structures, bending moments in beams, etc.

Calculating Charts may be defined as those which express mathematical relations of quantities. They are of two varieties: Those upon which certain mathematical operations may be performed according to any sequence, the quantities being either concrete or abstract and of any denomination and measure desired; and those designed for dealing only with concrete numbers of definite measure and denomination, the quantities involved having a fixed mathematical relation and sequence.

Under the first subdivision, if this liberty of classification be permissible, come all forms of calculating instruments, such as the slide rule, Sexton's omnimeter, Thatcher's calculating machine, etc. The principles upon which these operate are quite generally known, leaving little to be said in this connection. There is, however, a spirit of distrust regarding the accuracy of calculations performed upon a slide rule far too prevalent. Because one reads from the rule 975 pounds as the weight of a casting and the actual multiplications give 974.235 pounds, is that any reason why the rule should not be used for estimating weights? In all probability one would set the weight down as 980 pounds for sake of even figures, and if a casting it might come out of the sand weighing over 1,000 pounds.

In calculating stresses, for instance, who cares for a hundred pounds more or less? If the assumed fiber stress be 10,000 pounds per square inch, an error of even 500 pounds is only 5 per cent. The rule has a wide sphere of usefulness

TABLE 1

No. of Rivets.	Deflection of Frame.	Pressure at Die, pounds	Total Length of Rivet Head to Head	Height of Head being Formed.	Remarks.
1	.016	6000	3 [illegible]	[illegible]	End stove up.
2	.022	9600	2 [illegible]	[illegible]	End stove up ¼ more.
3	.036	15000	2 [illegible]	[illegible]	Head commencing to form in die
4	.063	26000	2 [illegible]	[illegible]	Head formed in part only.
5	.095	39000	2 [illegible]	[illegible]	Head not completely formed.
6	.150	62000	2 [illegible]	[illegible]	Fairly well formed head.
7	.208	82600	2 [illegible]	[illegible]	Better head, hole well filled.
8	.214	87800	2 [illegible]	[illegible]	Some hotter than last rivet; good head

and those persons who cry out so against it as an unreliable instrument are only lacking in judgment as to where and where not extreme accuracy is required.

The settings, Figs. 1 and 2, next page, illustrate the location of two much used constants which may be applied to any slide rule, and after used a short time their utility will become apparent.

Explanation: Set 4 on the B scale under π on the A scale; at left index make mark a on the C scale. See Fig. 1. Set second 4 under π and mark a_1.

Setting a or a_1 to any diameter on the D scale gives the area on the A scale opposite either index; setting runner to length on B gives volume on A.

Set the rule as above, Fig. 1, and the runner at 283 on the B scale as indicated at x; set the right index of the slide at this line xx and at left index make mark W, Fig. 2, on the C scale. Mark second W in line with the middle 1 of the A scale.

Setting either W to any diameter on the D scale gives the weight per inch of round steel bars on the A scale, setting runner to length on B gives weight of bar.

As an aid to the memory for the uses of these points, a stands for areas and W for weights.

Calculating Charts.

Taking up Calculating Charts in detail, simple mathematics may be divided into three elementary operations, each class consisting of a couplet in which the one member is the inverse of the other, viz.: addition and subtraction; multiplication and division; raising to a power or extracting a root.

Chart No. 3 illustrates how the operations of addition and subtraction may be performed graphically. Following the broken line in the direction indicated by the arrow heads represents operations as follows: $7 - 4 = 3$, $7 + 4 = 11$, $7 + 4 + 4 = 15$, $9 + 2 = 11$, $9 + 2 + 4 = 15$. Following these lines in the opposite direction would perform the inverse operation. It will be noticed that when the zero line is crossed to find the next value, addition is performed but when the zero line is not so crossed subtraction results, *i. e.*, the quantities represented by the diagonal lines on the same side

* The writer is indebted to Mr. A. L. Goddard, M. E. of the Edison Laboratories for the tabular data of this test.

of the zero line, as the quantity it is desired to combine with are negative.

Chart No. 4 illustrates in a similar manner the operations of multiplication and division. The arrows indicate the following: 6 ÷ 2 = 3, 6 × 2 = 12, 6 × 2 × 1.25 = 15. The line *A-A* represents multiplication by 2 combined with addition of a constant whose value is also 2, thus: 6 × 2 + 2 = 14. This line is drawn parallel to the multiplier (in this case 0-2) and has its point of origin at the constant. Line *B-B* represents division by 2 with addition of a constant 2, thus: 12 ÷ 2 + 2 = 8. It will be noticed that in addition and subtraction the parallel diagonal lines have their origin at the value they represent, and their terminus at a similar value on the side adjacent, if the scale on that side were reversed; while in multiplication and division the lines are divergent and have their origin at the common zero point of the two scales.

In Charts Nos. 3 and 4 the operations may be carried on continuously within the range of their readings, thus: [(9 + 2 = 11) + 4 = 15] — 2 = 13, and similarly in Chart No. 4 [(6 × 2 = 12) ÷ 1.5 = 8] × 1.25 = 10. This is dealing with abstract numbers, however. A single line chart handling concrete values will combine two quantities and give the result of whatever the operation may be. A chart having two sets of sloping lines will combine three values giving the result. If more than three values are to be combined, a multiple chart, as illustrated by Chart No. 5, may be used. The

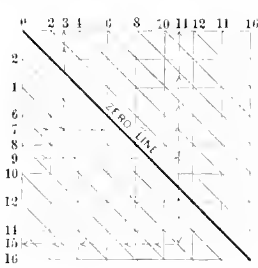


CHART NO. 3

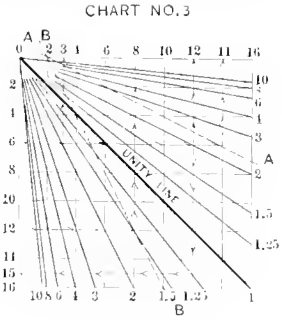

CHART NO. 4

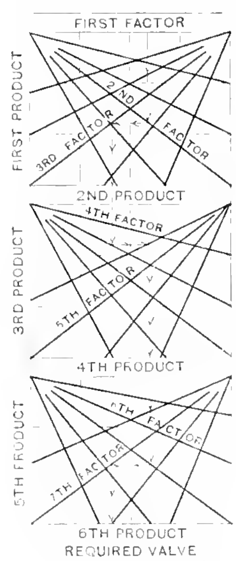

CHART NO. 5

Machinery, N.Y.

following is a concrete example of the last-mentioned chart, illustrating plain multiplication and division. (See Chart 6.)

Tank Chart.

Required: the thickness of tanks of various diameters and heights for containing different fluids. The formula for thin cylinders is as follows: $t = \frac{pd}{2sy}$, where t = thickness in inches, p = pressure in pounds per square inch, d = diameter

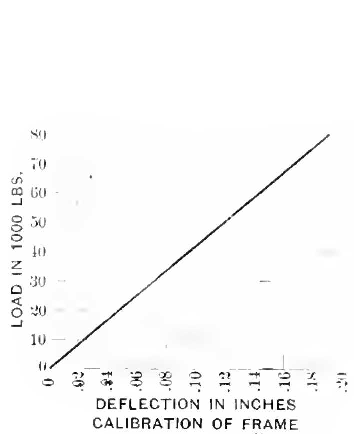

Chart No. 1.

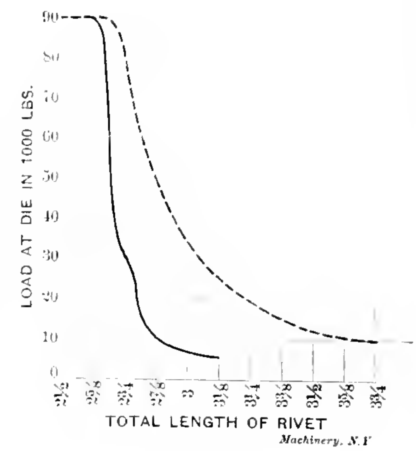

Chart No. 2.

in inches, s = allowable working stress in pounds per square inch and y = the efficiency of the riveted joint.

Let D = diameter in feet, H = head in feet, and G = specific gravity of fluid; then

$$\frac{.433\ H\ G\ 12\ D}{2\ s\ y} = 2.598\,\frac{H\ G\ D}{s\ y}$$

In operations of multiplication and division the order in which the factors are taken does not affect the value of the result; it is therefore advisable to choose those quantities which are most constant for any given problem as the first factors of the chart. In this case the order has been chosen as follows: diameter, specific gravity, stress, efficiency of joint and head.

Next in order of importance comes range of readings and scales. It is always desirable to make the range of a chart as great as is consistent with reasonable accuracy. In the case under consideration the range of diameters has been chosen between 6 and 120 feet, but in order to secure this range three different scales have been used; 2 feet per space from 6 feet up to and including 20 feet; 5 feet per space from 20 feet up to and including 60 feet; 10 feet per space from 60 feet up to and including 120 feet. (Chart No. 6.)

This change of scales necessitates three different points of origin for the lines representing the second factor, but the error of interpolation is thus kept within reasonable limits without making a chart of abnormal proportions.

To aid one in deciding upon appropriate scales and limits of readings for the other factors and products, it is well to tabulate these factors and their resulting products: first choosing assumed limits of readings for the intermediate

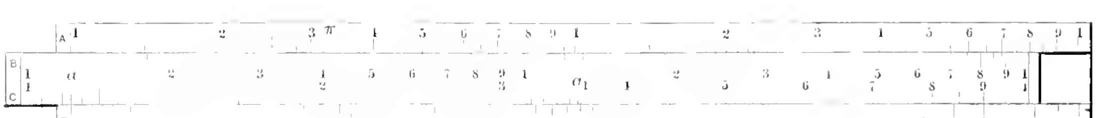

Fig. 1

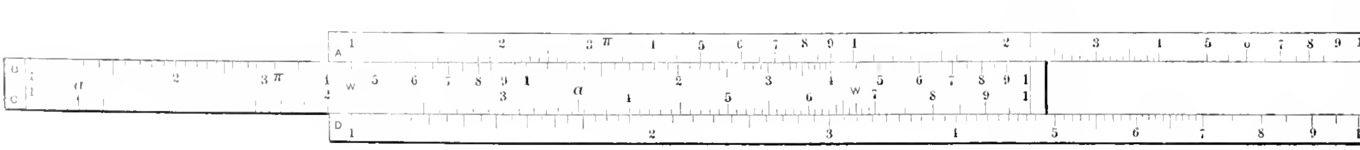

Fig. 2

quantities which will produce the minimum final value, then vice versa, and lastly, what may be considered a practical problem of maximum sizes. (Table No. 2.) From these values the range of the different products has been chosen, as indicated in the last two lines of the table. Their scale will be determined by the size of the sheet it is desired to use. Since it is not necessary to have the points of origin lie within the border lines, it is desirable to keep the minimum readings greater than zero when this can be done without impairing the utility of the chart.

The problem illustrated by the arrows in Chart No. 6 is a tank 85 feet in diameter, specific gravity = 1.0, 16,000 pounds fiber stress, 65 per cent. efficiency of joint, and 35 feet head.

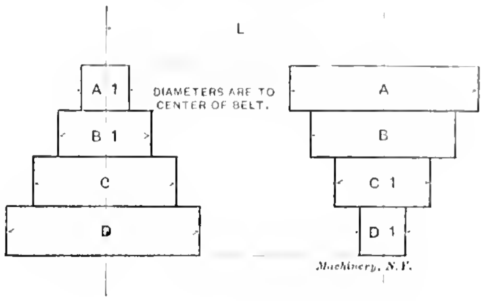

Fig. 3.

The thickness is read to the nearest even fraction on the side of safety as ¾ inch.

Cone Pulleys.

The following chart (No. 7) for cone pulleys illustrates the variable scale principle combined with subtraction and division. For crossed belts the belt will be of uniform tension when $A + A_1 = B + B_1 = C + C_1$, etc., but for open belts the middle steps must be larger in diameter than for crossed belts.

The formula used by the machine tool combine for this case is as follows: (See Fig. 3.)

$$x = \frac{(A - A_1)^2 - (B - B_1)^2}{2\,\pi\,L}, \quad x_1 = \frac{(A - A_1)^2 - (C - C_1)^2}{2\,\pi\,L},$$

$$x_2 = \frac{(A - A_1)^2 - (D - D_1)^2}{2\,\pi\,L}, \text{ etc.}$$

where x = total correction to be added to the sum of $B + B_1$, x_1 = total correction to be added to the sum of $C + C_1$, etc., to preserve a uniform belt tension, the diameters used in the formula being to the center of the belt.

Proceeding to construct a chart which will give the values of x, x_1, x_2, etc., for any case within its range, we first inspect the formula. We have three main values involved $(A\text{-}A_1)^2$, $(B\text{-}B_1)^2$ and $2\pi L$, the difference between the first two being divided by the last. As 2π is a constant it does not enter as one of the variable factors. The first two factors are to be squared. This is best accomplished in the following manner: Lay out at the top of the chart in lead pencil a uniform scale, in this case the range has been chosen from 0 to 1,000; this represents the values of $(A\text{-}A_1)^2$; now spot off underneath this scale by the aid of a table the square roots of such numbers as will make a fairly uniform looking scale, inserting their values in ink and erasing the former. In this case we wish to subtract from the first quantity $(A\text{-}A_1)^2$ a similar quantity $(B\text{-}B_1)^2$ Since the range of $(B\text{-}B_1)^2$ should be nearly

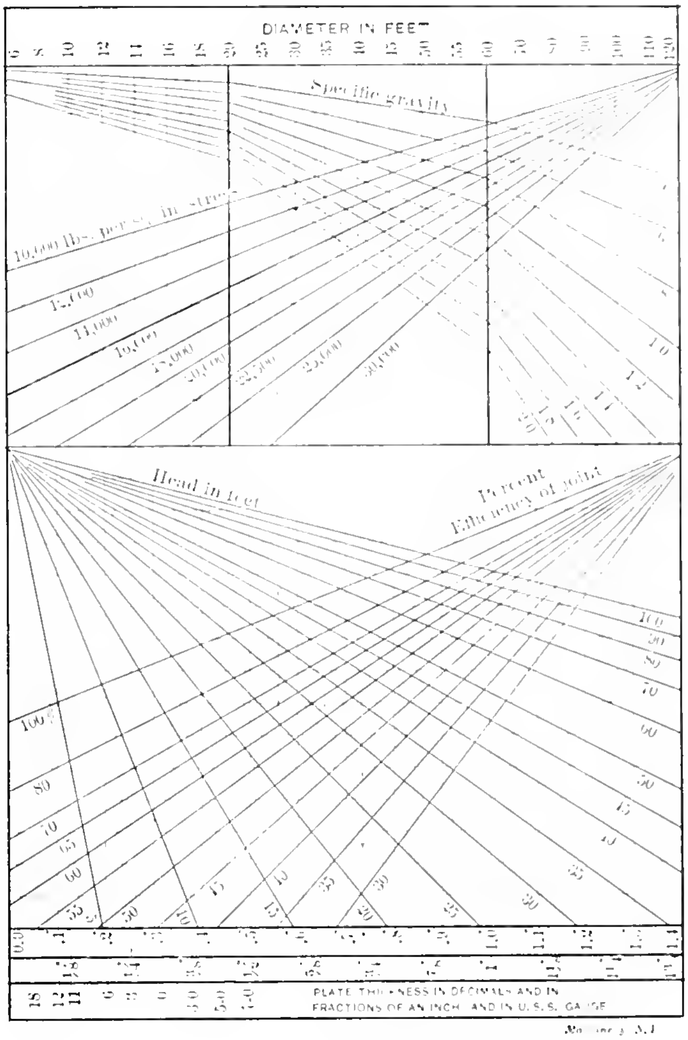

Chart No. 6.

TABLE II. TABULATED FACTORS AND PRODUCTS FOR USE IN SELECTING LIMITS OF READINGS AND SCALES.

	First Factor, Diameter in Feet = D	Second Factor, Specific Gravity = G	First Product = DG	Third Factor, $\frac{1}{\text{stress}} = \frac{1}{S}$	Second Product $\frac{DG}{S}$	Fourth Factor, Efficiency of Joint $\frac{1}{E}$	Third Product $\frac{DG}{SE}$	Fifth Factor, Head in Feet, Constant $= H \times 2.598$	Fourth Product, Thickness in inches
Assumed values which would give minimum final reading	6	.65	3.9	$\frac{1}{25000}$	.000156	$\frac{1}{.80}$	.000195	10 × 2.598	.005
Assumed values which would give maximum final reading	120	2.0	240	$\frac{1}{8000}$	.03	$\frac{1}{.50}$	.06	100 × 2.598	15.6
Practical problem of maximum size it is desired the chart shall handle	120	1.1	132	$\frac{1}{16000}$	.00825	$\frac{1}{.60}$	.01375	40 × 2.598	1.43
Fixed upon as minimum reading	6	.4	0	$\frac{1}{30000}$	.0002	$\frac{1}{1.0}$	0.0	5 × 2.598	0.0
Fixed upon as maximum reading	120	2.	160	$\frac{1}{10000}$	.0086	$\frac{1}{.30}$	.015	100 × 2.598	1.4

the same as for $(A\text{-}A_1)^2$, lay off on one side of the chart the same uniform scale from 0 to 1,000, starting with 0 at the same corner as on the top scale. Now, parallel lines drawn from one value on the top scale to an equal value on the side scale will represent the values $(B\text{-}B_1)^2$, and perform the operation of subtraction; the lines having the same values as their point of origin on the top scale need not be numbered, and the squaring operation having already been performed by the

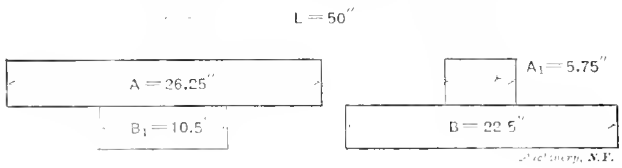

Fig 4

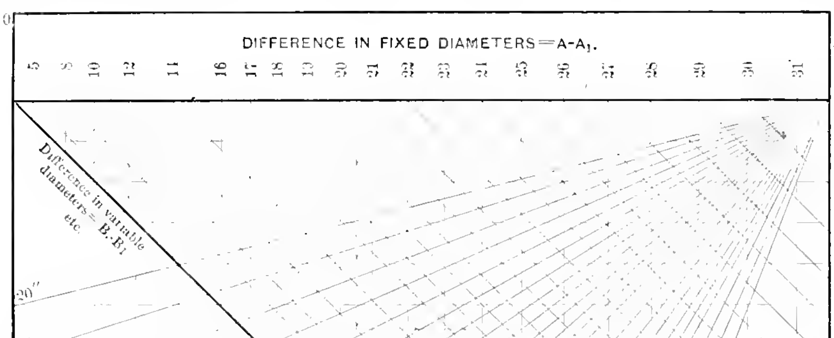
variable scale designate them $B\text{-}B_1$. The values on the side now represent the result of the first operation and are equal to $(A\text{-}A_1)^2 - (B\text{-}B_1)^2$, which value is to be divided by $2\pi L = 6.283L$.

Now lay off a uniform scale on the bottom for values of x, x_1, x_2, etc., which is the required answer. The range of this scale has been chosen from 0 to 2 inches, as this is probably the limit to which one could trust to the accuracy of the chart, since 2 inches increase in the sum of the diameters would make approximately 6 inches increase in belt length.



TOTAL CORRECTION= x, x_1, x_2 ETC.

Chart No. 7.

Choosing the intersection of the 1,000 line of top uniform scale with the zero line of the side scale as a point of origin, draw diverging lines to perform the last operation which is one of division. While these lines have a value of $6.283L$, they are designated by the values of L, the constant affecting the final value only.

Example in a pair of cones, Fig. 4:

$A = 26.25$ inches,
$B = 22.5$ inches,
$A_1 = 5.75$ inches,
$B_1 = 10.5$ inches,

as calculated for crossed belts according to the formula $A + A_1 = B + B_1$, the ratio of speed reduction being fixed by other conditions. $L = 50$ inches. $A\text{-}A_1 = 26.25 - 5.75 = 20.5$ inches, $B\text{-}B_1 = 22.5 - 10.5 = 12$ inches; correction

$$x = \frac{20.5^2 - 12^2}{6.283 \times 50} = .879.$$

Solving this same problem by Chart 7, follow as indicated by the arrows; the result is read off at the bottom as .88 inches, which is near enough for all purposes. If the pair of cones are both to be cast from the same pattern, the corrections need only be carried out up to and including the middle step, as the remaining steps are obviously duplicates of the already corrected ones. The formula upon which this chart is based is said to be nearly correct and practically perfect for a leather belt even on a foot lathe.*

* * *

TRACK INSPECTION APPARATUS.

The increase in speed, load and number of trains on the Northern Ry. of France during the past ten years has led the engineers of the system to adopt a more efficient method of track inspection than that previously used, since the stresses upon the permanent way have been considerably increased in spite of the fact that rails have been increased in weight from 60 pounds to 90 pounds to the yard. The principle of the revised method lies in the substitution of an inspection of conditions for the older one.

It is no longer based on observations derived from an examination of the conditions of the track, which may be modified by impressions that are more or less variable according to the position and temperament of the man who makes them, the condition of the cars from which the observations are made, or the mere external appearance of the section submitted to inspections. It is important that each case should be accurately defined, and that this may be done the vertical and horizontal irregularities of the track must be registered.

The author gives some reports on the methods used to inspect the tracks of the Northern Railway in a rapid and methodical manner and of preserving a record of the work done. These observations are made by means of a registering apparatus placed in a special car, which may be hauled at the rear end of any train. Two platforms located at the ends afford every convenience for an inspection of the track, of noting special points and controlling the operation. The irregularities are registered by inertia pendulums of the Sabouret type, whose oscillations are shortened by the addition of springs. The kilometer posts, the changes of grade and other points are noted on the strip of paper which is moved by a suitable mechanism and on which all results are recorded. The conditions, shown by these diagrams, are then communicated to the several section foremen, whose watchfulness is thus always kept on the alert and who will be held responsible for the repairing of such defects as may be pointed out.—*General Review of Railroads*, December, 1903.

* * *

A rule adopted in some mines is to reject a rope when it ceases to stretch. At this point the rope acquires a permanent set and thereafter the behavior of the material becomes irregular and is eminently unsafe.—*Mining Reporter*.

* This formula was developed by John B. Croker, formerly Chief Designer of the Niles Tool Works. He died about two and a half years ago.

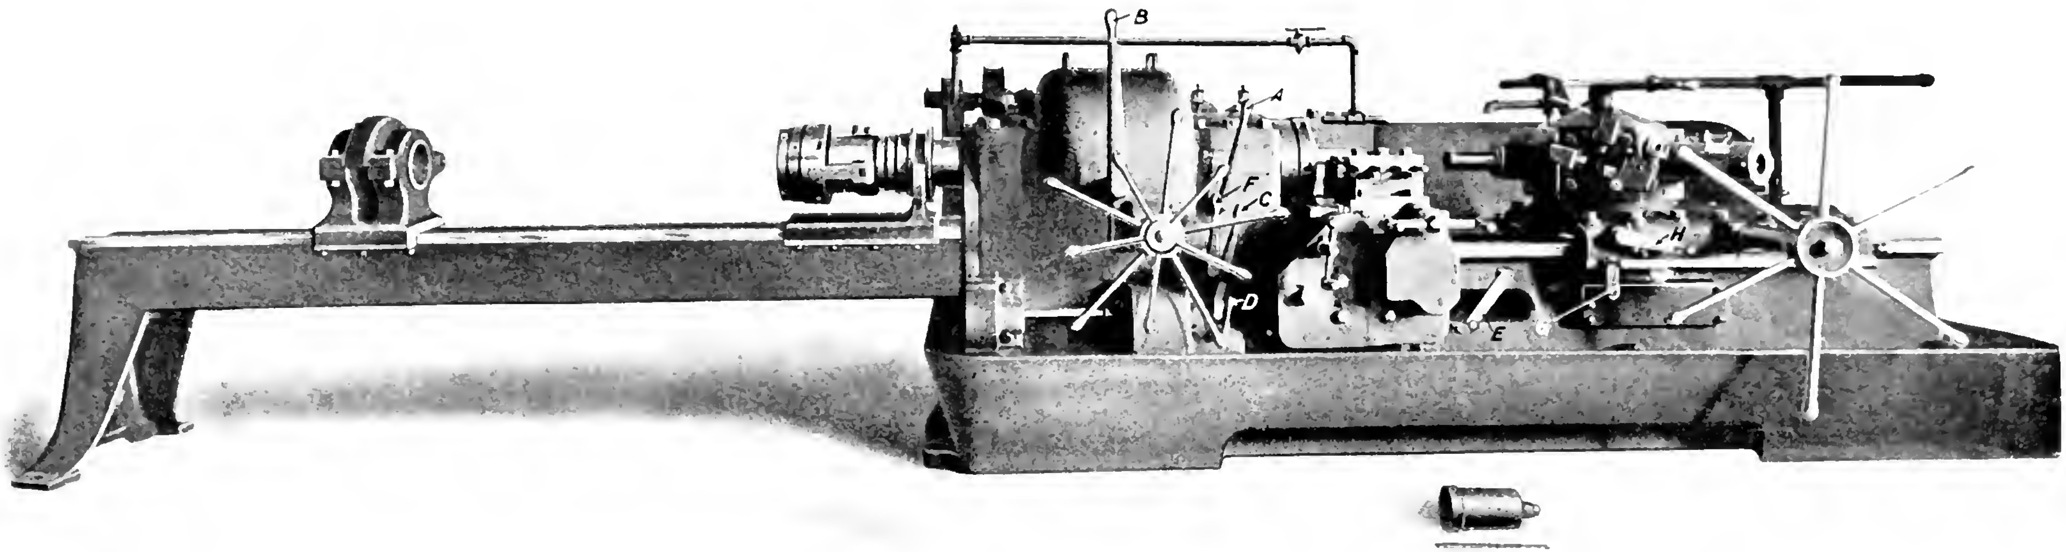


Fig. 1. Heavy Turret Lathe for Operating on Bar Stock up to six inches in diameter. Locomotive Cross-head Pin in Foreground Completed from the Bar in eighteen minutes.

A LARGE BARDONS & OLIVER LATHE.

What is probably the most powerful automatic chuck turret lathe ever built has been shipped by its builders, Bardons & Oliver, Cleveland, O., to the new shops of the Canadian Pacific Railroad Co., Montreal. The lathe is designed for operating on bar stock up to 5 inches in diameter, and is proportioned to meet the exacting requirements of the modern shop where the use of high-speed steel is the rule and not the exception.

Turret machines taking as large as 5-inch round bars have been built before, and are regularly manufactured to-day, but it has been customary on these large machines to use a special type of lathe chuck for gripping the stock. The makers of this machine have adhered to a modified form of the automatic chuck used on screw machines, believing from their experience that no method of holding a bar equals in gripping power the so-called spring chuck or collet, provided it is properly designed and constructed. With this style of chuck the stock is gripped equally around the entire circumference, and the cutting tools can be brought nearer to the spindle bearing than with any other form.

Another departure from the ordinary practice is in the support of the outer end of the bar. There are two usual methods of doing this, one to place a chuck at the rear end of the spindle, which must be opened and closed after each piece is made. The other is to allow the bar to revolve freely in a forked bearing or bushing on the upper end of a light support some distance from the rear end of the head.

In this machine a heavy guide is bolted rigidly to the rear end of the head, and extending far enough to reach the end of a twenty-foot bar when in place in the machine. Sliding on this guide is a carrier, revolving in which is a bushing or chuck, with four screws spaced equally around its circumference. By means of this the outer end of the bar can be made to revolve concentrically with the front end, and almost perfectly round work obtained when using forming tools.

The lathe head is double friction geared, giving four spindle speeds without stopping the machine, and if all three pulleys of the triple friction countershaft, which is regularly furnished with the machine, are used for "go ahead speeds" twelve spindle speeds can be obtained without stopping the machine. The greatest ratio of gearing is about 20 to 1, while the smallest ratio is about 3 to 1. The cone spindle is driven by a 7-inch belt from a triple friction countershaft, with pulleys 24 inches in diameter. The machine can be arranged for motor drive if desired. The construction of the gearing on the cone spindle is of the ordinary back gear type, a sliding wedge which engages the friction through the fingers being operated by the lever *A* on the front side of the head.

The cone spindle is connected with the main spindle through an intermediate shaft carrying a sleeve gear and pinion meshing into the two large gears on the main spindle. These last two gears are loose on the spindle, and either can be clutched to it as desired by means of the lever *B* working through a similar friction mechanism to that used on the cone spindle. Babbitt is used for the main spindle and also the cone spindle bearings. The main spindle bearings are oiled through sight feed lubricators located on the tops of the caps. The front bearing is 8 inches diameter by 13 inches long.

The cone spindle has a hole in the center running almost the entire length, connecting at one end through a stuffing box with a fixed lubricator. Smaller radial holes lead from this central hole to all bearings of the spindle and friction parts, ensuring thorough lubrication, by centrifugal force, from this one source of supply. As this is a fast-running shaft, the necessity of some such arrangement as this can be readily understood. The intermediate gear shaft is lubricated in a similar manner. All gears and rotating parts are fully enclosed.

The combined forming tool slide and cutting-off tool slides constitute one of the most striking features of this machine, and have been designed for the special purpose of producing as much of the work as possible with wide forming tools fed crosswise against the work rather than with end cuts by the turret tools. Experience obtained in the manufacture of

bicycle hubs, projectiles and other irregularly-shaped pieces of circular cross section has demonstrated the superiority of this method wherever practicable. The forming slide, shown in longitudinal section in Fig. 3, is made long and heavy, and carries two massive tool blocks, one at the rear for the roughing tool and one at the front for the finishing tool. Tools to form up to twelve or fourteen inches in length can be held in these holders. The holders are removable and special attachments can be fitted for other classes of work when desired. The forming tools are adjusted vertically by means of taper wedges, which in turn are moved by screws. They are clamped solidly to the holders by bolts passing directly through them. Screws are also provided for the lateral adjustment of the tools. A very little practice enables them to be set quickly and accurately. The forming slide can be fed by hand or power in either direction. The power feed has four changes by means of the lever C, and the reverse is obtained by the lever D, Fig. 1. The feed has an automatic release in either direction. In practice the roughing tool is usually fed by power and the finishing tool by hand. A graduated dial on the handle enables work to be formed accurately as to size.

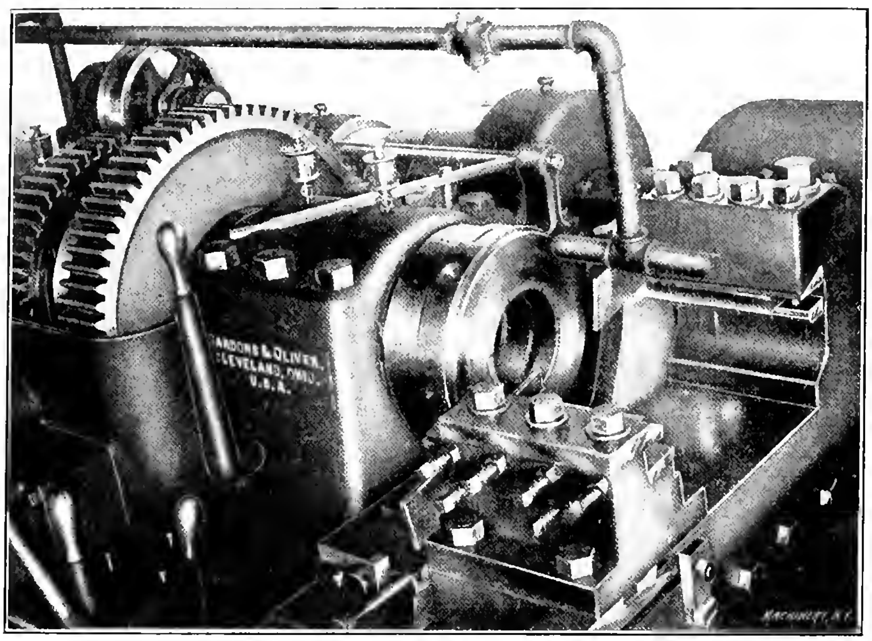

Fig. 2. View of Forming and Cut-off Tool Slides.

The cutting-off tools are two in number, mounted on separate slides, shown in longitudinal section in Fig. 4, which have an entirely independent cross feed from the forming tool slide, although they are carried on the same saddle casting, this saddle having a longitudinal adjustment of $3\frac{1}{2}$ inches by means of the handle E. These cutting-off tool slides are fed in simultaneously by a right and left-hand screw either by hand or by power. The power feed is taken from the same shaft as the power feed to the forming slide, but has separate throw out. The front cutting-off tool slide has an adjustment so that the tools can be set to cut equally. The cutting-off blades are made of high-speed steel and are of special cross section. Four changes of feed can be obtained by means of the lever C.

The turret and turret slide, Fig. 7, while amply large, are not so heavy that they cannot be readily operated by hand. The most severe duty falls on the forming slide, and with this fact in mind great care has been taken in designing the turret and slide not to make it clumsy and difficult to handle. It travels directly on the bed on flat bearings of ample width. Wipers on the front end of the slide keep these bearings clean. A taper gib runs the entire length of one side, and provides means for taking up side wear.

The turret is hexagon in form, and is 18 inches diameter across the flats. An independent stop is provided for each face of the turret, these stops having a range of 36 inches, while the total feed to the turret slide is 42 inches. Each face of the turret has eight $\frac{3}{4}$-inch tapped holes for the purpose of attaching the various tools. There is a $4\frac{1}{2}$-inch hole in each face of the turret and also through the center stud, thus enabling work up to $4\frac{1}{4}$ inches in diameter and 42 inches long to be turned. This diameter can be increased if desired. Power feed to the turret slide is provided, and four changes to this feed can be instantly obtained by means of the lever F, Fig. 1. The power feed can be tripped at any point by each of the independent stops, which also serve as dead stops for the hand feed. The power feed can be thrown in or out by hand by means of the lever G. The lock bolt is withdrawn by hand through the lever H, and the turret is revolved by hand. Means are provided for locking the lock bolt after it is withdrawn, if desired, so that the turret can be revolved in either direction past one or more holes. The lock bolt is tapered on the upper end and fits into hardened and ground steel bushings in the bottom of the turret. It also slides in hardened and ground bushings in the turret slide.

The turret has a large projection on the bottom fitting into a corresponding opening in the top of the slide. This serves to take the major part of the thrust, but in addition to this a taper bushing is inserted in the center of the turret, taking its bearing on the steel turret stud which extends from the under side of the turret slide to the top of the turret. This bushing is adjustable endwise to take up all wear. The turret stud extends through the large washer on the top of the turret, and is threaded on the outer end to receive the binder handle, by means of which the turret and slide can be clamped solidly together.

The stock is held at the front end of the spindle by means of a master collet, Fig. 5. The false jaws are easily changed without removing the collet or collet ring from the spindle, as the jaw screws extend through large holes in the spindle to a point nearly flush with the outside. A sliding ring covers these holes when the machine is in use. The false jaws are usually serrated to increase their gripping power. The collet is closed upon the stock by means of the large turnstile on the front of the head which operates the sliding wedge and fingers on the rear end of the spindle.

Variation in the size of the bar is provided for by making this wedge with three steps. The collet is adjusted by means of the adjusting nut at the extreme rear end of the spindle, so that the fingers rest on the middle step of the wedge when gripping stock of the correct diameter. If the stock comes a little small the fingers are run up to the large step of the wedge; if a little large they stop at the small step, so that the bar is always securely held by the collet.

The feed dog or carrier, Fig. 6, as has already been explained, has been designed to serve another purpose besides the mere feeding of the stock. It is in reality a four-jaw independent chuck, by means of which the stock is not only supported at the outer end, but can be made to run concentrically with the spindle at that point, thereby insuring that the finished piece will be round.

The feed dog is moved along its bed by means of the smaller turnstile on the front of the head. The shaft of this turnstile passes through the center of the shaft of the turnstile which operates the mechanism for opening and closing the collet. It has been customary to make one turnstile serve both of these purposes, but with this construction ample power can be had for operating the chuck, while for feeding the stock forward (which requires comparatively little power) a quick motion of indefinite length is obtained. Connection between the smaller turnstile and the feed dog is by means of an endless sprocket chain.

The base of the machine is cast in the form of a pan. This pan has a large reservoir at the back so that there is room for an abundant supply of lubricant without keeping the pan itself filled. A perforated plate over the reservoir keeps the chips from entering, and the lubricant that runs down

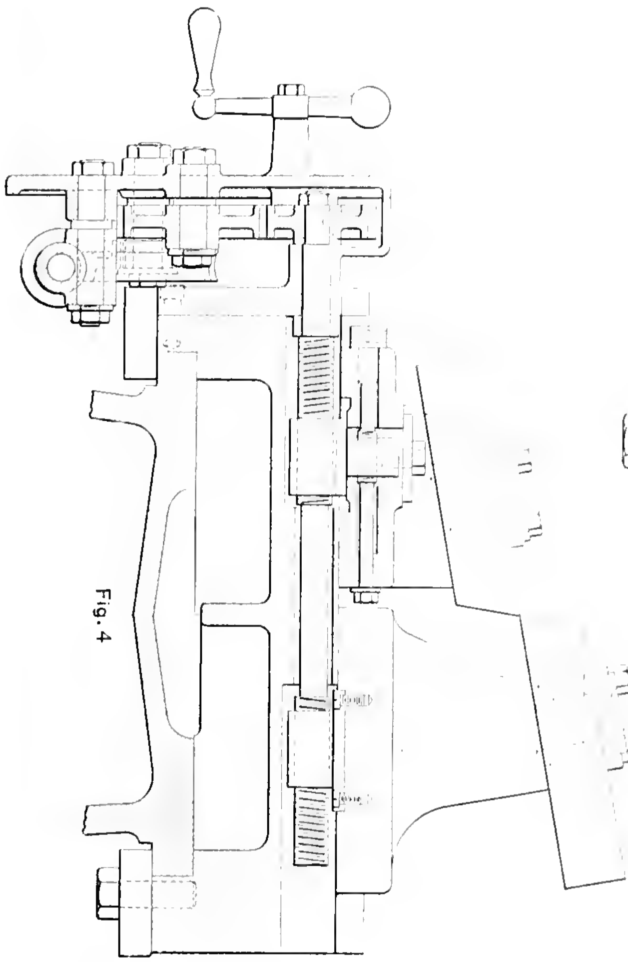

Fig. 4

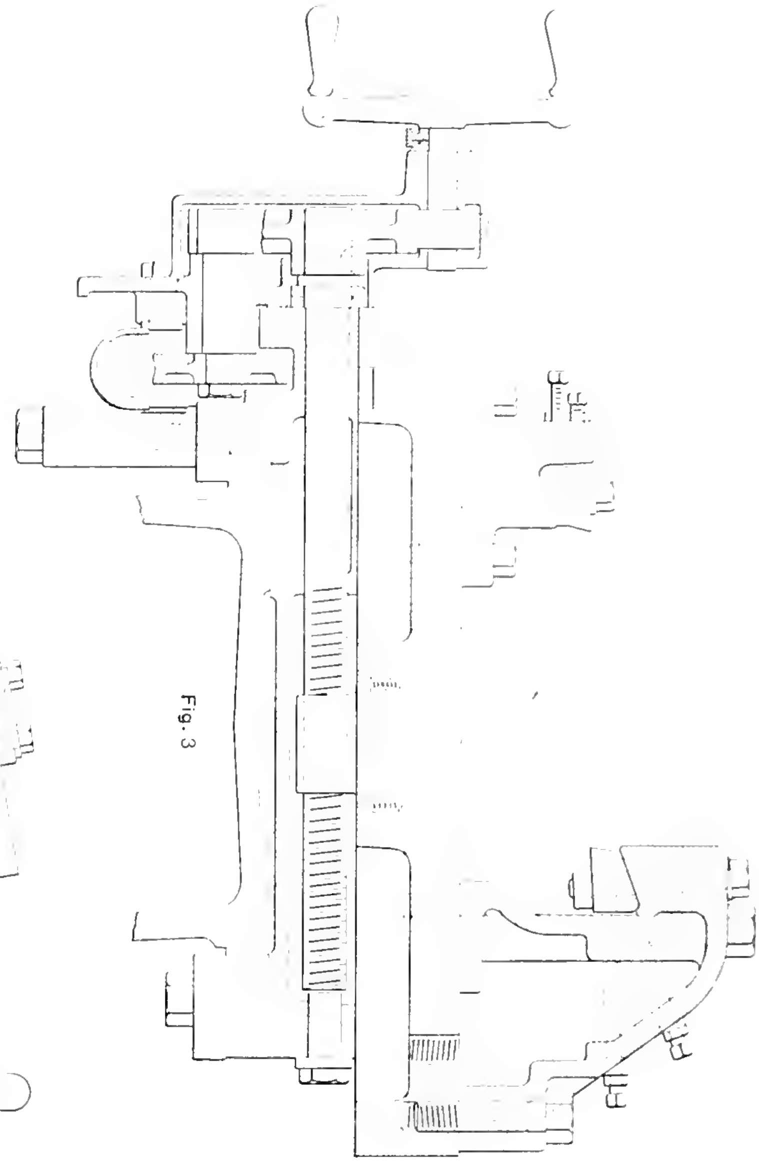

Fig. 3

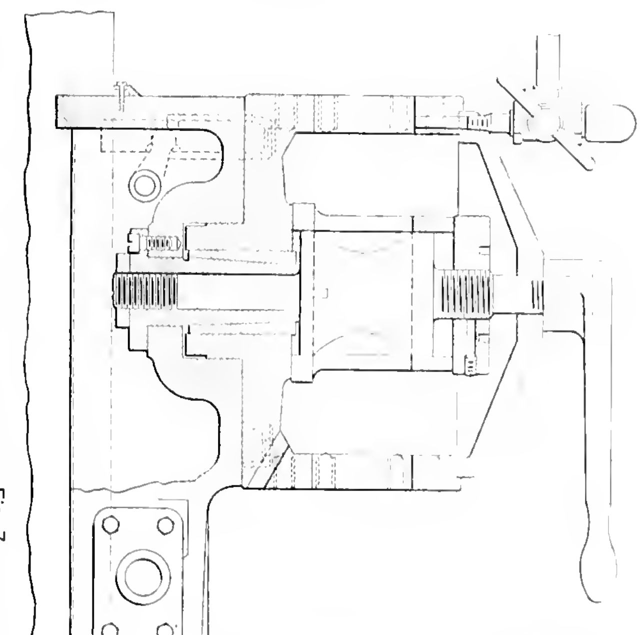

Fig. 7

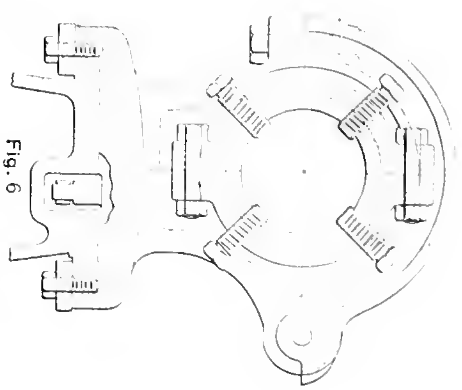

Fig. 6

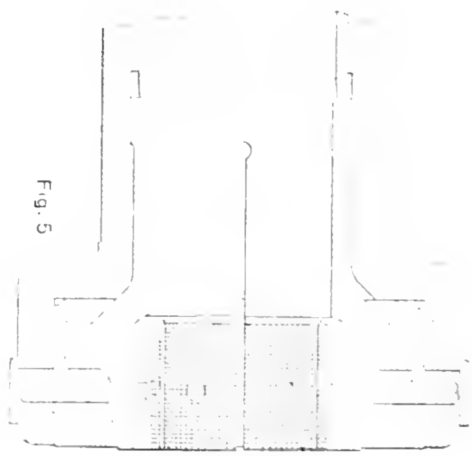

Fig. 5

Some Details of the New Bardons & Oliver Turret Lathe.

Machinery, N.Y.

the front side of the machine is conducted back to the reservoir quickly through an opening under the center of the bed. There is also an opening in the top of the bed between the turret slide and the forming slide, which allows chips and lubricant to fall directly into the back of the pan.

As an example of the capabilities of this machine, in Fig. 8 is shown a locomotive crosshead wristpin which was made from a 4¾-inch steel bar stock, in the remarkably short time of eighteen minutes. The first operation after chucking was to turn down the end to 2 inches diameter from *B* to *C*, which took seven minutes with a box tool. This tool is exceedingly strong. The cutter, which is made of high-speed steel, is provided with a releasing mechanism so that the work will not be scored when the tool is moved back. The tool has two back-rests, which are adjustable in and out, so that the work is able to be backed up at the proper place. The cotter pin end was turned by means of a pointing tool held in a tool-holder clamped to the face of the turret. The 2-inch thread was cut by a self-opening die head with roughing and finishing attachment. The section *A* and *B* was turned and shaped by means of large forming tools of high-speed steel. While the piece was being formed the cutting-off tools were started, thereby saving time. Pieces thus turned out are guaranteed to be within .001 inch of round.

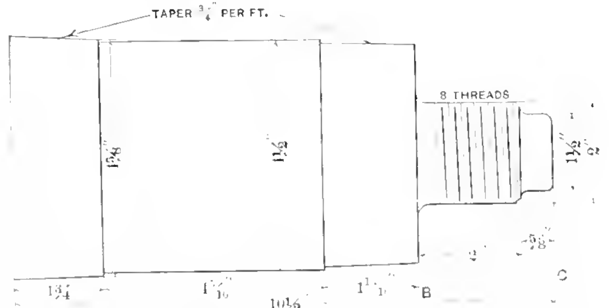

Fig. 8. Locomotive Cross-head pin made from the Bar on a Bardons & Oliver Machine in eighteen minutes.

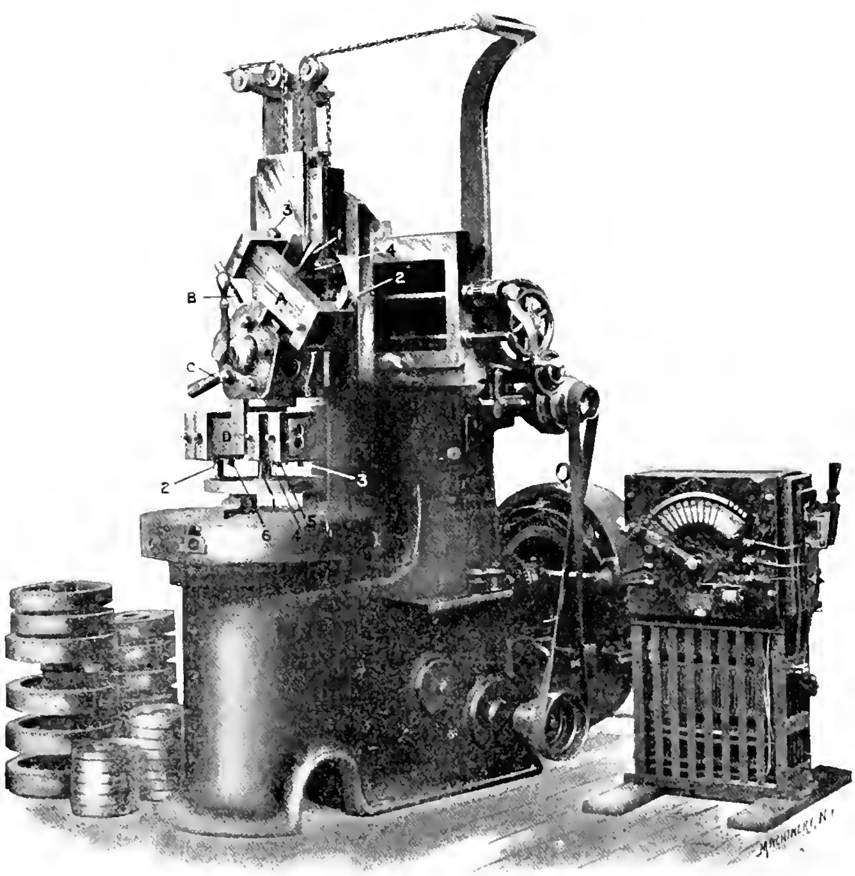
This machine can also be furnished to take bar stock 6 inches in diameter.

METHOD OF FINISHING GEARS AT THE BULLARD MACHINE TOOL COMPANY.

The accompanying illustration of a 30-inch boring and turning mill with turret head, equipped with a full set of adjustable tools for finishing gear blanks ranging in size from 4 inches to 24 inches in diameter with but two settings, will prove of undoubted interest.

The various operations and tool holders therefor are designated alphabetically, and the tools are numbered according to the successive operations performed. The blank is secured by finger jaws gripping inside of rim. It is readily brought to true by the combination chuck in table, and is brought level with the table by the parallel blocks on which it rests.

Tool holder *A*, carrying a four-lip core drill No. 1, outside turning tool No. 2 and facing tools No. 3 and No. 4 for the rim and hub, completely roughs one side of the blank while the hole is being rough bored. Tool *B*—a single-point boring tool—is next run through the bore at a racing cut to insure concentricity, leaving just enough metal to be cleaned up by the special universal joint reamer *C* to finish the bore absolutely true and to size.



Bullard Boring Mill Fitted for Rapid Production of Gear Blanks.

The tool holder *D* is of the same design as *A* but carries a standard size guide plug (No. 1) which, in entering the bore, insures concentricity of diameter, and also adds to the stability of the tool. Tool No. 2 finish-turns the outside diameter of the blank to size and has completed its operation before finish-facing tools No. 3 and No. 4 are brought into action on the rim and hub. The corners of the rim and hub are rounded off by tools No. 5 and No. 6.

In the second setting a stud (the diameter of the bore of blank) is fitted into center of hole in table and a driving stud set in T-slot of chuck jaw. A blank is then dropped over it and tool holder *A*, minus tools No. 1 and No. 2, roughs the faces of rim and hub, which are finished by the corresponding tools in tool holder *D*; the rounds being formed as before.

The method of holding blank from the inner surface of rim insures uniform thickness of the rim when finished, and by the use of the guide plug in finishing tool *D*, the outside diameter is not only turned absolutely true to size but runs on centers within .0005 inch. The tools used in the holders number twelve, and all operations are completed without moving the turret slide from its central position on the rail, thereby saving all time usually required to set tools and caliper for diameters. Most of the tools employed are of the ordinary form and can be used on other boring mill work.

All gears of the above sizes are finished in this way at the shops of the Bullard Machine Tool Co., Bridgeport, Conn., U. S. A., and a saving of from 50 to 75 per cent. is made over the more common method of separate chucking and turning on arbors.

* * *

A hydraulic lift lock was recently completed in the Trent Canal at Peterborough, Ontario, which is a unique piece of engineering on this side of the Atlantic, there being no other example of such work in American canal systems. The Peterborough lift overcomes a difference of level of 65 feet. It consists essentially of two immense steel troughs side by side into which the barges are floated, provision, of course, being made for dropping the end pieces or gates out of the way. These troughs move up and down in vertical guides and one trough counterbalances the other through the hydraulic pistons and cylinders by which they are handled. The rams of the presses are 7½ feet in diameter and have a stroke of 65 feet, working under a gage pressure of 600 pounds per square inch. It is believed that the presses are the largest ever built.

TOOL MAKING.—10.

ARBORS.

E. R. MARKHAM.

Arbors are used to provide a means of holding pieces which have holes passing through them. They may be supported by means of centers, or by portions at the end which fit in recesses of the proper shape and size; or they may have tapered shanks which fit in holes of a corresponding size and taper.

Almost every machine shop is provided with one or more sets of arbors used in providing centers for pieces of work having holes in them and which must be machined after the holes are made. These arbors are slightly tapering in order that work may be tightly forced on them to insure their holding when being machined. This taper also takes care of any *slight* variation that may occur when machining the hole to size. Arbors of this description are generally termed *mandrels*, although in some shops they go by the name of tapered arbors.

Mandrels 1½ inches in diameter and smaller are usually made of a grade of steel that will harden. For those larger than the size mentioned custom varies, some mechanics making them of steel that will harden, while others use machinery steel and caseharden it, claiming it to be sufficiently stiff for the larger sizes. As a consequence they can produce a satisfactory article at less cost than when using tool steel,

Fig. 1.

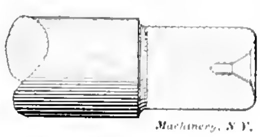


Fig. 2.

or even a low grade of steel having sufficient carbon to cause it to harden when heated to a red and dipped in water. Some mechanics make all large mandrels with the ends hardened, the balance of the mandrel being soft. As local conditions must determine the advisability of using any method, we will consider the operations involved in making them by each method.

When making mandrels from tool steel in the ordinary shop it is the custom, generally, to make them of such grade of tool steel as is in general use in the shop. However, if many mandrels are to be made this becomes a costly method, as a grade of steel can be procured that answers nicely for this class of tool which is much cheaper than steel suitable for the general run of cutting tools. Then again, steel for cutting tools—if efficiency is considered—should be made from a reasonably high-carbon steel; while mandrels are less liable to break or spring when hardened, if made from a steel containing less carbon.

The ends of mandrels are turned to size before hardening. The centers should be deeper than for tools of a corresponding size which are not to run on centers, or which are not to resist as great pressure on the centers when in use. In order that the centers of mandrels may not become mutilated when

Fig. 3.

in use, they should be made as shown in Figs. 1 and 2. The cupping shown removes the outer ends of countersunk portion from liability of mutilation when the mandrel is forced out and in the pieces of work.

The center portion of the mandrel is turned to a size somewhat larger than the finish size, the amount depending on the size of the mandrel and the method employed when hardening. Under ordinary circumstances, however, for mandrels ½ inch in diameter and smaller, an allowance of .015 inch will be found sufficient. For diameters from ½ inch to 1 inch an allowance of .020 to .025 inch; and for arbors over 1 inch, .025 to .030 will be found sufficient. As the length of mandrels larger than 2 inches does not increase relatively to the size, the last amount of allowance will be sufficient for most purposes if proper care is exercised when hardening.

The size of a mandrel should be plainly stamped on the end adjoining the large end of mandrel. This method of stamping should always be observed, as it will save endless confusion.

The corners *b b*, Fig. 3, should be rounded, as shown, to prevent their chipping if the mandrel is driven by means of a hammer. The flat spots *c c* for the dog screw to bear against should be milled or planed. In some shops it is considered

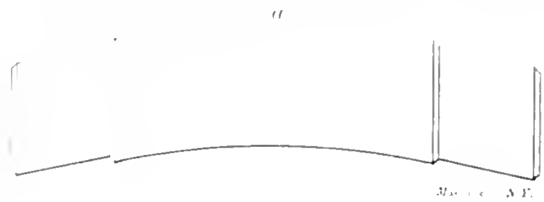

Fig. 4.

advisable to make both of the flats on the same side of mandrel as shown in Fig. 3, while in others they are located on opposite sides. This seems to be a matter of choice, and practice must correspond to the notions in the individual shops.

Before hardening, the centers should be re-countersunk to true them. For this operation a countersink made specially for this purpose should be used, the included angle of whose cutting edges should be 59 degrees instead of 60 degrees, as in the regulation article, as it simplifies the operation of lapping the centers to alignment after hardening. This operation is necessary if we wish a mandrel that will prove satisfactory, as the natural spring of the tool when hardened would throw the centers out of alignment, as shown in Fig. 4. If properly done the operation of lapping will grind these centers so they will bear properly on the centers of the machine.

When hardening extreme care should be exercised in heating, as uneven heating is a more common source of trouble than any other. In order to get uniform heats it is necessary to have a fire adapted to the piece we are to heat. Some furnaces are made which insure uniform heating, while others demand constant attention and considerable skill on the part of the operator to insure satisfactory results. If a blacksmith forge is to be used, have a fire large enough to insure a

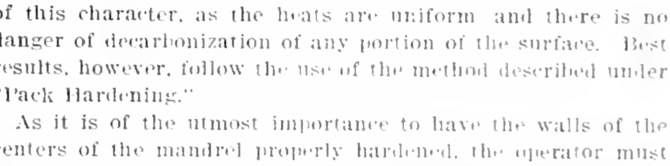

Fig. 5.

uniform heat throughout the piece. In the case of a large mandrel it is necessary to build a large, high fire, or we shall heat the article much hotter in the center than on the ends. A muffle furnace provides an excellent means of heating work of this character, as the heats are uniform and there is no danger of decarbonization of any portion of the surface. Best results, however, follow the use of the method described under "Pack Hardening."

As it is of the utmost importance to have the walls of the centers of the mandrel properly hardened, the operator must assure himself that the contents of the bath have free access to the center holes. This cannot be accomplished if the article is dipped in the bath by means of an ordinary pair of blacksmiths' tongs. In order to accomplish the desired result a pair of the description shown in Fig. 5 should be used.

Where an ordinary bath is used it is considered by many advisable to grasp the mandrel by the large end with the tongs in order that the small end may be the harder; the larger end would be more apt to come in contact with the head center of the lathe when in use and as it revolves with it, it would not be subject to as great an amount of wear.

If many tools of this description are to be hardened it is advisable to "rig up" especially for it, as better results are thus insured. It does not necessarily follow when we prepare in a thorough manner for a certain class of work that we must go to great expense in so doing; many times a comparatively inexpensive equipment answers as well as a more

costly one, and it has the further advantage of not keeping us from making changes when something better is shown us.

By using sufficient care it is possible to heat almost any mandrel of ordinary size and length in almost any fire ordinarily furnished for heating steel; but the use of fires not adapted to the piece are not to be advocated if many pieces are to be heated. It is not, however, advisable to attempt to harden work in a bath that will not give desired results; neither is it necessary as a rule, as baths can be constructed for most purposes at a comparatively small cost.

Now as we wish to harden the entire surface of the mandrel, we shall have best results if we force the contents of the bath against the sides, in order to drive away the steam which forms from the contact of the red-hot metal with the liquid. This steam, if not forced away from the heated metal, forms a cushion around or at portions of the surface, thus keeping the contents of the bath from coming in contact with the steel, causing soft portions or spots.

It is also very desirable that the walls of the center holes be hardened sufficiently to resist wear. To accomplish this we should have a supply of water coming up from the bottom of the bath and another entering it from the top. All this can be accomplished by using a bath of the description shown in Fig. 6, which has several pipes coming up from the bottom. These pipes are perforated to allow the water to be projected against the mandrel. A stream of water coming

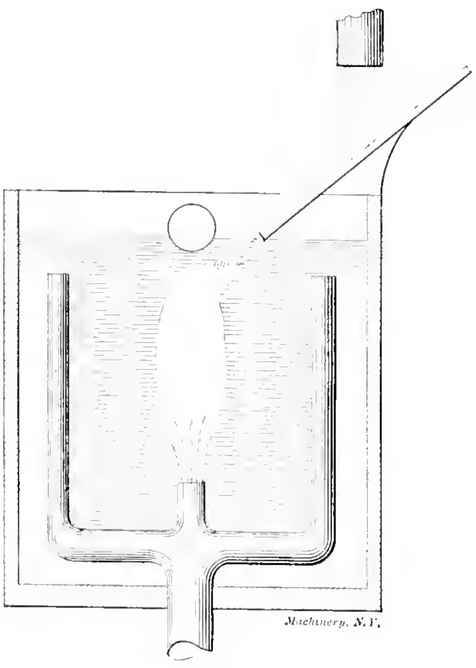

Fig. 6.

up from the bottom strikes the lower end. A pipe may supply a stream at the top of the bath, or water may run onto a board as shown, and running off the board onto the surface of the bath will give a sufficient supply for the upper end. In the absence of such a bath a barrel or tank of water, or brine will answer for small mandrels if these are worked up and down rapidly in the bath. I have hardened a great many articles of this sort in such a bath, but never with such uniform results as when a suitable bath was used. And as such a bath can be made very cheaply by taking an oil, or other suitable barrel, and making the necessary pipe connections, it seems folly to use something not suited to the job, provided, of course, we have a sufficient quantity of work to insure our going to even this slight expense.

As small mandrels would be very apt to break when in use if left as brittle as when taken from the bath, it is necessary to draw the temper of those smaller than ¾-inch diameter to a straw color. In order to do away with liability of chipping the corners of ends of mandrels when driving them in or out of work it is advisable to draw the *ends* of all mandrels to a straw color, leaving the *bodies* of the larger sizes, however, as hard as when taken from the bath. If the ends are softened by tempering, as suggested, the operator must be sure to leave them harder than the centers they are to run on; but as centers are generally drawn to a brown color, the arbor ends, if left at a light straw color, will be enough harder than the centers to insure the centers of the mandrel resisting wear. That is, the lathe centers, being the softer, will wear, which should be the case, as the lathe centers can be easily trued, while if the centers of the mandrel wear the tool is ruined.

After hardening and before grinding, the body of the mandrel should be cleaned of all scale or grease, as this would glaze the emery wheel used for grinding it to size. As long articles if hardened by the methods ordinarily used are liable to be somewhat sprung, they should be tested before grinding to ascertain if they have sprung more than will grind out before they are to size. This can be accomplished by cleaning the scale out the center hole, then trying on centers. If sprung, the smaller sizes may be straightened by the method illustrated in the article on counterbores. In order to straighten larger sizes it will be necessary to heat them as described and straighten them under a screw press or similar device. Generally speaking, however, if due care has been exercised when making and hardening it will not be found necessary to straighten the larger sizes, as they will rarely spring enough to require this operation.

The centers may be lapped to shape and alignment by means of a copper lap of the proper angle (60 deg.) charged with emery. The lap may be held in a drill chuck in the head spindle of a lathe and revolved at a fairly high rate of speed. The opposite end of the mandrel may be supported by the tail center of lathe, and the necessary pressure be applied by means of the tail spindle screw. After the centers are lapped to shape, carefully clean all emery from them by washing in a can of kerosene oil, or in benzine—preferably the latter. If benzine is used care must be exercised that it is not brought near a flame, as it is extremely inflammable.

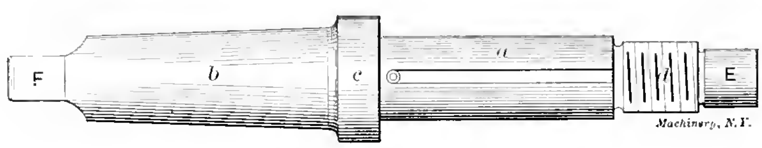

Fig. 7.

In shops where it is used it is kept in a can or dish having a cover which fits tightly. When the cover is removed a rod is passed through a loop in the top which is long enough to allow the cover to be put in place without burning the hands should the benzine catch fire. If it is used at all it should be in small quantities to avoid danger, as far as possible.

As the truth of the mandrel depends in so great a measure on the condition of the centers of the machine it is ground in, they should be carefully examined before using. A mandrel should be ground to size in a universal grinding machine if one is available, as both centers are dead centers; that is, neither of them revolve, the work instead revolving on them. However, if no such machine is available an engine lathe having the necessary grinding attachment may be used.

For work of this character it is best to have a machine which allows the use of water running on the work to keep it cool. In the absence of such facilities, however, it may be ground dry, but the operation is necessarily slower.

If the grinding is to be done on an engine lathe provided with a grinding device we should assure ourselves that the live center is to the proper angle and runs true. Should it *run out* when the mandrel is ground it will cause the piece of work to run out of true on the end adjoining this center. The dead center should be in good condition in order that it may have a good bearing in the centers of the mandrel. The live spindle of the lathe must fit nicely in the boxes, or any irregularities in the belt or the portion where the belt is laced will cause a jump in the spindle which will of course be duplicated on the work being ground. However, if reasonable care is exercised, and the lathe is in good condition, excellent work can be turned out without the latest form of universal grinding machine. In some shops it is the custom to convert the oldest lathe in the equipment into a grinding

lathe and as the work that should be finished by grinding is generally of a character that requires accuracy and truth anything but satisfactory results follow.

The work should be ground to within a few thousandths of an inch of finish size with a coarse wheel, as otherwise it would become heated and spring. Now pieces of steel are very apt to spring somewhat when hardened; it is obvious that when we start grinding it is on the convex side, as shown at *a*, Fig. 4. If we grind with a fine wheel, or one that is glazed we heat the work and this heating is on the convex side; and as the effect of heat is to expand metal it expands or becomes longer on this side, thus springing it still more.

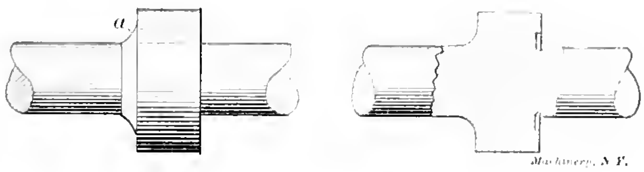

Fig. 8. Fig. 9

Mandrels for ordinary shop equipment are made somewhat tapering. It is generally considered good practice to give them one-half thousandth inch taper to an inch of length, and this seems to give general satisfaction. However, for some purposes it is advisable to give double this amount, or .001 inch to each inch of length, but never unless the pieces that are going on them are comparatively thin, or short. A long piece would get a bearing on only one end and as a consequence the opposite end when machined would be somewhat eccentric to the hole.

Special mandrels made for holding long pieces of work are made nearly, or quite straight, thus insuring a bearing the entire length.

The small end of a mandrel is ground slightly smaller than the size designated—say one-half thousandth inch for ordinary sizes. If larger than 1 inch make it one-thousandth inch smaller.

After grinding to within a few thousandths inch of finish size with a coarse wheel, the work should be finished to size with a fine wheel.

Mandrels with Hardened Ends.

The ends of this form of mandrel are made the same as those previously described. The center is roughed to a size somewhat larger than finish, the amount depending on the size of the mandrel and the method to be used in finishing. If the body is to be ground to size the amount need not be as great as when the mandrel is hardened all over. If, however, it is to be turned to size in the lathe it is necessary to leave considerable more, leaving it, say, 1-32 to 1-16 inch above finish. The ends should, of course, be hardened before

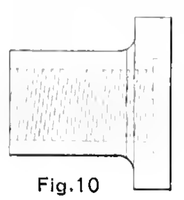

Fig.10

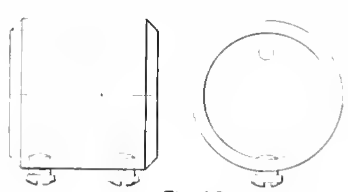

Fig.13

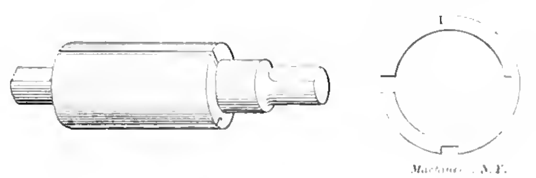

Fig. 16.

the body is finished, which can be accomplished by heating in an open fire or a crucible of red-hot lead, then dipping in a bath having a jet coming up from the bottom. It is necessary, of course, to heat one end and harden it, then proceed with the other end. If the piece is being heated in the open fire it will be found necessary to protect the end first hardened, while the other end is being heated, by covering it with a wet cloth or piece of waste that has been saturated with water. The same instructions given previously for grinding answer when mandrels are made with soft bodies. If the body is to be turned to size look to the condition of spindle bearings and centers.

Making Mandrels of Soft Steel.

When mandrels are made of soft steel, the same general directions given for making of steel that will harden may be followed, up to the operation of hardening. It will be necessary, of course, to caseharden them, which is done by packing in a hardening box, surrounding them with charred bone. The cover should be placed in position and the joints sealed with fire clay mixed with water to the consistency of dough. This is termed luting. After the clay is dry the box may be placed in the furnace and the work subjected to heat for a length of time that will insure its hardening to the required depth.

In order to insure the centers being sufficiently hard it is sometimes considered advisable to sprinkle a little powdered cyanide of potassium in the center holes after the mandrel is taken from the fire, and before dipping in the bath.

The depth of hardening necessary depends in a measure on the nature of the work to be machined on the mandrel and should be deep enough to prevent its being mutilated by carelessness.

Taper Mandrels.

This form of mandrel is made in the same manner as the ordinary form except that the body is of the desired taper. If other means are at hand it is not advisable to turn the taper on this form of tool by setting over the tailstock of the lathe, as this method has a tendency to distort the center holes; a lathe with a taper attachment should be used if

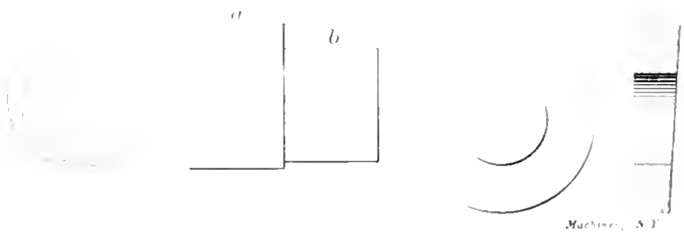

Fig. 11. Fig. 14

possible. If no such attachment is to be had and it is necessary to set over the tailstock, the centers may be carefully recountersunk before hardening.

If possible, grind taper mandrels on a universal grinding machine. If such a machine is not at hand and the lathe must be used by setting over the tailstock, exercise all the care possible to prevent distorting the center holes.

Milling Machine Arbors.

This form of arbor should be made from a stiff steel. As a rule crucible tool steel is used. Where many arbors are to be made it is advisable to use a cheap tool steel, or a machinery steel sufficiently stiff to prevent its springing when subjected to strain incident to arbors of this class. A good grade of open-hearth steel containing 60 to 70 points carbon answers nicely, and the arbor, or portions of it, may be hardened if desired.

Arbors of this class may be forged to shape, being left large enough to machine to size, or they may be turned from stock a trifle larger than the largest part; or they may be made from stock sufficiently large to turn to the size of shank (*b*) Fig. 7, or body (*a*); and the shoulder (*c*) made as a separate piece and shrunk on. If this method is followed it is advisable to leave a portion of the stock somewhat larger than the hole in the piece we are to shrink on, as shown in Fig. 8 at *a*. This prevents the shoulder *c*, Fig. 7, from moving if it is subjected to severe strain when tightening the nut. Another method consists in welding the shoulder *c* onto a piece of steel of the desired size.

After turning in the lathe to dimensions 1-16 inch larger than finish size the ends *E* and *F* should then be turned so that *E* will be .015 large in order that it may be ground to size after hardening, while *F* is brought to size and the tenon milled as shown. After this the centers should be recountersunk and the ends hardened. After hardening, the end *E* should be drawn to a full straw color, and *F* to a deep brown

The portion d should be turned to size and threaded to receive the nut, which should be made and hardened before this portion is threaded.

If a lathe having a taper attachment is not available, and it is necessary to turn the tapered shank b by setting over the tailstock, it should be turned before the portion a. If a grinding machine is available, a and b should be left .018 to .015 inch large and ground to size. If the portion a is to be ground the arbor should be splined before grinding.

Before splining, a hole should be drilled a trifle deeper than the depth of spline cut, and with a drill a little larger in diameter than the width of the spline slot. This hole is to furnish a place for the tool to stop in when cutting the spline slot. This operation should be done in the shaper or planer.

It was formerly customary to make the slots in arbors and milling machine cutters in the form of a half-circle. When the cutter was placed on the arbor a complete circle, more or less irregular, was formed. A piece of drill rod was used for a key. This method has been superseded in most shops by slots having vertical sides and which receive a square piece of stock to keep the cutters from turning on the arbor.

Fig. 12.

If the portion of arbor marked a, Fig. 7, is ground to size, it is advisable to grind the side of the shoulder next this portion in order that it may be at right angles and perfectly true with this portion, which may be accomplished very nicely if the side is made as shown in sectional view, Fig. 9.

It is customary to make nuts for arbors of machinery steel, which are casehardened when completed. They are made by placing the blank in a lathe chuck, drilling, boring and threading to the desired size. If a tap of the proper diameter and pitch is at hand the thread may be cut with an internal threading tool nearly to the proper depth, then finished with the tap. If a tap is not available it may be threaded to size with the threading tool. The outer end should be faced, and the threads at the end turned out for a distance of 1/8 to 1/4 inch. It may then be placed on a nut mandrel and finished. After the sides to receive the wrench have been milled the nut may be hardened. After hardening it is advisable to square the end a, Fig. 10, by grinding, in order to correct any irregularities caused by hardening. When grinding it is necessary to screw the nut onto a nut mandrel which runs perfectly true.

Eccentric Mandrels.

When it is necessary to machine a piece of work similar in form to that shown in Fig. 11, or any piece having a portion which is eccentric to the hole, it is necessary to have an arbor

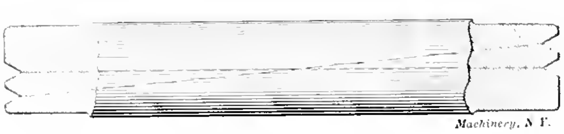

Fig. 15

which has a pair of centers in its ends located in the proper position to give the desired amount of eccentricity. If the piece is of the form shown in Fig. 11, then the portion marked b may be turned with mandrel running on the regular centers, and the portion a with it running on those which are eccentric to the outer surface. Fig. 12 shows a mandrel of this type.

When making this style of mandrel the instructions given for making the common form of mandrels should be observed, except that with the exception of large mandrels it will not be found advisable to cup the ends around the centers, or at least but very little.

There are several methods employed when locating the eccentric pair of centers, the method used depending on the accuracy necessary to observe when machining the work. If extreme accuracy is not essential the mandrel may be placed, before hardening, between the centers of a lathe. Having previously set a surface gage needle at the height of the point of the lathe centers, now draw a line on each end of the mandrel from the center to the circumference. The needle may be raised the proper amount to produce the desired eccentricity. The mandrel may be turned one-quarter revolution to bring the lines scribed on ends in a vertical position at the top of mandrel. Then lines may be scribed which will intersect the vertical lines at the desired distance from the center. Prick punch the ends where the lines intersect, after which the eccentric centers may be drilled and countersunk. If care is exercised when doing these various operations the result will be near enough exact for most work.

The same result may be accomplished if the mandrel is held in a V-block on a bench plate and the centers laid off by means of a surface gage. In this case, however, it will be necessary to caliper the ends, set the surface gage needle to the height of the top of end, then lower a distance equal to one-half the diameter of end.

If the eccentric centers must be of an exact distance from the center of mandrel and just alike, it will be advisable to make a jig of the form shown in Fig. 13. In order that the jig may do accurate work it will be necessary to turn the ends of mandrel so they exactly fit in the jig. A line must be drawn on the jig, as shown, then a line must be scribed the entire length of mandrel, or at least on each end, to set the jig by, in order to insure exact alignment of the eccentric centers.

It is sometimes necessary to face pieces of work as shown in Fig. 14, the one side to be at right angles to the hole, the opposite side to be at an angle as shown. This may be accomplished by making a mandrel having its eccentric centers on opposite sides of the center holes, as shown in Fig. 15. Either style of mandrel, Fig. 12 or Fig. 15, may, after hardening, be ground to size on the concentric centers.

When there is a slight variation in the size of holes in pieces to be machined on mandrels, a form known as an expansion mandrel is many times used. Not only will any slight variation be taken care of, but the mandrel bears the entire length of the hole in the piece as the bearing points of the mandrel expand on parallel lines. There are several styles of this form in use. That in Fig. 16 gives excellent satisfaction and is easily made. The mandrel proper is made sufficiently tapering to give the desired amount of expansion. It is hardened and ground to size, the sleeves are made with holes of a taper corresponding to the taper of mandrel and they are then split as shown. After the burrs are removed from the hole the shell is placed on the mandrel and ground straight and to the desired size. If a taper expansion mandrel is wanted the outside of sleeve may be given the desired taper. A valuable feature of the expansion mandrel is that it expands into the hole in a piece of work instead of being pressed through it. However, when it is desirable to maintain accuracy as to concentricity expansion mandrels are seldom used.

* * *

Ammonal is a new high-power explosive adopted for the bursting charges of shells by the Austrian Government. Like thermit one of its principal ingredients is powdered aluminum. The other principal ingredient is nitrate of ammonia, hence the name. Unlike guncotton, dynamite, lyddite, melinite and other high-power explosives that have been tried with little or no success for the bursting charges of shells, ammonal cannot be exploded by shock, but, like common black powder, it must be fired with a fuse. For this reason it is likely to become considerably used in the arts of both war and peace. It is the invention of Herr Hans Van Dahmen and is manufactured in the explosive works of Mayr & Roth, Felixdorf, Austria.

* * *

A recent consular report refers to a new application in Australia of the principle of the coin-in-the-slot machine, stating that if a stamp cannot be purchased conveniently it will be possible in the future to drop a letter into one orifice of a postal box and a penny into a second orifice, and the words "one penny paid" will be found impressed on the envelope when the box is opened by the postoffice authorities, thereby securing the transmission of the letter.

SOME ENGLISH LATHES.

JAMES VOSE.

In small, and even fairly large, shops the question arises: "How may we best obtain as great a proportion as possible of the benefits of a modern special turret lathe without sacrificing the 'all-round' handiness and capacity of the ordinary screw-cutting lathe?" Moderate cost is, in this connection, generally a matter of moment. The illustrations and particulars herewith indicate how one English concern—Clark's Engineering Co., Ltd., Luton—have endeavored to fulfill these conditions. Readers will form their own conclusions as to how far these efforts are successful from the sketch and time given for the job in Fig. 4. Before describing the tools more nearly answering the description of turret lathes, the 6-inch lathe, Fig. 1 (swinging 12 inches over bed) is a recent example of what in English phraseology is generally described as a "self-acting, sliding, surfacing, and screw-cutting lathe, with gap bed." It will be noted that, with a view to obviating the theoretical disadvantages of the gap bed—the springing of the bed out of alignment—the makers place the left hand leg, which acts as a change-wheel cupboard, underneath the gap—a plan first adopted, I believe, by Mr. Geo. Richards. The

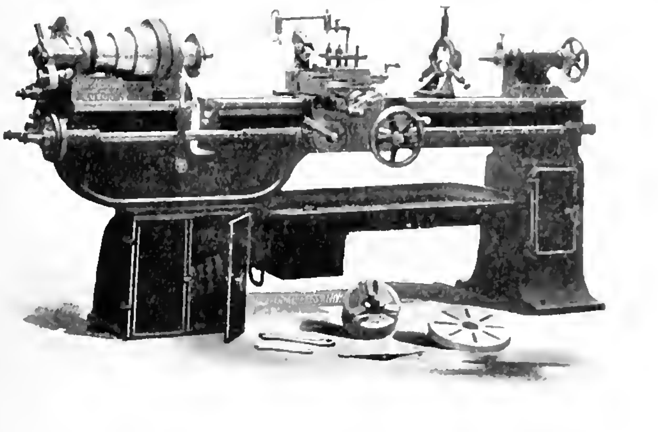

Fig. 1. Type of English Gap Lathe.

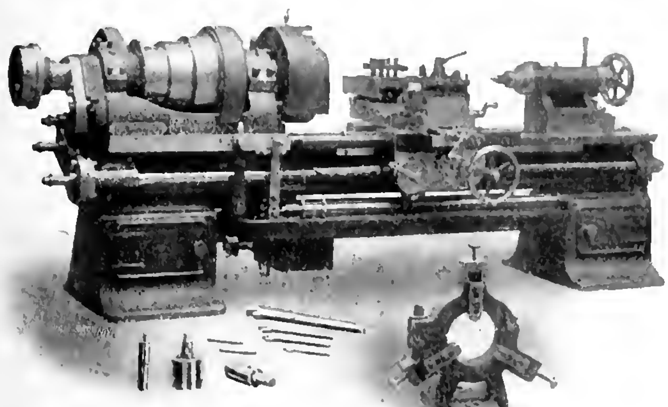

Fig. 3. Eighteen-inch Hollow Spindle Lathe for Operating on Bars four inches Diameter or less.

gap enables a job 24 x 7½ inches to be swung for boring, etc. Each step of the cone pulley is 2½ inches wide, and the diameter of poppet spindle is 1¾ inch. Three changes of feed are instantly available for sliding and surfacing. The characteristically British four-stud slide rest has a base almost the full length of the slide. On the transverse feed screw is the notched dial wheel of a "quick withdraw" motion, used when screw cutting, for drawing away the tool on the return traverse, and bringing it to its previous position ready for the next cut. The cut-away tailstock, popularized by American makers when they first endeavored to cater to British requirements, is arranged with transverse slide for taper turning, etc. The hinged steadyrest is also designed on American lines. The position of the traveling rest may be moved in the direction of the length of the bed, a facility well worth having. The lathe is fitted with a hollow spindle to take a 2-inch bar. The sud pump and chips pan are an optional portion of the outfit. As in other lathes by this company, the center holes are Morse taper. When the lathe is built to take a job 3 feet long between the centers its weight is 2,264 pounds.

In the hollow spindle capstan lathe, Fig. 2, which swings 16 inches and deals with 3-inch bars, the saddle is arranged to slide past the chuck, when desired, as in some of the more recent American heavy turret lathes. The automatically revolving turret is arranged with six stops. As in the lathe Fig. 3, the headstock bearings are parted diagonally, which would appear to tend toward steady running. The pump, sud fixtures, and splash trap allow of a wide range of brass and steel work to be dealt with in the general shop. The universal chucks generally fitted on these lathes are made by Chas. Taylor, Birmingham. When on a 6-foot bed the weight of this tool is about 2,100 pounds. In the 18-inch swing lathe, Fig. 3, the hollow spindle takes a 4-inch bar, with bed 9 feet long takes 4 feet 2 inches between the centers, and weighs over

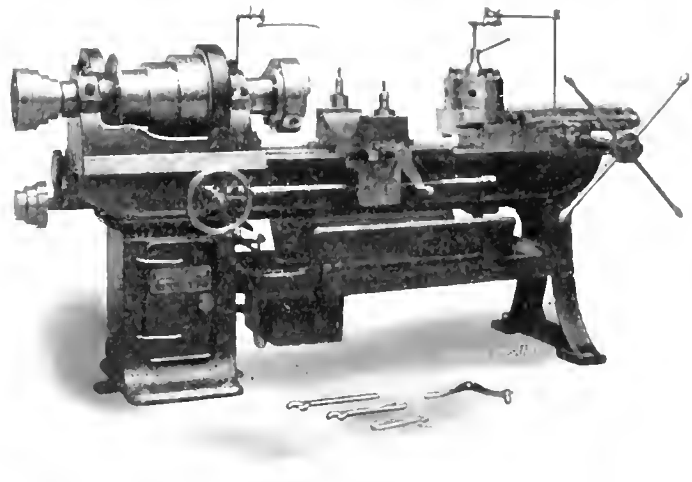

Fig. 2. Turret Lathe.

6,000 pounds. The usual three quick change feeds are available, and the sliding saddle is controlled by six longitudinal stops. The width of steps on the belt cone is 4 inches and the ratio of back gear is 11 to 1. Self-centering chucks are fitted at both ends of the spindle. The loose poppet-head is secured to the bed by two 1-inch bolts and a plate the full length of head. The diameter of the spindle in loose head is 3¼ inches.

The accompanying dimensioned sketch of a job produced complete from a 6½ square steel bar will give a better idea of the metal-removing capacity of the tool than any lengthy description. It will be noted how the outer end of the poppet spindle is notched to suit the projections on the drill socket, thus preventing scoring of the center hole when boring work. A 14-inch swing by 7 feet 8 inch bed by 3-inch bore hollow spindle lathe, built on the same lines as the above weighs 3,700 pounds, and takes 3 feet 8 inches between centers. The width of belt cones is 3½ inches, the ratio of back gears is 10 to 1 and the diameter of loose poppet spindle is 2 inches. The saddle is fitted in front with a 4-tool square turret and depth

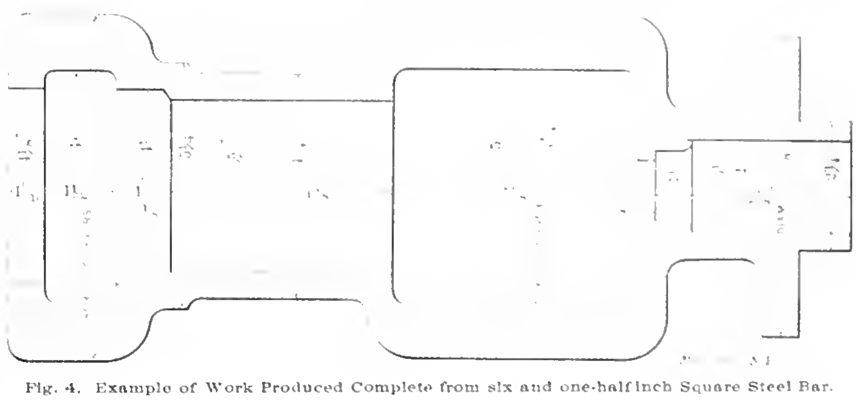

Fig. 4. Example of Work Produced Complete from six and one-half inch Square Steel Bar.

stops and at the rear with a cut-off and forming slide arranged also if desired to carry a die head of the Jones & Lamson or Geometric type. These features as well as an automatic feed to the poppet spindle, worked by gearing from the back spline shaft are applied to both the 14 and 18-inch swing lathes. It is claimed that these lathes are easily capable of utilizing the peculiar features of the latest high-speed tool steels, the cutting tools giving way before checking the speed of the lathes. In conclusion it may be mentioned that the

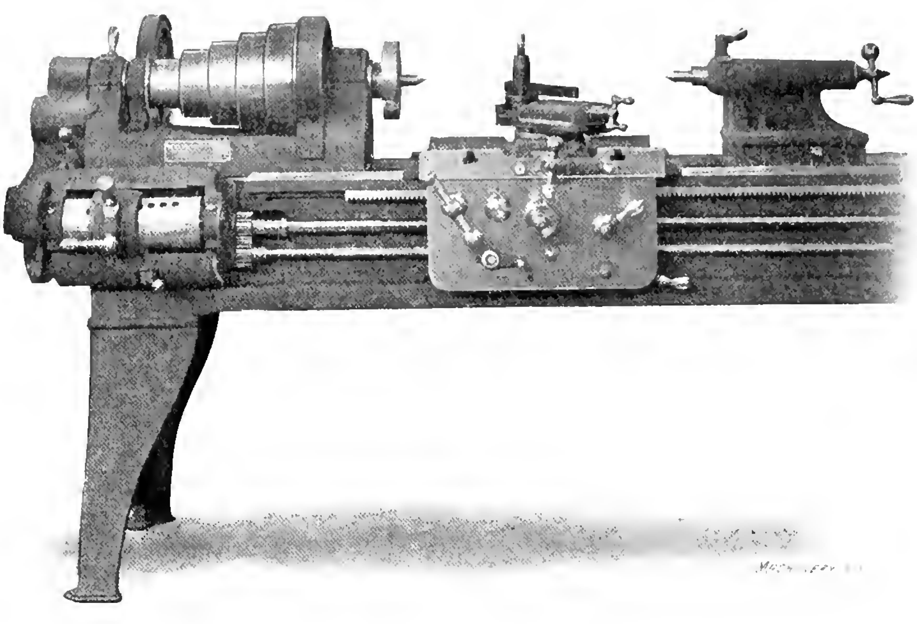

Fig. 1. Sixteen-inch Le Blond Lathe.

subject of quick removal of metal is exciting great interest in Great Britain, scarcely a week passing without a discussion taking place on the topic, or a new lathe for the purpose being placed on the market.

* * *

LE BLOND LATHE WITH QUICK CHANGE GEAR DEVICE.

A new quick-change gear lathe has been placed on the market by the R. K. Le Blond Machine Tool Co., Cincinnati, O. The lathe is fitted with a feed box containing a nest of gears for transmitting motion to the feed rod and leadscrew. These details as well as the gear connection between the feed box and the lathe spindle are shown in the accompanying engravings. The lathe, with the exception of these features, is the same as the standard engine lathe built by this company, and the headstock end is shown in Fig. 1, which gives a good idea of the exterior appearance of the change gear device.

The line drawing, Fig. 2, shows the connection between the feed box and the lathe spindle. The spindle gear A drives gear D on the stud D_1 through tumbler gears B and C. The tumbler gears are of the regular construction used for reversing the motion of the carriage in screw cutting, so as to cut either right or left-hand threads, as required.

Motion is transmitted from the tumbler gears through gears D, E_1, G and H, which latter is on the driving shaft of the feed box. In order, however, to obtain a second series of feeds there is a telescopic slip gear located on the stud D_1 which can be made to mesh with gear G in place of pinion E_1 which is shown in mesh with gear G in the engraving. To accomplish this G rotates on a pin in a quadrant G_1 which by means of the clamping handle G_4 and the stops G_2 and G_3, can be brought into the correct position for gear G to mesh either with pinion E_1 or gear F, as required. The hub of gear F is recessed so that it can be slid over pinion E_1, thus bringing this gear in the same plane with gear G. Gears D and F and the pinion E_1 all rotate with the stud, which is journaled in a bearing in the headstock casting. The introduction of the telescopic gear F makes a change in the feed ratio of 4 to 1.

Fig. 4 is reproduced from the patent specification and shows clearly the mechanism of the feed box. A is the driving shaft and B the driven shaft, which in this case is represented as being one end of the leadscrew, but in the actual lathe is connected with the latter by suitable intermediate gearing. However, the principle of the feed changes is the same in either case. Shaft B carries a cone of gears and shaft A an elongated spur gear C, which is the driving gear of the mechanism. Surrounding C is a cylindrical barrel D, which serves the double purpose of a casing for this gear and a bearing for a sliding bushing E, by means of which the adjustment of feed is effected. This bushing carries at F an intermediate gear which at all times is in mesh with gear C and can also be brought into mesh with any one of the gears in the cone by giving the bushing E a combined sliding and rotary motion on the barrel D. The portion of the barrel D which is toward the cone of gears is provided with a longitudinal slot, to allow the intermediate gear F to project through and mesh with gear C. The front portion of the barrel is provided with a series of holes, corresponding in number and position to the gears of the cone, so that the bushing which carries the intermediate gear F can be locked in its proper position for each gear by means of a spring pin, after the usual manner. The bushing which acts as carrier for the gear, and the barrel which encases the elongated gear, are clearly represented in the general view of the mechanism, Fig. 3.

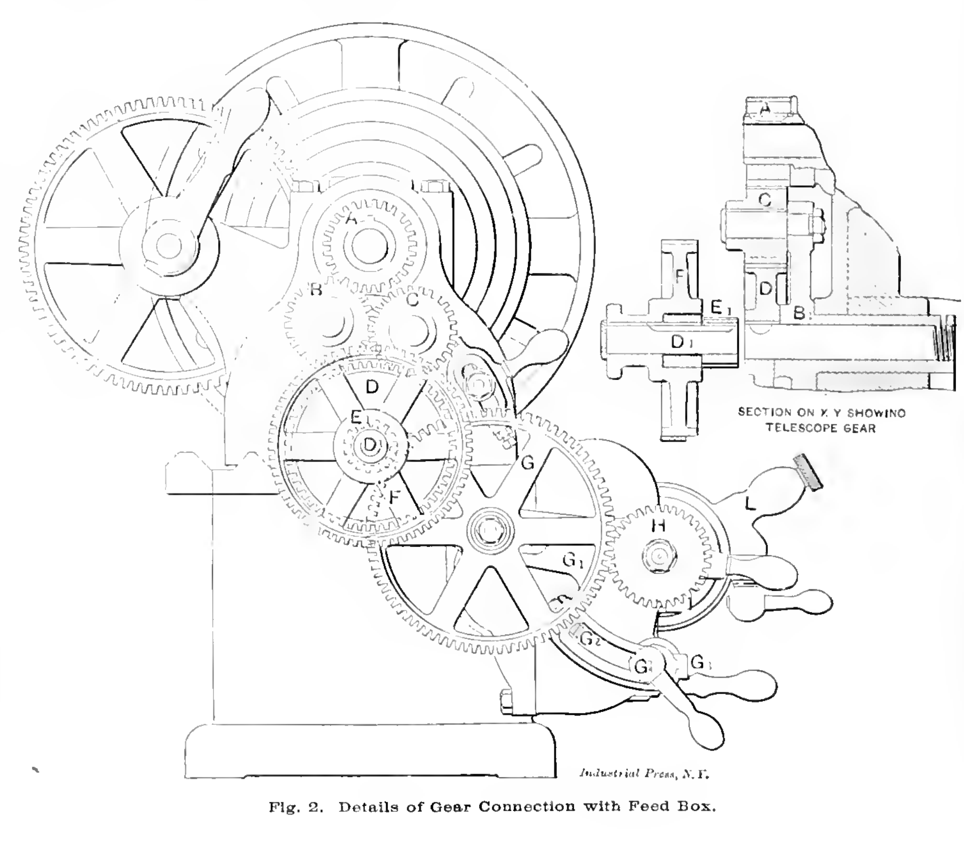

Fig. 2. Details of Gear Connection with Feed Box.

Fig. 5 is a view looking at the rear of the mechanism and its casing, and shows the modifications that have been made in the device to adapt it to the engine lathe. The cone shaft carries besides the eight gears of the cone an additional gear, *K*, and below this shaft, which is marked *B*, is the shaft *L*, which is connected directly to the feed rod, *R*, and carries a sliding sleeve, *S*, on which are two pinions, *M* and *N*. In

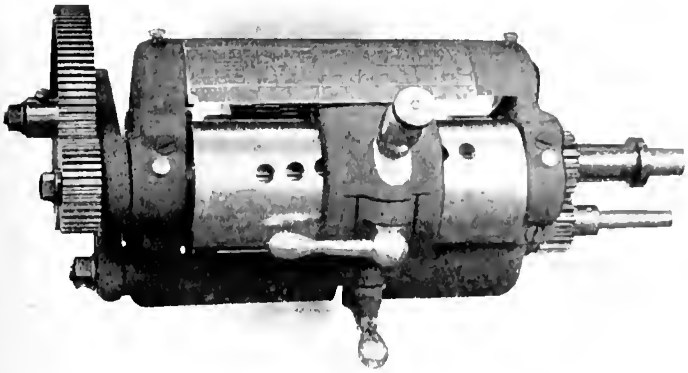

Fig. 3. Feed Box containing Gear Cone.

the position shown in this view power is transmitted from the cone shaft *B* to the gear *N* by means of the auxiliary pinion *K*, and as the sleeve *S* is splined to shaft *L* the motion is transmitted to this shaft and thence to the feed rod. By sliding the sleeve to the right, gear *N* no longer meshes with pinion *K*, but instead pinion *M* meshes with one of the gears of the cone, causing the feed rod to rotate at a faster speed. The leadscrew *T* is driven from the feed rod by a slip gear, *W*, in the usual manner.

In the general view, Fig. 3, the quadrant and the pinion on the shaft with the elongated driving gear appear at the left, while the upper shaft at the right is the leadscrew and the lower one, the feed rod. The slip gear, by which an additional set of speeds is obtained for the feed rod and leadscrew is operated by the handle on the bottom of the engraving.

From the above description it will be seen that with the gear box itself, eight changes of feed are obtained. The slip gear on the auxiliary shaft in the feed box makes 16 changes, and these 16 changes are again doubled by the telescopic gear on stud D_1, in Fig. 2, making 32 changes and giving a range of threads from 3 to 46 per inch, covering every standard thread, including 11½.

This entire range of threads can be made without stopping the lathe or removing a single gear. The feeds are four times the number of threads per inch. It will be noticed that the compounding generally adopted on this style of lathe is done away with, and that wherever there are coarse feeds or heavy threads the increase comes directly from the 4 to 1 gear on the stud D_1 speeding up the feed mechanism of the feed box in the same proportion, so that it is placed under no additional strain.

* * *

THE IRON THAT GAVE US LEADERSHIP.

The economic results of the discovery and development of the Mesabi range of ore form one of the most important industrial facts in the past half century, says F. N. Stacy in the *World's Work* for September. Since the first shipment from the Mesabi in 1892, the iron ore production of the United States has increased from 16,000,000 to 35,000,000 tons per annum; the pig iron product from 9,000,000 tons to 18,000,000; the steel output from a little more than 4,000,000 tons to 15,000,000; while the iron and steel exports of the United States have grown from about $25,000,000 a year to $120,000,000. During these dozen years, we have become the greatest iron and steel producing country. The Mesabi was the greatest single factor in this achievement, and, without the vast resources of the Mesabi, the present dominance of the United States in iron and steel would have been delayed perhaps for decades. A sixth of the annual iron-ore product of the world—which is more than a third of the yearly production of America—comes from an iron range that was unknown in 1890. The Mesabi range on Lake Superior yields ore enough to make as much iron and steel as all Great Britain makes; and her industrial dominancy was founded on iron. During the fifty years ending December 31, 1903, the Marquette range on Lake Superior yielded more ore than any other mines; but the Mesabi range has produced almost as much in twelve years as the Marquette produced in fifty. In the use of steel, the cheap and abundant ores of the Mesabi have produced a revolution. They have enabled the railroads, within the past

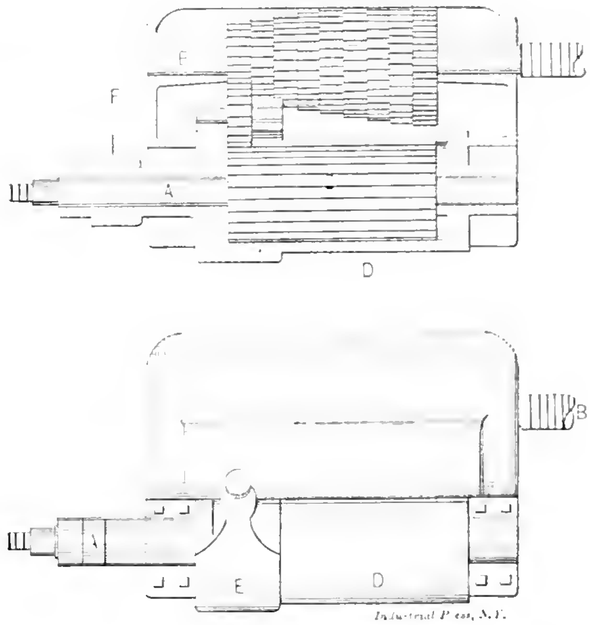

Fig. 4. Reproduction of Patent Drawings of Details.

six years, to relay, with heavy steel rails, almost the whole rail mileage of the United States. Steel cars, steel ties, steel bridges, steel warehouses, steel ships, steel construction for a thousand purposes for which wood and stone were used before, have followed. Exports of agricultural implements have multiplied five times in ten years. The tonnage on the Great Lakes has doubled. Finally, the iron tide from this vast iron deposit flowing into the channels of industry at the following rate of progression—4,245 tons in 1892, 1,793,052 in 1894, 2,882,079 in 1896, 4,613,766 in 1898, 7,809,535 in 1900, and

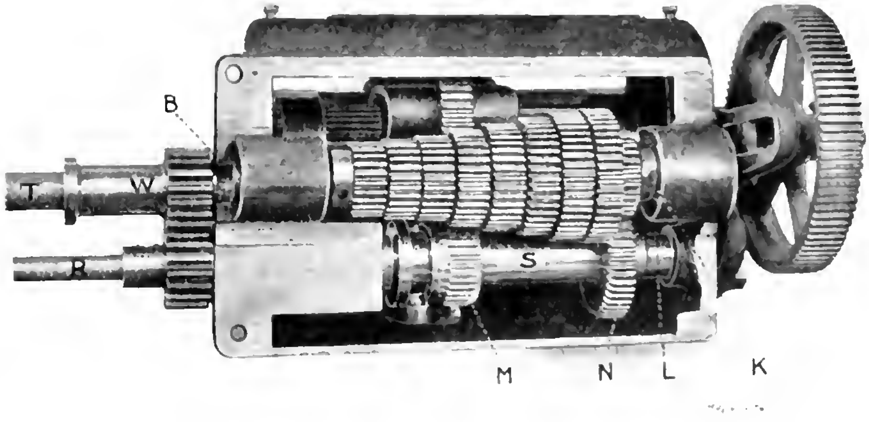

Fig. 5. Rear and Interior View.

13,342,840 tons in 1902—was one of the most powerful factors in the industrial and commercial revival of the United States after the panic and depression that began in 1893; and the impetus it gave our material progress continues to be world-wide.

MACHINERY

DESIGN—CONSTRUCTION—OPERATION.

PUBLISHED MONTHLY BY

THE INDUSTRIAL PRESS,

66-70 WEST BROADWAY, NEW YORK CITY.

LESTER G. FRENCH Editor.
FRED E. ROGERS, Associate Editor.

The receipt of a subscription is acknowledged by sending the current issue. Remittances should be made to THE INDUSTRIAL PRESS, and not to the Editors. Money enclosed in letters is at the risk of the sender. Changes of address must reach us by the 15th to take effect on the following month; give old address as well as new. Single copies can be obtained through any newsdealer.

We solicit communications from practical men on subjects pertaining to machinery, for which the necessary illustrations will be made at our expense. All copy must reach us by the 5th of the month preceding publication.

SEPTEMBER, 1904.

NET CIRCULATION FOR AUGUST, 1904,—22,705 COPIES.

MACHINERY is published in four editions. The practical work of the shop is thoroughly covered in the Shop Edition—$1.00 a year, comprising more than 430 reading pages. The Engineering Edition—$2.00 a year—contains all the matter in the Shop Edition and about 250 pages a year of additional matter, which includes a complete review of mechanical literature, and forty-eight 6 x 9 data sheets filled with condensed data on machine design, engineering practice and shop work. The Foreign Edition, $3.00 a year, comprises the same matter as the Engineering, but is printed on thin paper for transmission abroad. RAILWAY MACHINERY, $2 00 a year, is a special edition, including a variety of matter for railway shop work—same size as Engineering and some number of data sheets

MACHINERY is ten years old this month.

THE TREND IN STEAM TURBINE CONSTRUCTION.

Steam turbines may be divided into two classes, comprising those of the reaction type, like the Parsons turbine, and those of the impulse type like the De Laval, the Curtis, Rateau and Zoelly. In a reaction turbine part of the expansion of the steam occurs while the steam is flowing through the passages of the rotating wheels. The steam thus acquires additional velocity while it is passing through these wheels, so that as it leaves the vanes there is a reaction which gives a rotary motion to the wheel. No purely reactional wheels have been successful; they always combine the impulse principle with the reaction principle. In a turbine like the Parsons, for example, the steam acts the same as in an impulse turbine when it strikes the rotating vanes, and when it leaves the vanes it acts upon the reaction principle.

In impulse wheels there have been two principal methods used for reducing the rotative velocity of the wheels. In the Curtis turbine steam impinges against the blades of the first wheel, which latter turns at a lower speed than called for by the velocity of the steam. The energy of the steam, therefore, is not entirely utilized, and it leaves this wheel with a high residual velocity, part of which is again absorbed by a second wheel. The steam in turn acts upon a third wheel, and so on. This is the construction used in the earlier types of Curtis turbine, in which there were two sets of four wheels, each set being inclosed in a separate chamber.

In the Rateau and Zoelly turbines there is a succession of chambers with only one rotative wheel in each chamber. Each of these wheels acts like a single De Laval wheel, there being rows of nozzles which direct the jets of steam against its blades. Inasmuch as there are several chambers, however, the drop in pressure between the succeeding ones is comparatively small, so that the velocity of steam is much less than where the total expansion occurs all at once.

In a paper presented before the Chicago meeting of the American Society of Mechanical Engineers Prof. Rateau, of Paris, was inclined to "rub it into" the manufacturers of the Curtis turbine, by contending that they would finally give up their method of construction and adopt the Rateau turbine. Whether this will finally come about we, of course, cannot say, but the trend is in that direction. When steam is given a high initial velocity by flowing through an expanding nozzle and this velocity is absorbed by a series of wheels in succession, there is a great deal of dissipated energy due to the fact that the jet of steam breaks up and does not flow through the wheels in a solid stream. It seems to diffuse, to a greater or less extent, and much of the energy is lost by eddy currents and friction.

Two recent patents taken out by the General Electric Company are significant, in view of Prof. Rateau's remarks. One is upon a turbine in which the number of rotating wheels in each compartment is reduced to two; the other is upon a turbine in which there is only one rotating wheel in a compartment, just as in the Rateau and Zoelly types. Of course the latter patent is essentially a construction patent, since the principle is not new. It looks very much as though turbine construction were resolving itself into three standard types of machines: First, the De Laval type, in which speed reduction is secured by gearing; second, the Parsons or compound reaction type, and third, the Rateau or compound impulse type having but one rotating wheel in each compartment.

NOT AS RICH AS WE SEEM.

What sort of nabobs are Americans considered to be? Occasionally we are approached in this office by some foreign gentleman who has come to this country to dispose of "valuable patents" and who expects us to tell him what wires to pull and incidentally accept a liberal commission in case a sale is effected. Unfortunately for us, we have not yet been able to participate in profits of this description. It is somewhat out of our line.

Not long ago a representative wished to dispose of a patent on a type of milling cutter. The price was, as we remember it, $25,000, with 10 per cent. in it for us. He probably had a clear patent, so far as any investigation of records could show; but who doubts that many tool makers may have devised and used similar cutters in commercial work and who would pay a high price for a patent in the face of such a probability?

Another instance is the case of a refrigerating machine for domestic and hotel use. We saw an item about it, investigated in the hope of securing something interesting for our readers, and found incidentally that the American rights were for sale at the modest price of $400,000. In our opinion the patents do not introduce any new principle, but are merely construction patents, and combine old ideas in a new form.

Again, we have been visited by a promoter from abroad who controls a patent on a machine shop operation that has heretofore been performed by hand. He has a machine which does the work automatically by power and thus applies a new principle to accomplish a specific purpose. His patent, however, contains no broad claim. It tells in detail what elements enter into the machine and each claim mentions the several elements. There was evidently a chance for a broad claim. stating merely the principle and its application; but it was not made, and as the patent stands there are a dozen ways to get around it. Yet with this imperfect patent the promoter expected to get $350,000 for the invention. He has been advised to consult a patent lawyer before attempting to collect the cash, however. Should it be possible to take out another patent on the device, covering its basic principle, which we question, it will probably be a salable invention; but we doubt its bringing over one-tenth of $350,000.

It is in view of such instances as these that we ask, What sort of nabobs are Americans considered to be?

* * *

One of the interesting exhibits in the Palace of Electricity at the St. Louis Purchase Exposition is a small transformer of 20 kilowatts capacity, working at an electrical pressure of 500,000 volts. With this enormous voltage the discharge between the terminals occurs through the maximum distance of 32 inches. While the machine is of a very spectacular nature and one well calculated to attract the curiosity of the ordinary sightseer, it is also of great interest to the electrical profession, giving, as it does, ocular proof that the limits of high-pressure power transmission lie not in the power station, but rather with the line outside.

A peculiarity of many photographs of automobiles running at very high speed, is that the wheels are apparently distorted to an elliptical shape with the top inclined forward. As such a distortion is obviously a mechanical impossibility it is interesting to know the cause for the change from the true shape in the photograph. The explanation of the phenomenon, it appears, is that most cameras used for taking high-speed pictures, use the focal plane shutter, a device consisting essentially of a curtain immediately over the plate which contains a narrow horizontal slit. As this slit travels downward over the plate the exposure is made progressively and not simultaneously. Hence, owing to the inversion of the image due to the lens, the lower portions of the wheels are exposed first and by the time the slit has traversed the plate so that the image of the upper parts of the wheels is impressed thereon, they have traveled perceptibly forward. This in connection with the angular view gives the peculiar inclined elliptical shape.

PROPOSED REVISION OF THE PATENT LAWS.

It is a matter of common knowledge that small unimportant improvements generally pay greater returns to their inventors than the great epoch-making inventions that work a revolution in any industry. One reason for it is that by the time the tide has turned so as to fill the inventor's pockets his patents have expired and the public may use his invention without royalty. A case in point is the Parsons steam turbine, the first patents on which expired last year. The world at large is just awakening to the possibilities in the steam turbine and its advantages over the reciprocating piston system; hence the not unnatural bitterness of the inventor over what he considers to be an unjust feature of the patent laws of Great Britain and other countries. In a recent address delivered by Mr. Parsons before the Engineering Section of the British Association he strongly advocated changes in the patent laws of all countries, especially in regard to the time limit. He pointed out that the development of any great scheme centering on a valuable patent, would be impossible if this development required a period equal to or in excess of the present life of patents. Capital could not be induced to invest in what must necessarily prove a losing game. As a solution of the problem Mr. Parsons suggested the formation of an international committee composed of members from all the countries having patent laws, and that this committee should have control of the life privileges of all patents. The inference is that inventors who have been unable to bring their inventions into general recognition and have not reaped a satisfactory reward, should at the pleasure of the international committee be given an extension of their patents as a reward of genius and to stimulate the development of inventions that require a long period of exploitation.

The full text of Mr. Parsons' address is not at hand so that criticism of his scheme must be based upon the more or less uncertain newspaper report, but the general idea, it seems to us, is unpractical if not dangerous. When we remember the abuses and shady transactions growing out of re-issues and extensions of patents in this country, now happily discontinued, we are in no hurry to give an international committee the power of extending privileges of enormous value for the whole civilized world. Such a committee, no matter how conscientious and upright its members, could not help being moved by the persuasion and arguments which great interests would bring to bear upon them. In general if a company which has developed an invention to a commercial state during the life of its patent, has not acquired momentum sufficient to enable it to compete with all comers, something must be wrong in its business methods, and it savors too much of paternalism to ask a government to put a premium on business incompetency. With the development of large corporations, also, has come the possibility of perfecting and marketing an invention in a much shorter time than when this had to be accomplished entirely by individuals or small concerns. This is not inferring, however, that there are not individual cases where an extension of patent privileges would be no more than justice, but patent laws must be made for general conditions and not for specific cases.

THE MINNESOTA.

Announcement is made of the completion of the *Minnesota*, one of the two sister ships built by the Eastern Shipbuilding Co., New London, Conn., for the Great Northern Steamship Co., Mr. James J. Hill's line across the Pacific. The other ship, the *Dakota*, is still under construction The Eastern Shipbuilding Co. was organized and the plant equipped for the purpose of building these two ships, which are the largest American-built vessels yet constructed. The *Manchuria*, built at Newport News for the Pacific trade, had heretofore been the largest American vessel, but the *Minnesota* exceeds her in displacement by about 6,500 tons. When fully laden with cargo and stores the displacement of the *Minnesota* reaches 33,000 tons. Other dimensions are: Length over all, about 630 feet; breadth, extreme, $73\frac{1}{2}$ feet, and depth from the bottom of the keel to the upper navigating bridge, 88 feet $3\frac{3}{4}$ inches- the height of an ordinary ten-story building. As a matter of course the vessel is of massive construction to withstand the enormous strains to which its hull will be subjected. The stern post alone weight 55 tons.

The passenger accommodations are commodious and planned to make the fifteen-day trip across the Pacific a voyage of pleasure. First-cabin passengers have accommodations in a large deck house amidships. Practically all state rooms have outside windows and many of them are arranged en suite, with bath rooms attached. There are the usual library, boudoir, smoking room, etc., and the children have been provided for by an attractively-furnished nursery or play room. The total accommodations are for 218 first and 68 third cabin passengers, while below deck provision is made for carrying thirteen hundred troops or twenty-four hundred steerage passengers. Large and well-equipped toilet and wash rooms are provided for the steerage, also separate galley and pantry.

Four large evaporators for changing salt water to fresh are located in the engine room, furnishing abundance of fresh water to the boilers and for the passengers, should the fresh water carried in tanks give out. These evaporators have a combined capacity of about thirty thousand gallons of fresh water per day. The electric lighting plant is very extensive, as electricity is used for not only lighting all parts of the vessel, but for heating the state rooms, running numerous ventilating fans and supplying power to steer the vessel and operate the cargo hoisting machines.

The ship is driven by twin-screw triple-expansion engines of about 10,000 horse power furnished with steam at 250 pounds pressure by water-tube boilers of the Niclausse type. Each engine is located in a separate water-tight compartment, and the boilers are also divided into two similar compartments, accessible one to the other through small water-tight doors.

The anchors each weigh $8\frac{1}{2}$ tons and the anchor chain, which weighs over 80 tons, is the heaviest ever built. The full equipment of life-saving appliances as prescribed by the United States government is carried on board, and for putting out flames a patent fire-extinguishing system is installed, by means of which any compartment of the ship may be immediately filled with a gas in which a fire cannot possibly burn. For handling the cargo in and out of the numerous hatches thirty-two electric winches are placed on the deck, for while the *Minnesota* is to be classed as a passenger ship, she is intended primarily to carry enormous cargoes of freight across the Pacific.

* * *

THE DATA SHEET FOR SEPTEMBER.

The data sheet for this number deals with the proportioning of the arms, hubs, faces, etc., of gear wheels, such as are used particularly in mill work and heavy machine construction. This sheet is one of several that have been contributed by W. O. Renkin, Valley Park, Mo. For several years Mr. Renkin was in charge of the toothed gear work at the Union Foundry and Machine Co., Pittsburg, Pa. He has traveled extensively, selling and designing gears for all kinds of service, and has accumulated much tabular matter on the subject which is now given for the benefit of our readers.

VARIABLE SPEED MOTORS.—6.

THE C. & C. ELECTRIC COMPANY'S SERIES PARALLEL SYSTEM.

WILLIAM BAXTER, JR.

This system was designed specially for the operation of large printing presses, and is not recommended for use in connection with small machine tools. It has been applied very successfully for driving large grinding and polishing machinery and is specially applicable to all cases where a strong starting torque with quick and even acceleration is required and with such a degree of speed variation, at the higher velocities, as can be obtained by field regulation.

The system is used in connection with a compound wound motor that is provided with two distinct armature windings, each one being connected with an independent commutator. In starting, the two armature windings are connected in series, by properly connecting the commutator brushes, and the velocity is gradually increased by cutting out the starting resistance in the armature circuit, and after this the series field coils, these being cut out in two or more steps so as to properly graduate the acceleration of velocity. To increase the speed beyond this point the two armature windings are connected in parallel, and an amount of resistance is cut into the armature circuit that is sufficient to prevent violent acceleration. This resistance is then cut out gradually and the full running speed is attained. To increase the speed beyond this point resistance is cut into the shunt field circuit until the velocity is increased fifty per cent. or more, as may be required.

From the foregoing it will be seen that in starting, a very strong torque is obtained with a comparatively small current, from the fact that both the armature windings are connected in series, and for the same reason the velocity is very low. The two armature windings are alike, so that when they are connected in series, the velocity is one-half as great as when they are connected in parallel. By means of the armature resistance, and the series field coils many different speeds can be obtained between the starting velocity and that obtained when the armature windings are connected in parallel; but, as has been explained in previous articles, variations produced by means of resistance in the armature circuit cannot be used with satisfactory results except in cases where the load is constant, or nearly so. Speeds obtained above the series parallel velocity can be used whether the load is variable or not as they are produced by introducing resistance in the shunt field circuit.

The Controller for the Series Parallel System.

The controller used with this system is illustrated diagrammatically in Fig. 1. It consists of two electro-magnetic switches that are actuated by the movement of a hand-operated controller, and this latter also affects the necessary circuit combinations to cut resistance in and out of the armature and the field circuits. The magnetic switches are for the purpose of making the changes in the connections that are required to change the armature windings from series to parallel. Fig. 2 is an elevation that shows the relative position of the motor and the controller when applied to a large printing press. Figs. 3 and 4 show in detail the main controller. Fig. 5 is a more complete detail of the front of the controller, showing the various contacts. Figs. 6 and 7 show the front and back of the magnetic switches, with the various details of construction. Figs. 8 and 9 are photographic views of one of these switches. Fig. 10 is a photographic view of the front of the main controller.

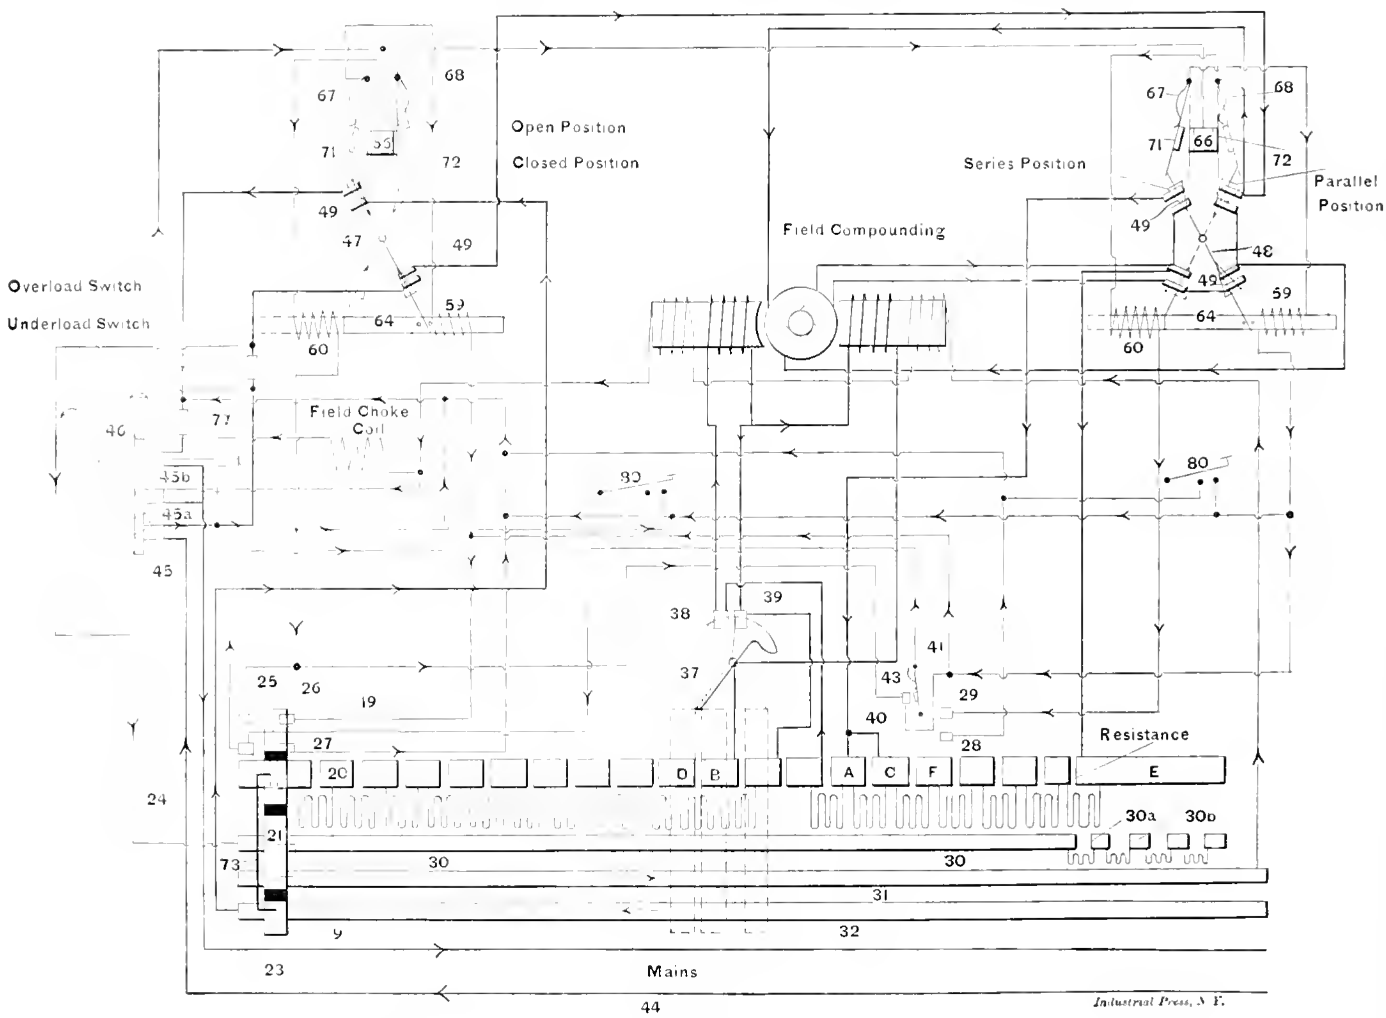

Fig. 1. Controller for Series Parallel System, C. & C. Electric Company.

Referring to Fig. 2, 1 represents the frame of a printing press, 2 is the floor line, 3 is the motor, 4 is the gearing through which the motor drives the press, 8 is the main controller which is provided with a number of contacts disposed in circular form, as shown in Fig. 5, over which swings the lever 9. This lever is rotated by means of a segment 11, which meshes into a gear mounted upon the shaft 10 around which 9 rotates. The segment 11 is actuated by the connecting rod 16 attached to the slotted end 15 of the hand lever 12, the latter

being mounted to swing around the stud 13. The position of the magnetic switches is shown at 47, and at *SB* is located a switchboard.

The Main Controller.

The main controller is shown clearly in Figs. 3, 4 and 5. The lever 9 carries contacts 19, 20, 21 and 23. Contact 19 connects with the stationary contacts 24, 25, 26, 27, 28 and 29 (See Fig. 5). Contact 20 connects with the circular row of contacts 8,

pin 63 at one end, that passes into a slot in the core 64 of the magnets. To throw the switch lever 47 more power is required at the beginning of the movement than at the end, owing to the fact that the friction of the blades 49 against the stationary contacts has to be overcome. To increase the initial pull of the magnets, auxiliary cores are provided as shown in Fig. 6, and these are made movable. In addition a slot 65 is made in the main core, so that when it moves it strikes a

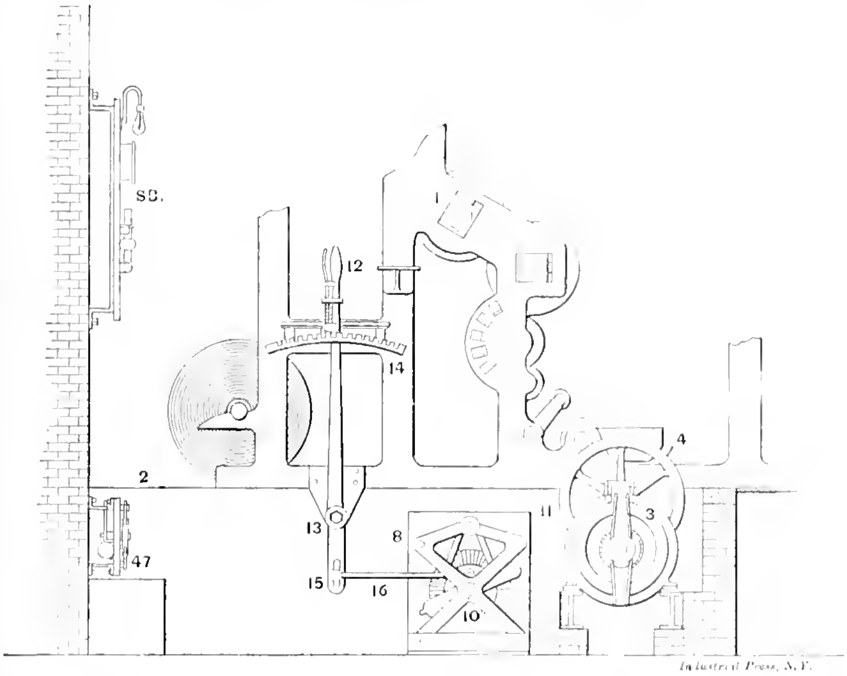

Fig. 2. Elevation showing Relative Position of Motor and Controller.

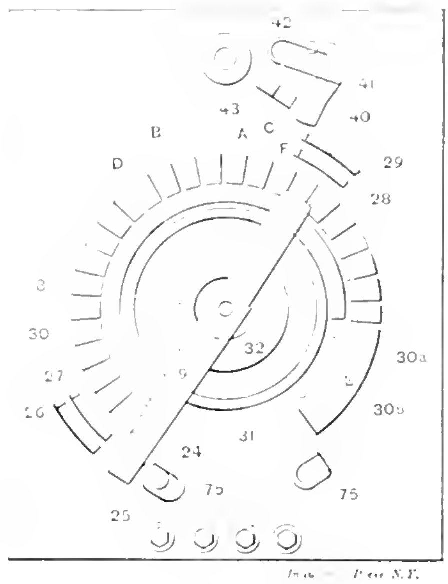

Fig. 5. Detail of Front of Controller

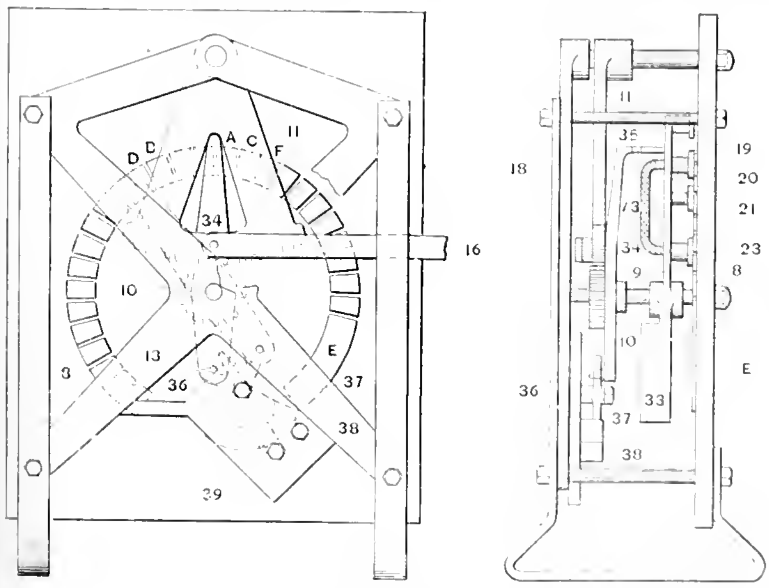
Contact 21 connects with stationary contact strips 30 and 31, and contact 23 connects with stationary strip 32. A second lever 34 is secured to shaft 10 and is provided with a pin 36 that engages with the forked end of a small switch 37 which swings over and connects contacts 38 and 39. Lever 9 in rotating forward strikes a pin 40 mounted upon a switch 41 that is spring-supported and pushes the same to the right. On the backward movement 9 strikes this pin again and moves con-

blow against the pin 63 and thus dislodges the blades 49 from the stationary contacts. The auxiliary cores, being movable are knocked out of the way by the main core, hence a long movement of the latter core is obtained with a comparatively short distance, or air gap, between it and the auxiliary cores; the result being that the strength of the magnet is greatly increased during the first part of its movement. The momentum of lever 47 and the other moving parts is sufficient to carry it over into engagement with the opposite set of stationary contacts, after the solenoid magnet gives it the initial movement, and on that account means are provided to automatically open the circuit of the solenoid soon after the switch lever has moved. The stationary contact 66, Fig. 6, and the switches



Figs. 3 and 4 Details of Main Controller.

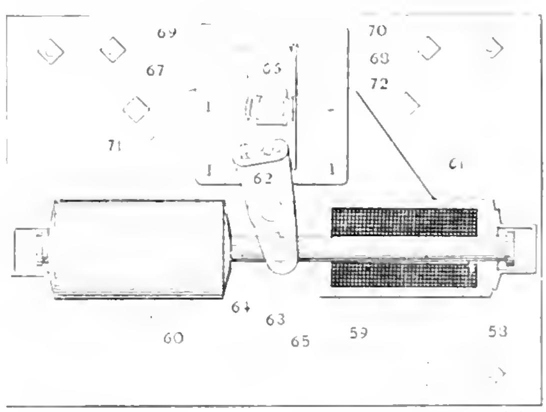


Fig. 6 Diagram showing Rear of Magnetic Switch.

tact 41 over contact 43, for a purpose that will be hereafter explained. Contacts 20 and 23 are connected by the cable 73.

The Electro-magnetic Switches.

In Fig. 7 the switch lever 47 and 48 is actuated by the solenoids 59 and 60 shown in Fig. 6. The blades 49 are insulated from the lever. The solenoids shown in Fig. 6 are mounted on one side of a slate slab, and the switch lever 47 and the stationary contacts with which it engages are mounted on the other, the shaft 61 passing through the slab. On the solenoid side of the slab the shaft 61 carries a lever 62 provided with a

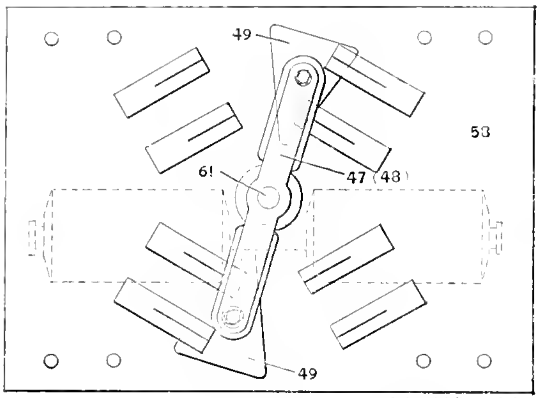
67 and 68 are for this purpose, and the manner in which they are actuated by lever 62 can be clearly understood. The solenoid magnets are energized when lever 9, Fig. 5, bridges either one of the pairs of contacts, 26, 27 or 28, 29.

Operation of the Series Parallel Controller.

From the foregoing explanations of the construction of the several switches the operation of the controller as illustrated in diagram Fig. 1 can be readily understood. To make this diagram as clear as possible the controller, Fig. 5, has been represented at the bottom of the diagram with the stationary

contacts rolled out into straight strips, and lever 9 is shown as a bar in the vertical position, at the left of the diagram. In addition, all the parts in Fig. 1 have been numbered the same as in the other illustrations.

The current enters through the mains 44, passes to switch 45, and thence through an overload switch to one terminal of the shunt field and to magnet switch 47, which is shown in the closed position by full lines and in the open position by dotted lines. When lever 9 is moved from the position shown in Fig. 5 to that of Fig. 1, block 19 bridges contacts 26, 27 and a circuit is closed through the arm then in contact with 66, down through solenoid 59 to contact 26 and thus to the main line.



Industrial Press, N.Y.

Fig. 7. Front View of Magnetic Switch.

Solenoid 59 being energized will throw 47 to the closed position shown in full lines. The current will then pass through blade 49, lower end of 47 to upper right side of 48 and thence through one armature winding to lower right side contact of 48 and thence through the other armature winding back to 48 and on to contact *A* of main controller. From this point it passes through a resistance coil to the contact at the left and thence through the series field coils to contact *B* from where it passes back to main 44 through lever 9 and switch blade 46. It will be noticed from the connections through the solenoid 59 of switch 48, that if the lever should happen to be in the parallel position it will be thrown over to the series position.

As lever 9 advances it cuts out the armature resistance, until it reaches contact *D* when it strikes lever 37 and cuts out one-half of the series field coils, by connecting *B* with 39. The further movement of 9 connects 38 and 39 with *B*, thus cutting

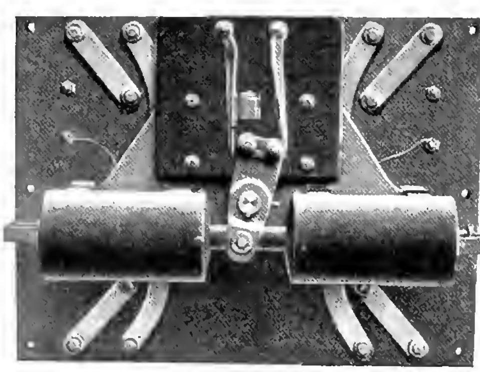


Fig. 8 Half-tone View of Fig. 6.

out all the series field. Advancing further, lever 9 connects contacts 28 and 29 and thus closes the circuit through solenoid 60 of switch 48, thereby drawing the core to the left and throwing the switch into the position shown in dotted lines. This change connects the armature windings in parallel, the armature circuit passing to the end contact *E* thus cutting into this circuit the resistances interposed between *E* and *F*. The further advance of lever 9 cuts out this resistance and finally cuts into the shunt field circuit the resistances interposed between the contacts 30a, 30b, etc.

In moving lever 9 back to the starting position it first cuts out the shunt field resistance, then cuts in the armature resistance and when it reaches pin 40 it carries contact 41 over onto 43, thereby closing the circuit through solenoid 59 of switch 48, thus opening the armature circuit and at the same time connecting the armature windings in series. Moving further to the left lever 9 will strike switch 37 and throw it off the contacts 38, 39. When 9 reaches the starting position, shown in full lines at the left, it will close the circuit through solenoid 59 of switch 47 and thus again close the armature circuit with the windings in series.

From the foregoing explanation of the action of the controller, on the return motion, it will be seen that if it is desired to stop the motor, lever 9 is returned quickly to the starting position; if it is desired to reduce the speed to a point not slower than is obtained with the armature windings in the parallel connection, the lever is moved back slowly to this

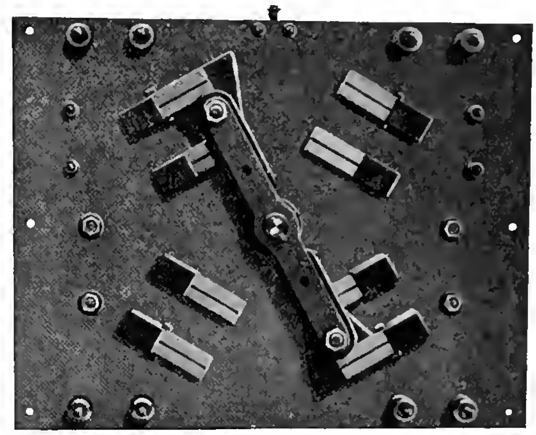

Fig. 9. Half-tone View of Fig. 7.

point; but if a still slower speed is desired, the lever is moved back to the starting position and is at once advanced until it meets the speed to which the motor has slowed down. If this speed is still too high, the lever is moved back step by step until the desired velocity is reached.

The switches 80 shown in Fig. 1 are emergency switches which can be located in any place from which it may be desired to stop the motor.

The hand switch 45 has its blades so arranged that when it is opened a spring-actuated switch 77 closes a circuit around the shunt field coils. This circuit includes a choke coil and thus the danger of puncturing the insulation of the shunt field coils by opening the circuit is obviated.

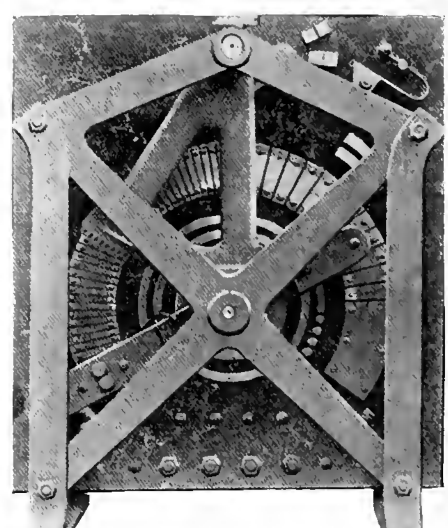

Fig. 10. Front View of Main Controller.

The electro-magnetic switches 47 and 48 can be located in any convenient position, as they are connected with the main controller through circuit wires only; but the main controller itself, must be so located that the lever 9 may be moved by means of a connection with a hand lever, as is clearly shown in Fig. 2. When the controller can be placed within easy reach of the man that operates the machine driven by the motor, the hand lever can be replaced by a wheel mounted directly upon the end of shaft 10, as is shown in Fig. 11 which illustrates a motor with the whole controlling apparatus mounted upon its back.

BEAMS AND PLANES WITH SEVERAL SUPPORTS.

Editor MACHINERY:

Some of the points in Mr. Blake's article on "Problems In Beams and Planes Severally Supported and Eccentrically Loaded," in the July number of MACHINERY, do not seem to conform to the theory of flexure of beams. Referring to Fig. 2 of his article, if the beam is supported at y and loads placed at A, B, and C, whose values are determined according to his formula, the beam will be in equilibrium, but it does not follow that the load W will produce reactions of the same magnitude at these points. If the beam were perfectly rigid and the points A, B and C would yield in proportion to the reaction brought upon them by the beam, then his formula would give the reactions; but the beam is not rigid, neither are the points A, B and C. Nor do they necessarily yield in the same proportion. It is then evident that the reactions at A, B and C depend upon the stiffness of the beam and the rigidity of the points of reaction, as well as their location.

The following simple experiment will give a practical proof of the foregoing. Place a thin yard stick so that its broad side bears for about four inches on the under side of a table leaf and arrange a support near the middle of the stick, as shown by full lines in Fig. a. A load, well within the strength of the stick, placed at the outer end will bend the stick so that the extreme end under the table leaf leaves its support entirely, and the edge of the table leaf takes the whole reaction, as shown by the dotted lines of Fig. a.

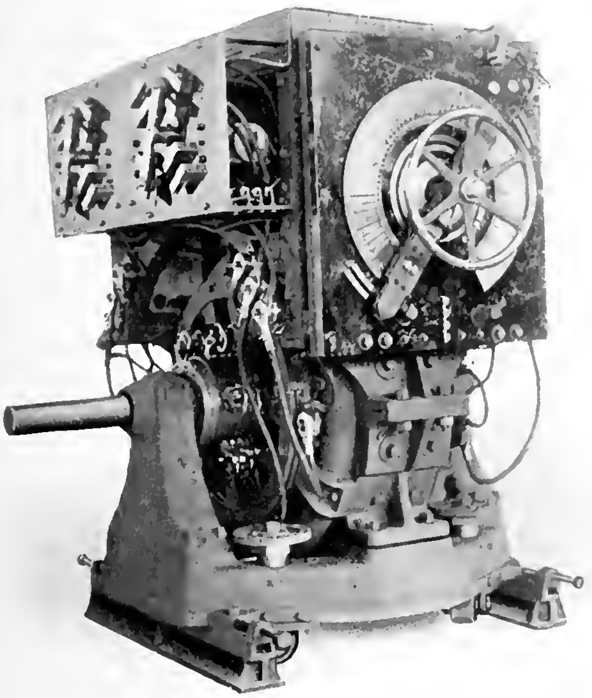

Fig. 11. Showing a Motor with all the Controlling Apparatus in Place. (See previous page).

Beams having more than two supports, as Figs. 2, 3 and 4 of Mr. Blake's article, are termed continuous beams, and the reactions at the supports depend upon the elastic curves of the beams. In other words, the bending of a beam which has more than two supports influences the reactions which occur at the supports. The imperfect adjustment or the sagging of a support of a continuous beam may cause stresses far in excess of those for which the beam was designed, and thus offset the theoretical advantage which a continuous beam has over a simple beam. The same reasoning as was applied to beams will lead to the conclusion that when planes have more than three supports the flexure influences the reactions. In the case of the four-armed spider, shown by Fig. 8 of Mr. Blake's article, if we take moments about rectangular axes we find it is not in equilibrium with the reactions as given.

The load and the reactions necessarily form a balanced system. Only three points are required to support a plane. If more are used the division of the load is arbitrary, provided the conditions of equilibrium are filled. In the following the load is divided in inverse proportion to the lengths of the arms taking $O\ A$ and $O\ C$ together and $O\ B$ and $O\ D$ together.

$$\text{Then } A + C = \frac{O\,B + O\,D}{(O\,B + O\,D) + (O\,A + O\,C)} \times 1000 = 488.37$$

$$\text{But } (A + C) + (B + D) = 1000 \qquad (1)$$

$$\therefore B + D = 511.63$$

The letters A, B, C and D in these equations represent the reactions at those points. It now remains to so proportion the sums of A and C and B and D that the system will be in equilibrium. Equation (1) and the following (2) and (3) express the conditions of equilibrium.

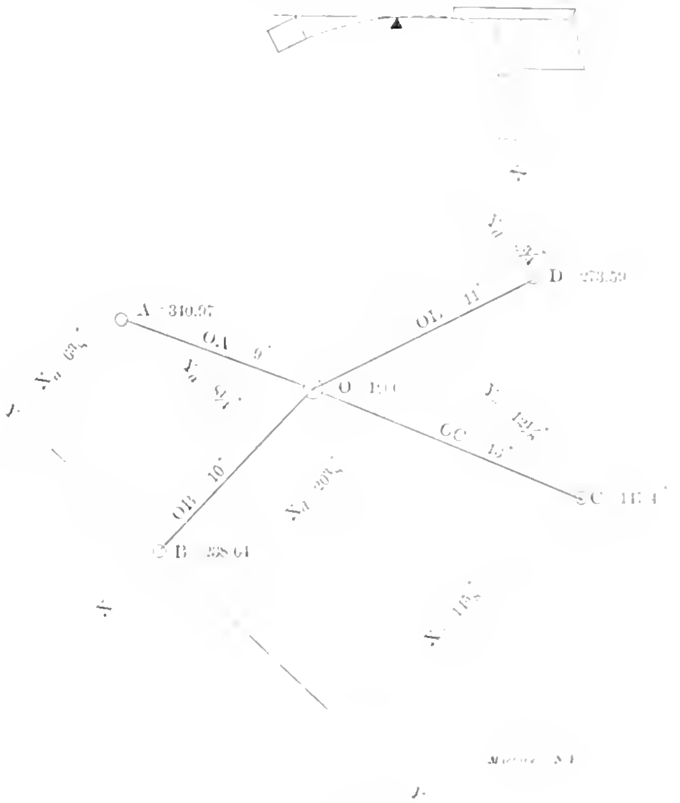
$$A\,X_a + B\,X_b + C\,X_c + D\,X_d - O\,X = 0 \qquad (2)$$

$$A\,Y_a + B\,Y_b + C\,Y_c + D\,Y_d - O\,Y = 0 \qquad (3)$$

The subscripts of X and Y indicate the point of which they are the co-ordinates, as is shown in Fig $8a$, which is the same as Fig. 8 of Mr. Blake's article with the co-ordinates added. Assume the erigin at B and let $O\ B$ be the X axis, then X_b, Y_b and Y_o are each $= 0$. Substituting in equations (2) and (3) the values of X and Y from Fig. $8a$, we have

$$6\tfrac{3}{8}\,A + 11\tfrac{1}{8}\,C + 20\tfrac{3}{8}\,D = 10 \times 1000 \qquad (2a)$$

$$8\tfrac{1}{4}\,A - 12\tfrac{1}{8}\,C - 3\tfrac{3}{4}\,D = 0 \qquad (3a)$$



Figs. a and 8a.

from which the values of the reactions are found to be as follows:

$$A = 340.97$$
$$B = 238.04$$
$$C = 147.40$$
$$D = 273.59$$

Consequently the arms should be proportioned for these loads.

The method of proportioning the arms now needs attention Since point O is common to all the arms, the deflection for all must be the same. Then, assuming that the maximum fiber stress is to be the same in all arms, it is necessary to design each arm so that its reaction will deflect it the same as the other arms are deflected by their reactions and at the same time produce the same maximum stress as in the other arms. Consider the two arms $O\ A$ and $O\ B$. The deflection of $O\ A$ under load A for uniform section of arm is

$$F_a = \frac{1}{3}\,\frac{(O\,A)^3 \times A}{E \times I_a} \qquad (4)$$

and of $O\ B$ under load B is

$$F_b = \frac{1}{3}\,\frac{(O\,B)^3 \times B}{E \times I_b} \qquad (5)$$

also

$$I_a = \frac{A \times (O\,A) \times e_a}{f} \qquad (6)$$

$$I_b = \frac{B \times (O\,B) \times e_b}{f} \qquad (7)$$

In which f = maximum fibre stress.

e = distance of extreme fibre from neutral axis of section.

E = modulus of elasticity.

I_a and I_b = moments of inertia of cross sections of arms $O\,A$ and $O\,B$ respectively.

Substituting the values of I_a and I_b from equations (6) and (7) in equations (4) and (5) we have

$$F_a = \frac{(O\,A)^3 \times A}{3\,E \times \dfrac{A \times (O\,A) \times e_a}{f}} = \frac{(O\,A)^2 \times f}{3\,E \times e_a} \qquad (4a)$$

$$F_b = \frac{(O\,B)^3 \times B}{3\,E \times \dfrac{B \times (O\,B) \times e_b}{f}} = \frac{(O\,B)^2 \times f}{3\,E \times e_b} \qquad (5a)$$

But these deflections are equal, hence

$$\frac{(O\,A)^2 \times f}{3\,E \times e_a} = \frac{(O\,B)^2 \times f}{3\,E \times e_b} \qquad (8)$$

Remembering that f is the same in all arms we have

$$\frac{e_a}{e_b} = \frac{(O\,A)^2}{(O\,B)^2}$$

Hence the depths of the arms should be proportional to the squares of their lengths and the moments of inertia of the cross sections should be of such value that the desired fiber stress is secured.

If the depths of the arms are to be the same where they join each other, then equation (8) becomes

$$\frac{(O\,A)^2 \times f_a}{3\,E \times e} = \frac{(O\,B)^2 \times f_b}{3\,E \times e} \qquad (8a)$$

Since e is now to be made the same, we have from (8a)

$$\frac{f_a}{f_b} = \frac{(O\,B)^2}{(O\,A)^2} \qquad (8b)$$

It is seen from this that the moments of inertia of the sections should be such that the maximum fiber stresses are in inverse proportion to the squares of the lengths of the arms. If the arms are made of uniform strength throughout their length instead of uniform section, the same results are reached by similar reasoning. E. E. GRAHAM.

Cleveland, Ohio.

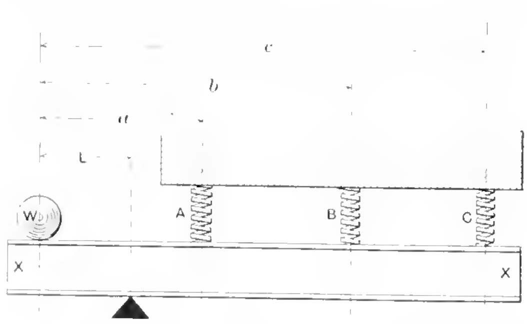
A CRITICISM.

Editor MACHINERY:

The writer is of the opinion that an erroneous idea is conveyed in the article on beams and planes severally loaded and supported, appearing in the July issue of MACHINERY.

For formulas 6, 7 and 8, in reference to Fig. 2 of the article, to be applicable one must assume the beam to be perfectly rigid, and the reactions as being uniformly elastic.



Since elasticity is one of the universal properties of matter—*i.e.*, all beams deflect—this is an impossible condition. Fig. 1 illustrates a close approach to these conditions.

If the beam XX be loaded to a fractional part of its ultimate strength, thus reducing flexure to an inconsiderate factor, and the reactions A, B and C be produced by springs of equal strength and elasticity, the distortion of the springs, *i.e.*, the amount compressed or elongated, would be proportional to their distance from the point of rotation y. Since stress is proportional to strain within the elastic limits the force at A, B and C would also be proportional to their respective distances from the point y. Now, since the magnitude of each force, and its moment, are both proportional to its distance from the point of rotation, it follows that its moment, or torque, is proportional to *the square* of this distance; hence torque due to spring

$$\left.\begin{aligned} A &= \frac{a^2}{a^2 + b^2 + c^2} \\ B &= \frac{b^2}{a^2 + b^2 + c^2} \\ C &= \frac{c^2}{a^2 + b^2 + c^2} \end{aligned}\right\} \text{ of the total torque } W\,L.$$

If the reactions A, B and C be practically rigid in comparison to the beam, the entire load would be concentrated upon A by reason of the beam's deflection.

If the relative elasticities of the beam and the several reactions be known the resulting magnitude of the forces, the consequent moments, strains, etc., may be determined; but in practice such constructions are usually avoided, as inaccuracy of workmanship, unequal settlement or some other practical consideration would usually make the problem indeterminable. Even with theoretical conditions, if one must take into account the elastic curve of the beam, the calculations would become very complicated.

Philadelphia, Pa. JOHN S. MYERS.

ECCENTRIC LOADING.

FRANK B. KLEINHANS.

The subject of eccentric loading, although treated in a number of text books, is one that is not very clearly understood, and a few illustrations of the application of eccentric loading may be of assistance to the reader. The principle of the eccentric load, as shown in Fig. 1, is that the line of the load P does not coincide with the center line, $c\ c$, along which the reaction is taken up. This load acting at a distance L from the center of gravity of the supporting section produces a bending moment $P \times L$ about this section. At the same time we have also a uniformly distributed load over this section which is equal to P. One other thing which will be noticed is that the bending action is the same for any section $A\ B$, no matter how great or how small D may be.

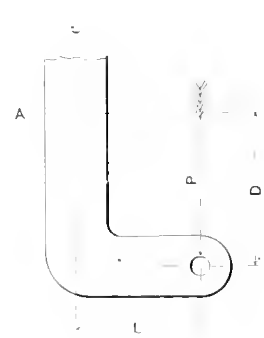

Fig. 1.

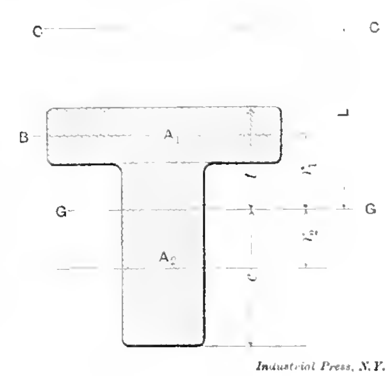

Fig. 3.

Fig. 2 represents a punching machine which must be figured according to this principle of eccentric loading. The size of the gap at A and the load determine the size and shape of the section as the frames for these machines are invariably made of cast iron, and as we cannot use as high a working stress in tension as in compression, it is advisable to make the section as shown in Fig. 3, where the amount of metal is greater on the side nearest the load. We first lay down the section to scale on a piece of heavy paper, then cut it out and balance it on a needle point, thus obtaining the center of gravity of the figure. Then draw a line $G\ G$ through the center of gravity. Now divide the figure into two rectangles A_1 and A_2, the moment of inertia of each one of which about

its center of gravity is 1-12 $B H$, in which B is the width and H is the height of the rectangle. Knowing the moment of inertia of each one of these areas about its axis as shown, we can obtain the moment of inertia about any other axis $G\ G$ thus:

Let A = total area of section,
I = moment of inertia about $G\ G$,
I_1 = moment of inertia of area A_1 about its axis,
I_2 = moment of inertia of area A_2 about its axis.

We then have:

$$I = (I_1 + A_1 r_1^2) + (I_2 + A_2 r_2^2)$$
$$A = A_1 + A_2$$

Let P = the load,
L = the distance from load to centre of gravity,

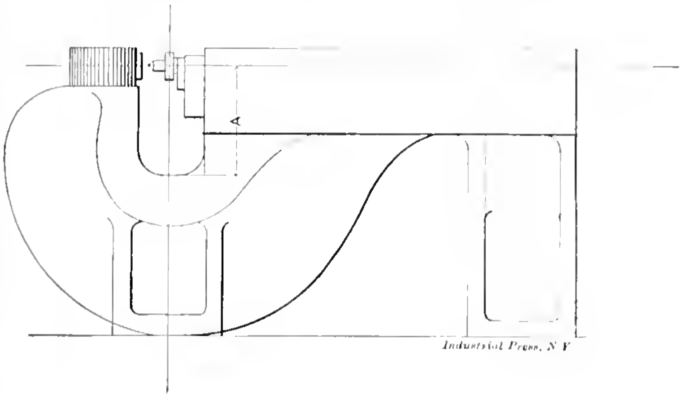

Fig. 2.

S_t = tension stress,
S_c = compression stress.

We then have:

$$S_t = \frac{P}{A} + \frac{P\,L\,t}{I}$$
$$S_c = \frac{P}{A} - \frac{P\,L\,c}{I}$$

In calculating these sections for eccentric loads, St for cast iron should not exceed 4,000 pounds, while Sc may equal 12,000 pounds. In steel castings, St would be taken at 9,000 pounds and Sc at 10,000 pounds.

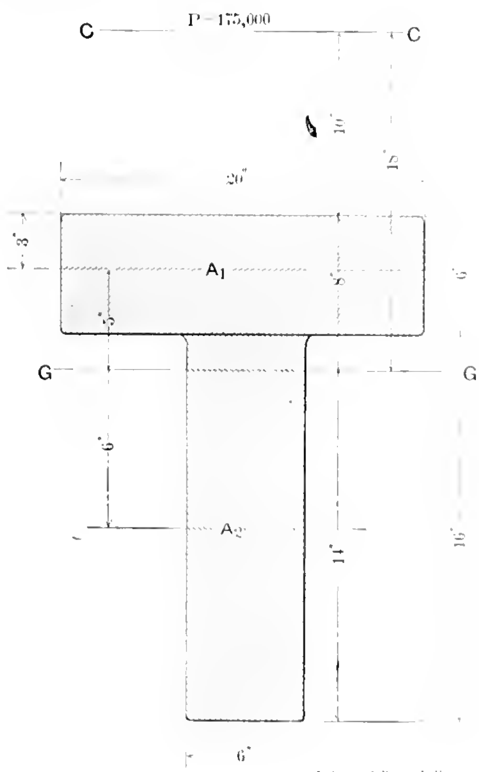

Fig. 4.

In order that the above expressions may be better understood, the following example will be given:

Let Fig. 4 represent a section the strength of which we wish to determine.

We will then have

P = 175,000 pounds
$A_1 = 20 \times 6 = 120$
$A_2 = 16 \times 6 = 96$
$A = A_1 + A_2 = 216$

$$I_1 = \frac{20 \times (6)^3}{12} = 360$$
$$I_2 = \frac{6 \times (16)^3}{12} = 2048$$
$$I = (360 + 120 \times (5^2)) + (2048 + 96 \times (6^2)) = 8864$$
$$S_t = \frac{175,000}{216} + \frac{175,000 \times 18 \times 8}{8864} = 3653 \text{ tension}$$
$$S = \frac{175,000}{216} - \frac{175,000 \times 18 \times 14}{8864} = -4161 \text{ compression}$$

As this section is for cast iron and as both stresses are within the safe working limit, the section will be satisfactory.

If the section was to be made of steel, however, it would have to be shaped like an I-beam in order to keep the stresses from running too high in compression.

A peculiar feature about eccentric loading is that with material like wrought iron, for instance, where the tension and compression should be the same, the section to resist the load cannot be made rectangular, but the tension side must be made heavier and therefore the section assumes more or less the shape of a T-iron. This fact is sometimes lost sight of and we only too frequently have a breakdown.

A cause of such a failure is shown in Fig. 5. This was the upper portion of a hydraulic punch and shear, the hook portions at H being shaped up so as to receive a steel cylinder, which fitted snugly under the flanges. The total pressure of the cylinder was therefore to be resisted by the two hook portions of the frame at H. The capacity of the machine was 100,000 pounds, and using the same notation as before, we have:

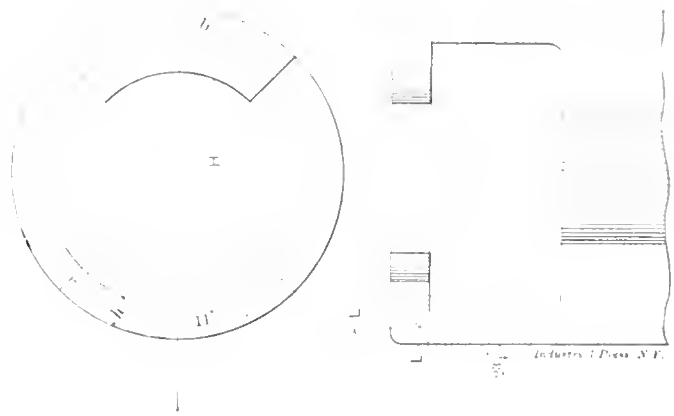

Fig. 5.

$$S_t = \frac{P}{A} + \frac{P\,L\,t}{I} \text{ in which}$$
$$I = \frac{b\,h^2}{6} \quad \text{We then have}$$
$$S_t = \frac{100,000}{2\frac{3}{4} \times 11 \times 2} + \frac{100,000 \times 2 \times 1\frac{1}{2}}{\frac{2 \times 11 \times (1\frac{1}{2})^2}{6}}$$
$$= 1,600 + 10,000$$
$$= 11,600 \text{ pounds stress in tension.}$$

This should not have exceeded 4,000 pounds fiber stress and we can readily see why it was that these hook portions failed at the first application of pressure.

It is surprising to note where the action of eccentric loading comes in; in fact, a uniformly-distributed load being very rare in the members of any machine. We should, therefore, trace out the manner in which the stresses act and make proper calculations for those cases where eccentric loading occurs.

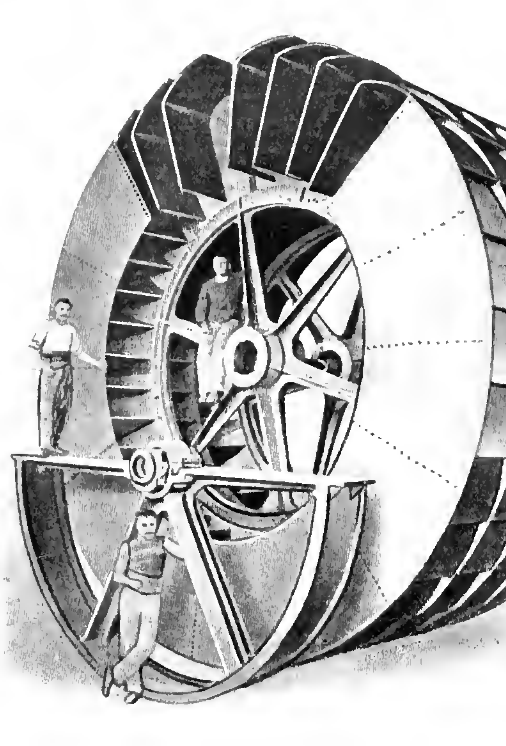
THE VENTILATOR OF THE ALBESPEYRE TUNNEL.

DR. ALFRED GRADENWITZ.

At a recent meeting of the Society for the Encouragement of National Industry, Paris, Mr. E. Denis-Farcot, Plaine St. Denis, France, read a communication on the ventilation scheme employed by him in connection with the Albespeyre tunnel.

This tunnel, situated on the Langogne-Alais line, of the Paris-Lyons-Mediterranean Co., traverses the parting of water between the Atlantic and the Mediterranean. It is a single-track tunnel, 24 square meters in cross section, 1,503 meters in length; its mean gradient is about 25 millimeters per meter.

The ventilation of the tunnel, which is traversed by rather numerous and heavy trains, presented special difficulties. The natural ventilation, being frequently opposed by violent winds, was found inefficient, and three vertical shafts, each one square meter in cross section, and 60, 120 and 150 meters in depth respectively, were sunk into the tunnel, but these afforded practically no relief. In the beginning, the trains going up grade would be pushed by an auxiliary engine placed at the rear of the train. As, however, the latter traversed an atmosphere contaminated by the smoke and gases from the engine ahead, the men in charge of the auxiliary



Mammoth Ventilating Fan.

were in serious danger of asphyxiation. So this plan was eventually abandoned, and the train divided into two parts; but as the atmosphere of the tunnel would remain in a contaminated condition for as long sometimes as 40 minutes after the passage of the train, this method did not by any means prove satisfactory.

In order to obviate this drawback, the company decided to install a system of artificial ventilation, and Mr. Farcot was entrusted with the work.

The ventilator fan which he has installed is 6 meters in diameter by 2½ meters in breadth, with vanes bent in a direction opposite to that of the rotation of the wheel, and gives an output of 150 cubic meters of air per second. The fan wheel has 64 sheet-steel vanes and is built in halves. The total weight is 10 tons. It is encased with the lower half enclosed by masonry and the upper half by a sheet-steel cover. The fan operates by induced action and the air issues through a conduit, a cross section of which increases from 9 to 21 square meters.

The fan is driven by a 150-horse-power Corliss engine, at 122 revolutions per minute. Although the speed of the fan is very little above that of the engine a belt drive was preferred to direct coupling, lest the engine obstruct the passage of the air from the fan; and, moreover, it was believed that the low temperature of the air current would seriously affect the economy of the engine.

With an output of 150 cubic meters per second, as measured at the outlet, a mean air movement as high as 7½ meters per second is obtained throughout the tunnel, resulting in a total output of 185 cubic meters, as some of the air entering at the mouth of the tunnel is carried along. This speed, however, inconveniences workmen employed in the tunnel and puts out the torches. A speed of 5 meters per second, corresponding to a total output of 120 cubic meters, is still too great; in fact, three meters should not be exceeded during the time the men are working.

The service is performed as follows: As long as no train going up grade is signalled, the ventilator runs at a low speed, viz., 50 turns per minute. On the approach of a train the speed is raised to 150 revolutions, and maintained for about 8 minutes. Four minutes are required for the passage of a train through the tunnel and an additional four minutes are necessary for clearing out the smoke.

As up-grade trains move in a direction opposite to the air current and at a speed of 25 to 30 kilometers per hour, or 7 to 8 meters per second, the air current is practically stopped during the time the train traverses the tunnel. But as a certain amount of air still surrounds the train, the atmosphere of the tunnel will remain in a condition respirable for the personnel and it has been found possible to again use the rear locomotives. As the atmosphere is renewed after the passage of each train, the front locomotive does not contaminate the air to such an extent as to seriously incommode the crew of the second.

In Mr. Farcot's communication on mechanical ventilation, recently made in Paris on the Metropolitan Railway between the Vincennes and Bastille stations, some further experiments are recorded. A ventilator, 2½ meters in diameter, giving an output of 50 to 60 cubic meters per second and being susceptible both of aspiring and blowing actions, had been installed at Vincennes, with a view to ventilating this tunnel as far as the Bastille, where the tunnel terminates in the open air. As this ventilator was in operation during the hours of service, as soon as the doors of either the Vincennes or the neighboring Nation station opened, there was produced a most violent air current which was absolutely unbearable, whereas the regular air current did not go as far as the Bastille, on account of the frequent passage of trains running in an opposite direction. By night, however, as well as outside of the working hours and whenever the doors of the station were closed, the air current would be established regularly throughout the length of the tunnel, at a speed of 1½ meters per second, corresponding with an output of 10 cubic meters.

* * *

The vitality of some totally unpractical mechanical ideas seems marvelous at first thought, but the probable explanation is the vitality of the inventors who persist in pushing them. "Poleforcia," a scheme for gaining power or, in other words, a perpetual motion machine, had its day in Philadelphia some years ago, and is now troubling the Britons. Another idea equally unpractical from a correct mechanical standpoint, which originated in America and has crossed the Atlantic, is a ball-bearing rifle gun. In this gun the ordinary rifling grooves are replaced by deep grooves in which are placed a multitude of hardened steel balls over which the projectile is supposed to ride without friction as it is discharged from the gun. No space is allowed for the balls to roll so it is difficult to understand the inventor's claim for an anti-friction bearing. The inventor appears to labor under the misapprehension that the chief resistance caused by a projectile to rapid flight is its frictional resistance in the bore, when, as a matter of fact, this resistance is but a small fraction of that due to the inertia of the projectile, in heavy ordnance.

Four-cycle gasoline engines for motor bicycle use are made that develop one brake horse power for each 20 pounds weight of motor.

ENGINEERING REVIEW.

CURRENT EVENTS, TECHNICAL AND MECHANICAL—LEADING ARTICLES OF THE MONTH.

The August data sheet erroneously states that watts × 746.00 = horse-power, and that horse-power × 0.00134 = watts. The factors should be transposed so as to read: Watts × 0.00134 = horse-power, and horse-power × 746 = watts.

A correspondent of the *Woodworker* says that a good rust joint mixture is made of ten parts of iron filings (or borings) to three parts of chloride of lime. Mix into a paste with water, apply to joint and clamp together. In twelve hours it will be set solid.

The old New Bedford whalers are mines of copper wealth according to *Marine Engineering*. The timbers were heavy and white oak put together "on honor" which apparently meant the liberal use of copper fastenings. It is said that from $2,000 to $3,000 worth of scrap copper is often realized when one of these old vessels is broken up.

A novelty in time-keeping devices is a handless clock which shows the time in hours and minutes on direct-reading celluloid tablets. These tablets or leaves are arranged in two rows around a vertical cylinder, each leaf being pivoted to the outside of the cylinder, and on the "face" portion of the cylinder they are turned in opposite directions like an open book. As the cylinder turns successive leaves flip over from one side to the other, thus exposing the successive figures denoting the hours and minutes.

In a recent interview Mr. Charles M. Schwab, the former president of the United States Steel Corporation, said that in 1879 the steel production of this country was 1,000,000 tons per annum; in 1889 it had increased to 7,000,000 tons; and in 1899 it was from 12,500,000 to 15,000,000 tons. The consumption is now 15,000,000 to 16,000,000 tons a year and in ten years will be over 20,000,000 tons. The consumption of steel rails required to replace those worn out is 2,500,000 tons annually, and 600,000 tons are used in the manufacture of steel cars.

The true and, therefore, persistent inventor is satisfied with no device or product; he is continually working out new combinations or changes in the things previously created. Even the humble carpet tack has not been allowed to retain its original concrete form, but in a new shape it assails our eyes, having a double head arranged tandem fashion, one over the other. The true inwardness of this invention is not, as might be imagined, to foil its peculiarly fiendish propensity for standing upright on chair seats or on the floor awaiting the bare foot of the unsuspecting night prowler, but to facilitate its removal from tho floor in spring house cleaning time.

Men get the notion into their heads that you cannot run wood-working machinery fast enough, and speed up their planers and saws to the last limit. This is probably the poorest kind of policy. Saws running above a normal speed will not run as easy or do as good work as at much lower speed. If any one does not think so, let him take a common bench saw, speed it up high and feed it by hand himself. He will soon find that the stock pushes hard. Then he concludes the saw is dull. After filing, he tries it again, with the same result. The trouble is, one cut follows the other too quickly and glazes it over. Every wood-working machine shows the same effect following a too high speed. There is a normal speed for saws and planers.—*Woodworker*.

The liquid condition of petroleum is ordinarily an advantage when considered for fuel purposes, but sometimes it is a decided disadvantage, especially when it is to be used temporarily in coal furnaces or where the conditions are such that the liquid fuel is a grave fire risk. Considerable attention has been given to briquetting petroleum so as to make it available where liquid fuel is not permissible. A recent consular report gives a brief outline of a German process for petroleum briquetting which appears simple and apparently requires practically no machinery. To one quart of petroleum is added soft soap, 150 grains; rosin, 150 grains; and caustic soda lye wash, 300 grains. The mixture is heated and thoroughly agitated. This takes about forty minutes and during this time care must be taken to prevent the liquid running over; this is achieved by adding a little soda. The mixture is poured into briquette molds to solidify and allowed to cool, after which the briquettes are dried in an oven for an hour or two.

NEW GALVANIZING PROCESS.

A new process of galvanizing, known as "Sherardising," has been developed abroad to a commercial basis, which promises to overturn the present hot galvanizing process used on iron and steel. By the new process the work is covered with an even coating of zinc without dipping it into a molten bath, and it is done at considerably less than the melting temperature of zinc so that the deteriorating effect of high temperature is considerably reduced. The work to be galvanized is thoroughly cleared of surface oxide or rust by sand-blasting, acid bath or other preferred means, and is then placed in an air-tight cast iron muffle or oven charged with the zinc dust of commerce. After being kept at a temperature of from 500 to 600 degrees F. for a few hours, the work is removed and allowed to cool. The process of coating with zinc has been perfectly effected during the baking process; the thickness of the coating of zinc depends upon the time the work is kept in the muffle. The galvanizing is thus done at a temperature about 200 degrees less than that necessary by the hot bath process; moreover, it has the advantage of wasting none of the zinc. The waste of zinc by the common process is a quite considerable percentage of the total amount of the bath. Although common bar zinc melts at something over 700 degrees F., the zinc dust of commerce does not melt at an even much higher temperature, so that there is no danger of its melting in the muffle.

THE TELEPHONE PARADOX.

A writer in the New York *Times* explains the "telephone paradox," that is, why the cost of telephone service per subscriber instead of decreasing with an added volume of business, increases at a faster rate than the increase of subscribers.

"The switchboard in the exchange is built in sections, each of which contains on an average the terminals of the lines of 200 incoming subscribers. These terminals are called 'jacks,' and the panel containing them is called the answering panel. In addition to these 200 incoming jacks, each section must contain the outgoing jacks of each subscriber in the exchange. This is necessary in order that the operator in each section may be able to connect any of the incoming subscribers in a section with any other subscriber in the exchange. The panel containing these outgoing jacks is called the multiple panel. On the above basis the switchboard in an exchange of 2,000 subscribers, would contain ten sections, that of a 5,000 exchange 25 sections, and that of a 10,000 exchange 50 sections, consequently each section in exchanges of these capacities would contain respectively 2,200 jacks, 5,200 jacks, and 10,200 jacks. The total number of jacks in a 2,000 exchange is therefore 22,000. The average mind would at once arrive at the conclusion that the total number of jacks in a 5,000 switchboard would be two and one-half times that of a 2,000, or 55,000, and that the total number in a 10,000 switchboard five times that of the 2,000. A 5,000 capacity switchboard, however, would contain twenty-five sections of 5,200 jacks each, or a total of 130,000, while a 10,000 capacity switchboard with its fifty sections of 10,200 jacks each, would contain 510,000 jacks. For sake of argument, we will say that each jack with its connection and labor, represents a cost of $1. Each new subscriber added to a 2,000 exchange has to be 'multiplied' into ten sections, necessitating ten jacks; but each new subscriber added to a 5,000 exchange has to be 'multiplied' into

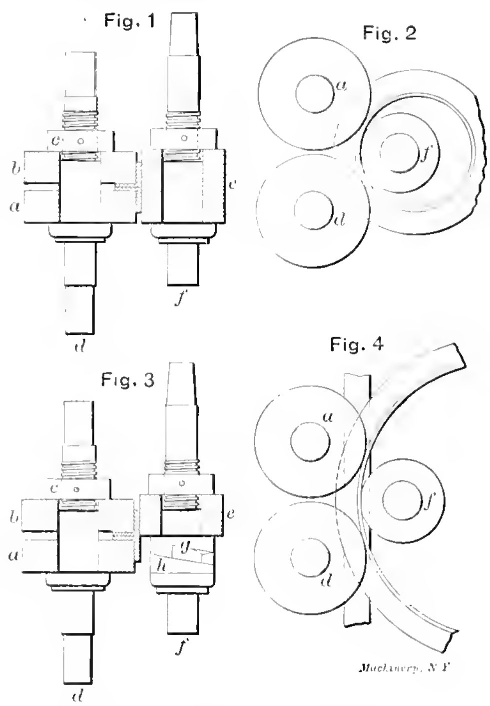
twenty-five sections, requiring twenty-five jacks; while each new subscriber added to a 10,000 exchange has to be multiplied into fifty sections, requiring fifty jacks. Now, as to the number of 'hello girls' necessary to operate exchanges of the size mentioned. While one operator can take care of each section of a 2,000 capacity switchboard, the larger exchanges require three or more operators per section, besides assistants, relief operators, and monitors. It is, therefore, evident that a company starting out with 2,000 subscribers, on a basis of say $50 per year for service, makes less profit on each 200 subscribers added; and such is the decrease in the profit as the exchange mounts up to 5,000 or 10,000 that the company must either increase its rates or quit.

"One of the most interesting exhibits in the St. Louis Exposition is that of the invention of a German named Faller, who has succeeded in eliminating the multiple feature, not only from automatic practice, but also from present manual practice. So great are the savings effected by this elimination of the 'bugaboo' of telephony that we may, in the near future, look for, not only much lower rates, but also what is almost as much to be desired—infinitely better service."

METHOD OF BENDING ANGLE BARS.

Energie, December 5, 1903, p. 3.

When an attempt is made to bend angles into a circular form it frequently happens that the ends do not close because the varying resistances of the different parts of the section throws these ends out of the same plane. In order to avoid this trouble Kottgen & Co., of Barmen, have designed the apparatus shown in Figs. 1, 2, 3 and 4. The principle of operation is to set the angles back to back so that the varying forces



Illustrating Method of Bending Angle Iron.

in each are working in opposite directions to each other and thus hold them in the same plane. Figs. 1 and 2 show the apparatus as arranged to bend two angles at the same time. If but one angle is to be bent the arrangement shown in Figs. 3 and 4 is used. The regulating screw g and h makes it possible to so adjust the roller e that it only acts upon one angle, which is so guided by the other that it is prevented from turning out of its own true plane. G. L. F.

THE ACTION OF PUMPS.

Practical Engineer, August 5, 1904.

From a hasty and superficial consideration no mechanical operation appears simpler than pumping fluids, whereas, under some considerations, it requires most carefully-designed machinery, and a thorough grasp of all the effects of moving fluids, before the operation can be successfully accomplished. Referring in the first place to the suction action of a pump, the plunger is followed by a plug of water in the whole length of the suction piping, and the effect of this water may be likened to so much dead weight added to the plunger, the inertia of which will be felt by the reciprocating parts and the crank pin. This action will show that an air chamber on the suction is a very necessary provision where the length of suction pipe is considerable. Turning now to the delivery action, we have, when the pump is about to commence its stroke, the whole mass of water in the pump chamber and the rising main inert, and this mass is suddenly set in motion by the advance of the plunger. It is clear, therefore, that severe shocks will occur where the delivery pipe is of great length. The above conditions exist where the valve action of the pump is perfect, but when faulty valves are present further shocks will be encountered. Consider, for instance, the effect of a sluggish closing of the delivery valves. When the plunger has attained its extreme stroke and begins to return, it will be followed by the whole volume of water in the rising main, but this motion will only continue so long as the delivery valve remains open. When this has closed the motion will be suddenly arrested, and great shocks will be felt unless air chambers are provided. In addition to the actions just described, there is the effect of a sluggish action on the part of the suction valves, as well as the effect of a restricted suction passage, but enough has already been said to indicate the nature of the shocks encountered by pumps. When these are considered, the frequent fractures and breakdowns which occur will not appear to be very mysterious; and this article will have served its purpose if it will lead some designers to realize that pumps have to withstand other stresses than those due to the mere statical head of the fluid.

THE ENGINEER AS A BUSINESS MAN

Extract from Address by A. C. Humphreys to the Students of University of Wisconsin.

About eighteen years ago I was called in to examine a process for which it was claimed that from two barrels of oil could be produced 200,000 feet of gas, high in candle-power and high in calorific-power. The promoters were able to produce, in verification of their claims, certificates from a number of gas engineers, and, I am sorry to say, from two professors of high reputation, members then of the faculty of a prominent engineering college. The certificate of one of these professors stated that the volume of gas produced under his observation confirmed the claim as to volume. The other professor's certificate stated that the gas produced had been found to be equal in candle-power and calorific-power to the claims. I noticed, however, that these certificates showed that the work on volume and the work on intensity or quality had been performed on different days. I was reluctant to undertake an investigation because manifestly the claims were ridiculous. On account of several people strong in the financial world, friends of our company, being concerned I was finally persuaded to undertake the investigation. I went off with a number of my men, set up the apparatus and left it in charge of a man who is now my partner and who at that time had only recently graduated from Stevens Institute. In giving him his instructions I told him that when he signed his report it would be necessary for him to bear in mind that when he affixed his signature I should understand that every word in his report he was personally responsible for; that he had taken nobody's word for anything, even to the minutest detail. He made the remark that this would be liable to put him into some very embarrassing positions. I told him it was sure to do so. Being a very polished Southern gentleman, this was evidently very disagreeable to him. The work went on for six weeks. We were constantly hampered by objections to the measures we were taking for the final determination. I visited the works myself once a week and it was apparent finally that oil was being introduced to the apparatus surreptitiously and I told my men to find the hidden pipe which was so being used. Shortly after my return from this last visit I received a telegram from my assistant in charge saying: "Have discovered the pipe. Can do nothing unless I seal the valve. This will indicate a lack of confidence. What shall I do?" I wired back: "You have your instructions and know what will be expected if you sign the

report." I received another telegram in reply: "Valve sealed." The next morning I got another telegram: "Works burned down, valve, seal, and all." So we had finally forced them to face a disclosure of the fraud and they preferred to have an accident at the works.

THE RESISTANCE OF EMERY WHEELS TO RUPTURE.

La Revue Technique, June 25, 1904, p. 660.

The Prussian government have fixed a maximum limit to the circumferential speed of emery wheels. For wheels made with a vegetable binder this limit is 82 feet per second, and for those with a mineral binder it is 49 feet per second. In the opinion of some German engineers, these figures seemed too low, and Prof. Grubler was commissioned to ascertain the bursting speed of wheels of different sorts.

The apparatus used consisted of an arbor 2 inches in diameter which is guided at the upper end by two collars held between two horizontal plates, set about 7⅞ inches apart. These latter were supported by two I-beams set about 11 inches apart. The wheel is centered and mounted at the lower end of the shaft. The whole rested upon a block 11⅞ inches thick, which in turn was supported on the sides of a trough nearly 4 feet deep and about 35½ inches wide. The arbor is driven by means of a grooved pulley over which a cord runs, and which can be driven by an electric motor at a speed of 1,600 revolutions per second. This latter can, however, be regulated at will, and a tachometer, driven by gearing, indicated upon a dial the speed at any instant. The wheels were fastened to the arbor by two metallic disks of 7⅞ inches diameter between which felt washers were screwed.

As the speed of the wheels was increased two critical values were brought out that were characterized by the more or less violent vibration of the shaft. They were caused by its elasticity and the torsion of the supports. They did not appear to bear any ratio to the speed of rupture or the explosion of the wheel, but are the more pronounced as the center of gravity of the wheel varies from the center of rotation.

From theoretical consideration alone it would appear that the maximum stress carried by the wheel is to be found at the circumference of the circular hole in contact with the shaft, and an examination of the broken wheels showed that the cracking had proceeded from the center to the circumference.

These wheels were all about 19⅝ inches in diameter, and the highest speed attained was 4,340 revolutions per minute, or 374 feet per second at the periphery.

As an expression of the safe speed the following formula has been deducted which gives the value of the maximum tension t of a wheel with an internal diameter i, an external diameter e, a specific weight w, and a circumferential speed u.

With metric measurements the formula is

$$t = \frac{3\,w}{4\,g}\,u^2\left[1 + \frac{1}{3}\left(\frac{i}{e}\right)^2\right]$$

which when referred to English measurements becomes

$$t = \frac{w\,u^2}{62\,g}\left[1 + \frac{1}{3}\left(\frac{i}{e}\right)^2\right]$$

g being the acceleration of gravity.

By adopting 10 as a coefficient of safety, the above formula gives the following as the safe peripheral velocities of various types of wheels:

	Feet per Second.
Wheels with a vegetable binder (rubber)	102
Wheels with a mineral binder (magnesia)	88½
Wheels with a porcelain binder	78

RESISTANCE OF RAILWAY TRAINS.

Zeitschrift des Oesterreischischen Ingenieure Vereins, December, 1902.

The author, after having reviewed the trials of M. F. Barbier on the Northern Railway of France on the resistanee of trains, gives the results of other independent tests of the same kind to secure similar data regarding Austrian rolling stock. The result of these experiments has been presented in the same form as those of Mr. Barbier, and the formula derived is $R = a + bV + cV^2$, in which R is the resistance of the car in kilograms per ton of material, V the speed in kilometers per hour, and a, b and c constants which are then reduced to a graphic formula where the several factors are set forth.

These tests were not made by means of indicators and dynamometers, but by observing the speeds and accelerations which the vehicles attained upon different grades, a speed that amounted to from 36 to 18 miles an hour, and sometimes held this for a comparatively long time. In the matter of cars at least 323 trains were used whose weight, length and composition were varied to correspond with the condition of actual service.

The author also notes the difference between this method of testing and the dynamometer method, of which he has made no use. He also gives the principal dimensions of the vehicles used and the curves obtained, not only by himself but by Leitzmann, Wittenberg, Clark and others in former researches. Among other formulæ given are $R = 3.8 + 0.025V + 0.001V^2$ (between 24 and 48 miles an hour) for a 4-4-0 compound locomotive weighing 55.6 tons and having a six-wheeled tender weighing 36.7 tons in working order, attached; and $R = 1.6 + 0.184V + 0.00046V^2$ for four-wheeled cars weighing from 11 to 15 tons.

In conclusion, M. Sauzin summarizes the numerous influences which tend to modify the resistances of trains, such as wind, exposed areas, lubrication, temperature, etc.

MAKING CASTINGS IN ALUMINUM.

Practical Engineer, July 15, 1904, p. 75.

The method adopted in preparing molds and cores for aluminum work is necessarily somewhat the same as for brass, but there are particular points which need attention to insure successful work. Both in the sand and the making of the molds there are some small differences which make considerable variation in the results, and the temperature at which the metal is poured is a consideration of some importance.

In selecting the sand, which should not have been previously used, that of a fine grain should be chosen, but it should not have any excess of aluminous matter, or it will not permit of the free escape of gases and air, this being an important matter. Besides this, the sand must be used as dry as possible consistent with its holding against the flow of the metal, and having only moderate compression in ramming.

In making the molds it is necessary to remember that aluminum has a large contraction in cooling, and also that at certain temperatures it is very weak and tears readily, while all metals shrink away from the mold when this is wholly outside the casting, but they shrink on to cores or portions of the mold partly inclosed by metal. Thus, if casting a plate or bar of metal, it will shrink away from the mold in all directions; but if casting a square frame, it shrinks away from the outside only, while it shrinks on to the central part or core. With brass, or iron, or such metals, this is not of much importance, but with some others, including aluminum, it is of great importance, because if the core or inclosed sand will not give somewhat with the contraction of the metal, torn or fractured castings will be the result. Both for outside and inside molds, and with cores used with aluminum, the sand should be compressed as little as possible, and hard ramming must in every case be avoided, particularly where the metal surrounds the sand. The molds must be very freely vented, and not only at the joint of the mold, but by using the vent wire freely through the body of the mold itself; in fact, for brass the venting would be considered excessive. With aluminum it is, however, necessary to get the air off as rapidly as possible, because the metal soon gets sluggish in the mold, and unless it runs up quickly it runs faint at the edges. The ingates should be wide and of fair area, but need careful making to prevent them drawing where they enter the casting, the method of doing this being known to most molders.

If it is considered desirable to use a specially made up facing sand for the molds where the metal is of some thickness, the use of a little pea or bean meal will be all that is necessary. To use this, first dry as much sand as may be required and pass through a 20 mesh sieve, and to each bushel of the fine sand rub in about 4 quarts of meal, afterward again passing through the sieve to insure regular mixing. This sand should then be damped as required, being careful that all parts are equally moist, rubbing on a board being a good way to get it tough, and in good condition, with the minimum of moisture.

The molds should not be sleeked with tools, but they may be dusted over with plumbago or steatite, smoothing with a camel's hair brush, in cases where a very smooth face is required on the castings. Preferably, however, the use of the brush even should be avoided. Patterns for aluminum should be kept smooth and well varnished, as the better the face of the pattern the smoother the mold is left, as a rule, a point worthy of consideration in relation to the making of molds for casting all kinds of metals and alloys.

In melting the metal it is necessary to use a plumbago crucible which is clean, and which has not been used for other metals. Clay or silica crucibles are not good for this metal, especially silica, on account of the metal absorbing silicon and becoming hard under some conditions of melting. A steady fire is necessary, and the fuel should reach only about half way up the crucible, as it is not desirable to overheat the crucible or metal. The metal absorbs heat for some time and then fuses with some rapidity; hence the desirability of a steady heat, and as the metal should be poured when of a claret color under the film of oxide which forms on its surface, too rapid a heating is not advisable. The molding should always be well in advance of the pouring, because the metal should be used as soon as it is ready; for not only is waste caused, but the metal loses condition if kept in a molten state for long periods. The metal should be poured rapidly, but steadily, and when cast up there should not be a large head of metal left on top of the runner. In fact, it is rather a disadvantage to leave a large head, as this tends to draw rather than to feed the casting.

With properly prepared molds, and careful melting, fluxes are not required, but ground cryolite—a fluoride of sodium and aluminum—is sometimes used to increase the fluidity of the metal. In using this, a few ounces according to the bulk of metal to be treated is put into the molten metal before it is taken from the furnace, and well stirred in, and as soon as the reaction apparently ceases the pot is lifted and the metal at once skimmed and poured. The use of sodium in any form with aluminum is very undesirable, however, and should be avoided, and the same remark applies to tin, but there is no objection to alloying with zinc, when the metal thus produced is sold as an alloy.

Aluminum also casts very well in molds of plaster of paris and crushed bath brick when such molds are perfectly dry and well vented, smoothness being secured by brushing over with dry steatite or plumbago. When casting in metal molds, these should be well brushed out with steatite or plumbago, and made fairly hot before pouring, as in cold molds the metal curdles and becomes sluggish, with the result that the castings run up faint.

SUPERHEATED STEAM FOR LOCOMOTIVES IN GERMANY.

Abstract of Consular Report No. 2,016 by Dean B. Mason, Berlin, Germany.

Since the year 1898 the Prussian State railroads have been carrying on experiments with locomotives using superheated steam, and these experiments have done much to elucidate and overcome the technical difficulties incident to the use of superheated steam by locomotives. While during the last ten years the utilization of superheated steam with stationary engines has become general in Germany, it has been employed only on a small scale, during the past few years, with locomotives. Owing to the great amount of power which a locomotive of limited size must produce, it is far less economical of steam than the stationary engine, whose bulk is subject to no limitation, and its steam is far more heavily charged with moisture, so that theoretically, at least, the advantages obtained by the use of superheated steam in locomotives should be greater than in stationary engines.

The first two engines equipped with Schmidt superheaters, put into service in 1898 by the Prussian State railroads, are still running, and after various modifications had been made they gave, according to an official report, entire satisfaction, and are to-day considered two of the best simple engines for express and ordinary passenger service, in spite of the fact that they are in various respects not up-to-date in construction. The next order was for four simple locomotives in which the superheater was placed in the smokebox instead of in the boiler, and all of these engines have proved satisfactory, according to the report of Baurath Garbe, in respect to power, economy in the use of water and coal, and the ease with which they start. At present there are some 50 locomotives equipped with the Schmidt superheater in use or in course of construction for the Prussian State railroads, and all the different types of locomotives at present in use on this system are being tried with the Schmidt superheater. No official reports of the results obtained have been published more recently than 1902. In an article published by C. W. Kriedel, of Wiesbaden, the results shown by the tests made public up to that time were summed up as follows:

Locomotives using superheated steam under favorable conditions use 5 per cent. less coal and 15 to 20 per cent. less water than engines using saturated steam; owing to its lightness, superheated steam is especially effective when the action of the piston is very rapid; and greater power for a short time can be maintained by engines using superheated steam than by those using saturated steam.

Brückmann, one of the most indefatigable and exhaustive investigators, calculates that under normal conditions there is a saving of 20 per cent. in an ordinary simple steam engine that employs superheated steam over one that does not, while the saving in coal is only one-half per cent. when the work of a simple engine with superheater is compared with that of a compound engine without it. Owing to the difficulty of obtaining absolute accuracy, the results of the various tests of the efficiency of locomotives using superheated steam as compared with other engines have varied considerably, and there exists more or less difference of opinion as to the limit of economy in fuel and water that has been and is likely to be attained by the use of superheated steam.

Geheimrath Garbe maintains that in considering the question of expense the simple engine with superheater should be compared with the compound locomotive. He maintains that the use of the compound engine has been rendered desirable only by the defects of ordinary steam, that with highly superheated steam the simpler and less expensive twin engine, working with steam at much lower pressure, is capable of taking its place for all purposes, and that it will be possible by the use of superheated steam to reduce the types of engines used in Germany to five or six. He asserts that while the compound engine is more economical, is capable of attaining greater speed, and is more powerful at high speed than the simple engine when ordinary steam is used by both engines, the advantages of the compound engine disappear when it is compared with a properly constructed simple engine using superheated steam at from 570 to 620 degrees F. He bases his judgment on experience obtained on the Prussian railroad and on the inherent superiority of highly superheated steam.

The most recent trial that an engine equipped with the Schmidt superheater has undergone was at the high-speed steam locomotive tests made on the track between Marienfelde and Zossen, when an engine built by the firm of Borsig and equipped with a Schmidt superheater made a speed of 79½ miles with a full train of six cars, and a speed of 84½ miles an hour with a train of three cars, the energy developed being about 2,000 horse power. The Borsig engine, unlike the three other engines, was not built specially for these trials, but only one of its competitors equaled it in speed.

It is likely that the Schmidt superheater would have been adopted already on a much larger scale were it not for the opposition which it has encountered from the partisans of

other superheaters. Encouraged by the success obtained by Schmidt, other inventors have taken up the same line of work and have produced superheaters of varying degrees of practicability. Of these the Pielock is the one that has received the most attention in this country, and would appear to be the most serious competitor to the Schmidt invention. It consists of a chamber or metal box located in the boiler, from which it is separated by a metal wall through which the boiler flues pass. The interior of the superheater is divided up by walls in such a manner that the steam in passing through the different subcompartments is made to circulate along the boiler flues. Owing to the risk of injury to the flues, it has not been found desirable to place the superheater too close to the furnace. The temperature in the furnace flues is reduced by passing through the water of the boiler, and the temperature attained by the steam in the superheater is from 450 to 500 degrees F.

As will be seen by the foregoing, there exists a radical difference between the Schmidt and Pielock superheaters. While in the former the steam is heated to from 570 to 620 degrees F. by means of one large flue, which conveys part of the furnace gas to the superheater chamber, in the Pielock system all the furnace gas is passed through the superheater by means of the boiler flues, the steam being heated only from 450 to 500 degrees F.

In all, some ten engines have been or are to be equipped with the Pielock superheater by the Prussian State railroads, but it has not been possible to obtain satisfactory information as to the results recently obtained. Only old engines have been experimented with, one of the principal advantages of the Pielock over the Schmidt superheater being that old engines can be equipped with it without expensive alterations. In order to equip an engine with a Schmidt superheater capable of giving the steam a high temperature it is necessary to enlarge the smokebox in order to make room for the superheater, and in case the superheater is made smaller, the old smokebox being retained, it is possible to obtain only moderate temperatures, similar to those obtained by the Pielock system.

It is claimed for the Pielock superheater by its inventor that it can be used on old as well as new locomotives, as it can be adjusted to any boiler, and that no loss of power is entailed, as owing to the greater efficiency of the superheated steam, the space taken up in the boiler is more than compensated for; that owing to the simplicity of construction of the Pielock superheater it is cheaper than any other type, costing from $450 to $600 only for a two or four-cylinder Prussian express locomotive; that with it there is no loss from radiation, as any heat lost in the superheater raises the temperature of the water in the boiler; that it is less subject to repair than any other superheater, and needs no special cleaning other than the cleaning of the boiler flues, which would have to take place anyway; and that no extra labor is entailed on the part of the locomotive engineer.

It is claimed by the adherents of the Schmidt system that it is impossible to obtain sufficient increase in efficiency with the moderate temperature attained by the Pielock superheater to justify its use; that frequent repairs to the furnace flues passing through the superheater will be inevitable; that they cannot be examined without being taken out; that this involves serious damage to the superheater and to the walls to which they are made fast; and that a flue thus removed cannot be used again. The partisans of the Pielock system claim, on the other hand, that the large furnace flue used in the Schmidt system is likely to leak where it is connected with the superheater; that the highly superheated steam is very injurious to the machine parts which it comes in contact with; and that too much heat goes out of the smokestack.

WATER HAMMER IN STEAM PIPES.

The Locomotive, July, 1904.

Attention should be called to the danger of putting in steam pipes in such a way that they can act as traps, and collect any considerable quantity of water of condensation. When steam is turned into a pipe containing entrapped water, it is unfortunately common experience that the entering steam causes the water to surge about in some way that is not entirely understood, so that it is often thrown against the fittings with such violence as to cause some part of the pipe line, or its connections, to break. The reality of the danger from entrapped water in piping is often disputed by those who have not seen its results; but the extensive experience of the Hartford Steam Boiler Inspection and Insurance Company indicates that accidents from this cause not only happen, but happen often. In the following they give several cases of the kind that have recently come under their notice.

Figs. 1, 2 and 3 represent certain steam connections which gave trouble, not long ago, in an electric lighting plant. The boilers were of the water-tube type, with three drums each; the drums of one of these boilers being shown. Immediately

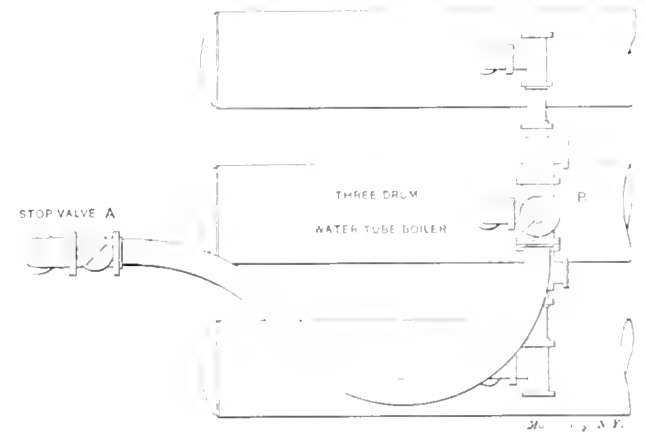

Fig. 1.

upon the top of this boiler there was a safety stop valve, *B*, which was designed to close automatically in case of any abnormally violent rush of steam through the feeder to which it was attached. This automatic valve was closed at the time of the accident, and another stop valve, *A*, situated on the same feeder where it entered the main, had also been closed. The boiler had been out of service for a time, but pressure had been raised upon it again, and it was about to be "cut in" with the other boilers in the battery. For this purpose the stop valve *A* was opened, the intention being to open the automatic valve, *B*, immediately afterward. It is probable that, owing to leakage through one or the other of the two valves, there had been an accumulation of water in the space between these valves; the entering steam causing this water to surge around through the curved pipe in such a way as to throw it violently against the automatic valve. At all events, the stop valve, *A*, was hardly opened when a section of the casing of the automatic valve was knocked out, as indicated by the shaded area in Fig. 3; several men who were standing near by being also scalded. Where two valves are used on a steam pipe in this manner, provision should always be made

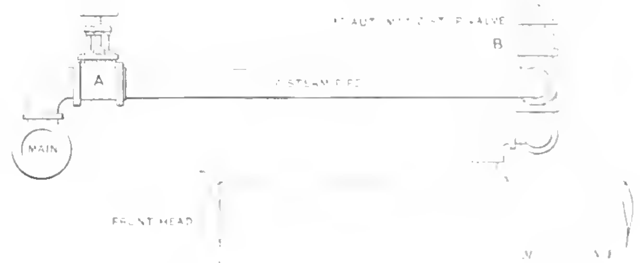

Fig. 2

for draining the space between them before either valve is opened; and when one of the valves is opened, it should be opened very slowly indeed. Furthermore, before any considerable quantity of steam is admitted to the pipe, both valves should be eased off from their seats slightly, to establish a moderate circulation, this being allowed to continue for some moments before the valves are opened further.

Fig. 4 illustrates another case, quite similar in its general aspects to the one described above. The boiler was here of the vertical water-tube type, and there was a gate valve in the branch pipe near the boiler, as well as a globe angle valve where the branch pipe entered the large main. From the circumstances attending the accident here under consideration,

and from the close similarity between it and other accidents in which water-hammer was undoubtedly the chief and perhaps the sole factor in determining the destruction, we are confident that this was also a case of water-hammer action. There had undoubtedly been leakage through one or both of the valves shown, so that the steam pipe had become more or less filled with water. At any rate, when the valve *B* was opened, the casing of the valve *Y* was almost immediately fractured, being broken into several pieces. It will be understood that in an accident of this kind it is often very difficult indeed to prove, beyond further argument, just what the cause was. In the present case, it has been pointed out that the valve *B*, being a gate valve, would naturally not be opened very rapidly; and it has

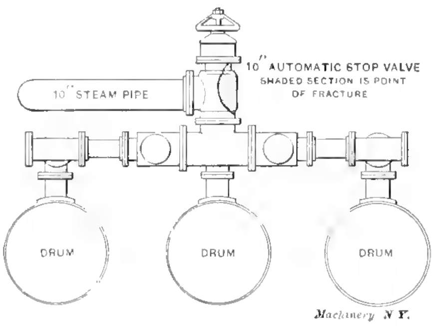

Fig. 3.

been argued that this lessens the probability that the accident was due to water-hammer action. However, the fact remains that the casing of the broken valve appears to have been abundantly strong to withstand any strain that could legitimately come upon it in its natural service, and, moreover, an examination of the fractured areas of the casing showed that they were sound, and without defects. It is also certain that the pipe would have trapped water if either of the valves had leaked, and that the accident occurred immediately upon steam being admitted through the valve *B*. Taking these various circumstances into account, assurance is felt that the cause was either water-hammer, or the sudden lifting of water from the boiler itself, as the steam was carried over into the comparatively cold pipe. Of these two explanations, that which assumes the presence of entrapped water appears to us to be the more probable, because, unless the gate valve, *B*, were opened with very unusual quickness, it is not probable that any great amount of water would be actually lifted from the boiler and thrown with violence down to the valve *Y*.

Drips are excellent things on a pipe line, if they are faithfully used; but there is a temptation to neglect them, after the attendant has operated the plant for a considerable time without trouble, and it is always better to design the pipe line so that no drips will be necessary, the pipe emptying itself by the natural action of gravity. The same precaution may be

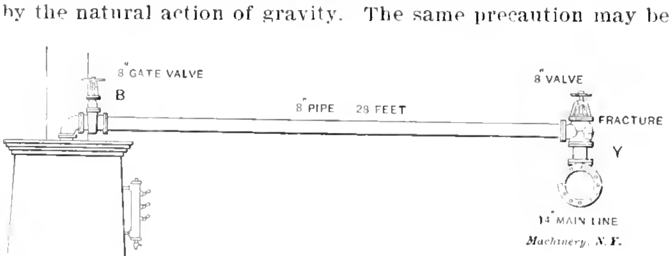

Fig. 4.

repeated here which was mentioned above—namely, in throwing a boiler into service which is connected with the main steam line by a pipe containing a double valve, the valves should be opened very slowly, each being eased from its seat and allowed to stand for a time, until the pipe becomes thoroughly heated, and any entrapped water that it may contain has had an opportunity to pass away.

In Fig. 5 is illustrated another accident, in which water-hammer was more evidently the cause of the trouble. In this case, the feeder pipe from the boiler to the main was bent, in order to clear a fore-and-aft line of pipe. There was only one valve in this instance, between the main pipe and the boiler; but it is easy to see that with the boiler out of service, and steam in the main pipe, there must be condensation in the bent feeder, and the water of condensation must collect, in large measure, in the lowest part of the feeder, near the stop valve. Some changes had been made in the steam plant where this accident occurred, and the valve was being opened for the first time. Two men were engaged in opening the valve, from which it may be inferred that it was not found to work entirely satisfactorily. Moreover, there was a difference in pressure of 30 pounds between the boiler and the steam main, the pressure in the main being 150 pounds, and that in the boiler 120 pounds. A boiler should never, under any circumstances whatever, be "cut in" with other boilers until the pressure within it is practically identical with that in the steam main; because, if this condition is violated, there is grave danger of the rupture of some part of the structure, owing to the suddenness with which the stresses are changed when the valve is opened. In the present case, water had collected in the lower part of the bent feeder, and when the valve was opened this water was thrown against the valve with such violence that the casing of the valve was fractured, the arch cap of the valve being broken away from the body of the chamber, and the valve disk, stem and part of the arch being blown up through the roof of the building. The casing of the valve was 5/8 inch thick, and subsequent examination showed that it contained a small blow-hole, though this defect was too trifling to affect the strength of the casing to any serious extent. Two men were seriously injured by this accident, one of them losing his eyesight entirely, while the other one lost one eye. The dotted lines in Fig. 5 show the ideal way in which this steam feeder should have been run, in order to avoid entrapped water. If it was necessary to bend the feeder, however, in order to avoid the fore-and-aft line of pipe referred to above, the feeder should have been bent in such a way that its highest part should come next to the boiler,

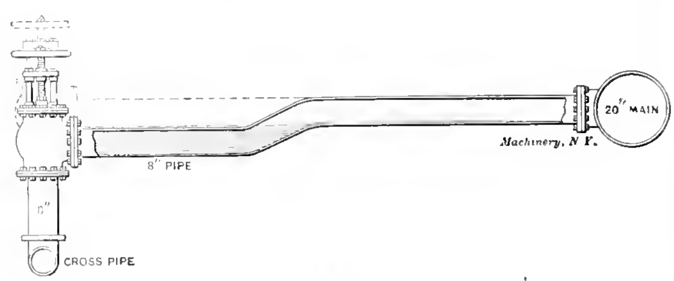

Fig. 5

instead of next to the steam main; the riser being correspondingly lengthened. There would then be no pocket in which water could collect, and the feeder would have drained itself into the steam main.

A steam line should never be arranged so that it can possibly entrap water. If there is any doubt about the perfect drainage in any particular case, drip pipes should be provided so that the doubtful part can be thoroughly drained before steam is turned into it; but it should always be remembered that any pipe whose safe condition depends upon opening of a drip, as a distinct operation to be performed before the valve is opened, must be regarded as an element of weakness about the plant. Steam valves, under all circumstances, should be opened and closed very slowly, and when a pipe contains more than one valve they should all be eased from their seats slightly for some moments, so as to permit of the establishment of a certain amount of circulation, before they are opened up fully. By attending to these various precautions, it should be quite possible to avoid, in large measure, the serious accidents that are continually occurring in connection with pipe lines, and which are attributable to water hammer action, or to other analogous causes.

CONDENSATION FALLACIES AND FACTS.

Mr. W. H. Booth, in Electrical Review, June 17, 1904, p. 983.

The excellence of a vacuum appears to be considered too much as a matter of the quantity of water sent through the condenser, if this is of the surface variety. This is because

the arrangement of a surface condenser is usually of an entirely promiscuous nature. A surface condenser has a large number of tubes, all equally supplied with water, and steam flows across these tubes equally in contact with their colder and warmer extremities. It would appear more rational to enclose the middle length of the tubes in a jacket fitting closely round the bundle of tubes, and compel the steam to effect an entrance to the bundle and travel longitudinally along the spaces between the tubes, emerging at the other end by a very much narrower uncovered band to the air pump. The water should flow along the tubes in a direction counter to the flow of the steam outside them.

The amount of water necessary for condensing a pound of steam can be calculated very simply and directly. Assuming that the water has a temperature of 50 degrees F., and that it is desired to leave at 105 degrees F., there is a gain of 55 degrees F., or a trifle above 55 thermal units per pound.

The steam contains about 1178 thermal units per pound, and if it leaves as water at 55 degrees F., it loses 1,123 units. Then 1,123 ÷ 55 is nearly 21. Therefore, with a properly designed condenser, the conditions named demand only twenty-one times the feed for condensation. If the passage to the air pump along which the air flows could be made to traverse tubes filled with the water flowing to the condenser, the bulk of the air might be reduced, and the vacuum improved somewhat. This supposes the dry air pump, or a separation between the water discharge and the air discharge. The excellence of a vacuum ought to be determined by the temperature of the effluent water, and this, in a counter-current condenser, should be a little warmer than the entering circulation water.

Ordinarily the condensed steam is as hot as, or hotter than, the circulation discharge. Thus, instead of 55 degrees F., it would have a temperature of 105 degrees F. The relative vacua at these two temperatures are 29½ and 27½, a difference of 2 inches, or 0.86 pound pressure. The temperature of the water marks the limit of the vacuum that can be obtained, but it is very doubtful, under even the best practicable conditions, if so good a vacuum as 29½ can be got. The air in the condenser, like any other gas, has a volume proportionate to the absolute pressure reciprocal. At 27½ inches vacuum, the absolute pressure is 1.189 pounds per square inch. At 29½ inches it is only 0.207 pound. The volume is thus nearly sixfold, and to maintain such a vacuum, the volume generated by the air pump would need to be multiplied by six.

This is, of course, the reason why the Parsons turbine condenser is fitted with a steam jet, the object of which is to gather air at extreme tenuity, and force it toward the air pump at a somewhat greater density, in order that the air pump may bite off a greater weight per stroke than it can when only drawing on an air space at 29½ inches vacuum. Let us see what is the relation between air and air pump. Each cubic inch of free air, or atmospheric air, which gets into the boiler or the engine, or the exhaust pipe, expands to seventy times its volume at 29½ inches vacuum. Reduced to air-pump dimensions, this means that an air pump, 13½ inches diameter, with a stroke of 1 foot, would only deal with about 25 cubic inches of air, or about two-thirds of a pint measure, whereas the same pump on a 27½-inch vacuum would deal with one-half gallon. It is to reduce this one-half gallon into two-thirds of a pint that a steam jet is employed. Its effective pressure to do this must be such as to overcome a resistance of one pound per square inch. It is not to be overlooked that this steam jet must be at once killed, or it would spread back into the vacuous space and vitiate the intensity of the vacuum. An air-pump bucket can only extract at each stroke its own generated volume of air, and this must be greater than the volume to which all the inleaking air expands. If this be not the case, the vacuum will fall off until the air density is so much greater that the pump can get hold of as much weight per stroke as leaks in during a stroke period. A very small difference of vacuum makes a very great difference in the capacity of the air pump to deal with it. The repeated use of the same feed water should cause very little air to find its way into boilers, and air, in a condenser, is in such cases almost wholly a matter of leakage at glands. Better vacua years ago were obtained than are usual to-day. One reason was the use of fibrous packings on low-pressure glands, and there is nothing to-day to prevent the same being employed on low pressure or vacuum glands, for these are no hotter than they were when steam of 30 pounds pressure was let into the cylinder. Another cause of air leakage is the long exhaust pipe to the condenser, carelessly jointed, and there are leakages through the valves which shut off the exhaust branches of each engine, not to mention other sources of air. These faults are what render the independent condensing plant so unsatisfactory in practice, because, instead of hunting up air leakages, the air pump is over-driven to conceal them.

The steam intensifier of the Parsons condenser is really a form of compound compressor, the steam jet representing the first cylinder of the compressor, and the ordinary pump representing the second cylinder. The whole combination is, of course, simply an air compressor, compressing to one atmosphere. The steam jet takes the place of the extra large first cylinders which it is necessary to use on the Rand, where the air at 6,000 feet elevation is of too low a density to provide weight sufficient in the ordinary sizes of machine used nearer sea level.

In a condenser the water demands a low temperature, or it will produce vapor to choke the air pump, and the air demands a large air pump to deal with it at high vacua. Hence the need for counter-current condensers for one purpose, and supplementary air condensers to cope with highly-expanded air.

INTERNAL COMBUSTION ENGINES AND THE DIESEL PRINCIPLE.

Mr. W. H. Booth, in Electrical Review, June 10, 1904, p. 975.

It has been pretty conclusively shown that economy in the gas engine attends on high compression, but practice has shown equally conclusively that high compression of an explosive mixture has a low safe limit. The compression of a gas requires the expenditure of energy, and this energy in the case of a perfect gas is converted entirely into heat energy, and manifests itself by rise of temperature. In a slowly running engine much of this heat could and would pass into the water jacket, and so far would be lost for useful work in the engine. Compressed quickly as it must be in any engine of moderate size per unit of effort, the gaseous mixture becomes heated to a high temperature, and becomes spontaneously explosive. Myself, I have little doubt that spontaneous ignition takes place more readily in the more highly hydrogenous mixtures, and this very real danger shuts out from high compression use the richer gases; and those with much hydrogen in their composition, such as the water gases and the coal gases, are unsuitable to be employed in high-compression engines. Mr. Thwaite, in his blast-furnace gas practice, has found that the very poor gas produced from a blast furnace, and containing very little hydrogen, is a very manageable gas. This may partly be due to its considerable constituent of carbon dioxide, which assists to delay ignition. Suffice it to say, that blast-furnace gas will safely endure an intensity of compression above what can be secured with richer and hydrogenous gas.

Now, in the Diesel engine, compression is entirely independent of the quality of the fuel, for the very simple reason that no fuel is introduced until it is wanted to ignite. Pure air alone is compressed, and therefore the intensity of compression is limited only by two factors—the ability of the mechanical construction to withstand the stresses, and the thermal possibilities involved. The high compression produces a temperature sufficient to cause ignition of the fuel, and this ignition takes place as soon as the fuel is introduced to the heated atmosphere in which it burns.

Thus the Diesel engine does act along very different lines from those casual lines of the ordinary internal combustion motor. Though the full cycle intended to be worked by Diesel has not been found practicable, a part of it has been secured, and combustion takes place on isothermal lines, the diagram of the Diesel engine being simply the compression

curve pushed forward by temperature, so that the air occupies a larger volume at the same pressure. Thermally, the advantage of this system is that the maximum pressnre may be employed that the machinery will permit, and there can be no pre-ignition. There is no sudden accession of pressure on the dead point, but the pressure may even rise a little after the crank has passed its position of zero effort. In this way there is less mechanical loss incurred through the imposition of a heavy pressure on the bearings during the time such pressure is producing no turning effort. Where early ignition takes place and produces this effect, much of the heat is passed directly to the water jacket, and therefore wasted. In gas and oil engine work it is of importance that the heat generated by combustion should pass very directly into mechanical work. Every engine is, of course, a compromise between full ignition on the dead point and the longest utilization of the pressure produced, and prolonged combustion, with a minimum of loss to the jacket. Early and complete ignition not only produces frictional loss, but jacket loss These losses are both saved by prolonged combustion, which, by purely academic men, is looked on as an error. Hence the importance of securing a satisfactory compromise. In the Diesel system this compromise, combined with the principle involved, enables an efficiency to be obtained as between indicated horse power and calorific capacity of the fuel of 42, if not 44 per cent., and well over 30 per cent. can safely be counted on, referred to brake horse power.

As a machine, the Diesel or other engine may be fully as frictionless as a steam engine, and recent tests of a Diesel engine have shown me that this is the case. I have also found that an indicated horse power hour can be got for about 0.32 pound of crude oil with a calorific capacity of about 19,000 B. T. U., and this points to a very efficient utilization of the heat value of the fuel. This high efficiency is a result due largely, of course, to the high compression which is possible only with the Diesel system of fuel admission. It is also partly due to the diminished friction and diminished jacket losses referred to, and these advantages may be more or less secured in other forms of engines than the Diesel.

The future improvement of internal combustion engines lies so much along the lines followed by Diesel that this motor may be studied to good advantage, for its system of compression removes the most serious limitations of the ordinary engine, and in weight of combustible per unit of energy output its record is far ahead of any other motor.

* * *

HOW CAR INSPECTORS ARE BEATEN.

A writer in the *Railroad Gazette*, who formerly was a car builder, throws a vivid light on some shady practices followed in car building shops when orders are taken on too close margin or the specifications are considered by the management to be somewhat too rigid. Perhaps equally as interesting tales could be told regarding the execution of certain supposed high-grade machinery if the perpetrators thereof were disposed to take the public into their confidence. The writer says:

"I remember when I was foreman of a shop in an Illinois town some years ago, before the advent of steel body and truck bolsters, we got a job that called for white oak bolsters. White oak was rather scarce and hard to get at any price, but it chanced that the shop was adjacent to a scrub oak country and that there were plenty of saw mills to supply the demand, so the superintendent decided to saw his white oak bolsters from scrub oak logs, securing thereby a much cheaper article and a much longer time on his bills. But the inspector whom the railroad sent out was wise on white oak, and the superintendent knew that the scrub oak has a peculiar smell which would distinguish it readily from the real article. The sample car was put up with white oak, as specified, and, in the meantime, the home product was cut and run to size as rapidly as possible, and was stacked up to dry in "the shade." Enough was run in this way to fill the entire contract. While this was going on, some fresh, recently cut white oak was procured and run through the planer. The chips were carefully collected and a decoction of white oak was brewed in a large iron kettle. Then we took a whitewash brush and gave the scrub oak bolsters a good smear of our special brewed white oak perfumery, and completed the job by painting the ends with mineral paint. The two together effectually killed the barn lot smell of the scrub oak. When the inspector came around he demurred at the dark appearance of the wood, but it was explained to him that it had lain out in the weather and was rain soaked. He passed our home-industry bolsters without a murmur.

"After the iron bolsters came into use it took a slightly different style of treatment to doctor them, but there were ways. Once the company by which I was employed had to turn out a thousand truck bolsters for another firm that was caught short on a contract. The understanding was that the other firm was to furnish the material and we were to do the work. The superintendent and I figured long and earnestly as a committee on ways and means, for our shop had never attempted anything like it before. There was an abundance of drilling and riveting to be done and no labor-saving appliances to do it. He finally decided that he would do it any way, and put on a night shift, as we got a pretty stiff price for the work. The bolster company sent an inspector down, who proved to be a terror, and we had to do most of the night shift work over again in the daytime, as they only got about one rivet out of ten tight. The inspector was always on the spot and every loose rivet had to be cut out and replaced by a tight one. Our night shift was recruited from around town and the surrounding country, and each of the boys was perfectly competent to follow along behind a mule, after the reins were around his waist so that the motive power would move man and plow together. They could haul logs, too, with a pair of steers at about one mile per hour, but when it became necessary to move up a peg and get a hot rivet down before the shrink was all out of it, the spurt lasted just one rivet, and that was all. Between the night shift, the superintendent, and the inspector, I had gotten to the stage where if any one so much as asked what time it was, I would tell him to cut it out and put in a new one, my mind being wholly on loose rivets.

"Finally, we got a new foreman for the night gang, and the new foreman sized up the situation and asked me to have a calker made. After that, we finished up the edges of our loose rivets with a good sharp calking tool, and when the inspector tested the plates, they sounded as tight and solid as if they were made out of one piece. The superintendent saw that it would not do to get perfect work all at once, so we left the inspector a few loose rivets now and then for the next week or so, but finally tightened them up to the satisfaction of all concerned. Out of that one thousand bolsters, I don't believe one hundred went out perfect, for there really did not seem to be any use in driving rivets tight when you could fix them up with the calker.

"When it comes to beating the inspector on castings, you have to get at it in a little different way, as castings have to turn out the way the patterns make them. A simple and effective way to get around this is to have a double set of patterns, with a private mark on each so that if you really want to you can tell which is which. This will save you maybe 10 or 12 dollars' worth of pig iron on each car, which would help keep the officers of the company in cigars and pay for an occasional watch or gold-headed cane if the inspector ever should happen to tumble on a short weight. When the inspector first arrives on the scene, with his mind full of responsibility and a disposition to test everything in sight, he finds a nice little stock of standard castings waiting for him. Maybe 25 cars of castings of all kinds are gotten out while he is familiarizing himself with the patterns and breaking a few wheels to test them for hammer blows and depth of chill. The scales are wheeled up to the piles, so that they can be weighed, the inspector pronounces his O. K., or suggests the desired changes, and then when he gets through we begin making green goods for him by exchanging patterns that make castings from eight ounces to ten pounds light, always keeping on hand a few of the right weight for emergencies."

SOME MICROMETER MEASURING INSTRUMENTS.

A. L MONRAD.

Having lately received letters from several persons inquiring about a combination micrometer I will endeavor to describe one of my own design, that I believe to be suitable for all classes of work. Fig. 1 shows an assembled view and the details of a 5-inch surface gage, which can be used as a height gage in obtaining the heights of projections from a surface, in locating bushings in jigs and work of various kinds. It is preferable to the vernier or slide caliper, now in use, because the different settings can be made more quickly and positively and for the readiness with which the graduations are discerned. It is also more convenient to handle in every respect.

The jaw projects beyond the base, is hardened and accurately ground for parallelism. One end is beveled and ground to an edge for use in scribing lines upon work. It has a 40 pitch, to a turning fit in the thimble *f*, and the adjusting nut *d* to compensate for wear.

On the same end a groove is milled 1-16 inch wide and 3-32 inch deep, that serves as a keyway for the pin *j*, which holds it in position and prevents it from turning. The barrel *b* is made of tool steel with a ¼ inch hole through the entire length. This must fit very nicely on the rod. It is graduated by a series of five annular grooves, 1 inch apart, that are of such form and depth that the clamping fingers at the end of part *h* when sprung in will fit accurately, thereby allowing the setting of the rod by inches to be quickly and positively made. There is also a 1-16 inch half round groove, planed its entire length on one side to fit the key *k*. The lower end is beveled so that the graduations on the rod are readily discerned. At the other end it is nicked down 3-32 inch, and ¼ inch wide to fit the bushing *e*, and this end is hardened and lapped to a true surface. Bushing *e* is made of tool steel, with a sharp

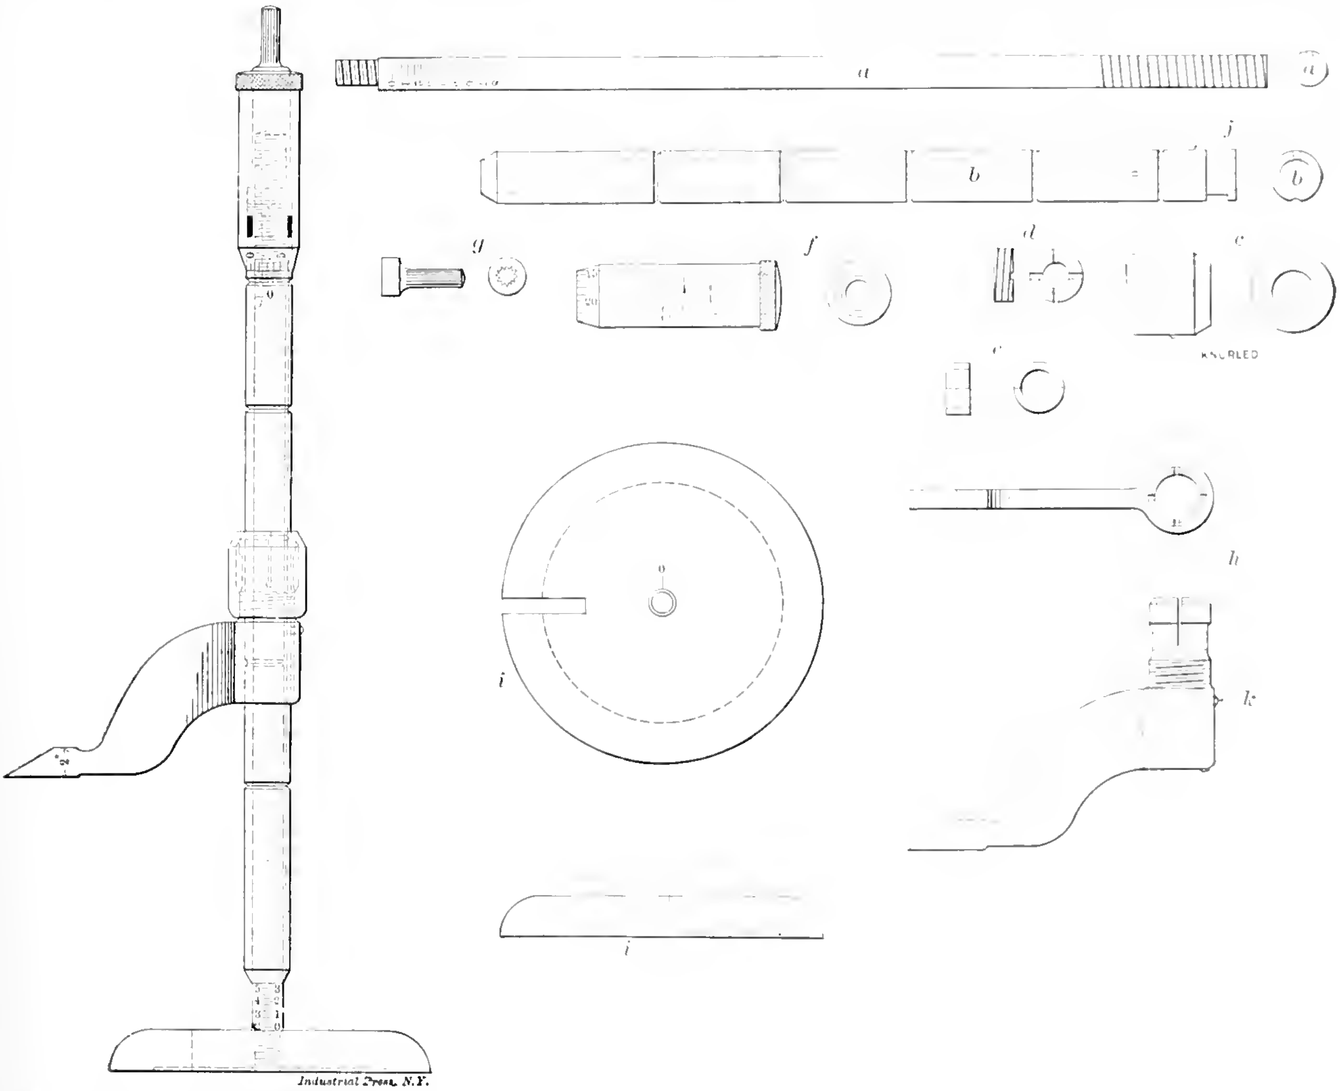

Fig. 1. Assembled View and Details of 5-inch Micrometer Surface Gage. The Spindle and Micrometer parts are used in other Combinations shown in the following Views.

range, by thousandths, from zero to 5 inches, and all fractions of an inch are obtained by means of the micrometer screw. Rod *a* is made of tool steel ¼ inch diameter and 7.5 inches long. At the lower end it is threaded 40 pitch to receive the base *i*. There are 40 divisions graduated on the lower end of the rod, each division being .025 inch wide. On the right are the figures for measurements from the surface to the point of the scriber, and on the left those for measurements from the faceplate to the top of the scriber, which may be used to set a tool to a certain distance, or to measure under a shoulder. (See assembled view.) The other end of the rod is threaded

A. L. MONRAD was born in Christiania, Norway, June 23, 1868. He received a high-school education and took a course in the Christiania College of Technology. His apprenticeship was served with the Winchester Repeating Arms Co., New Haven, Conn., and he has since worked for the Burgess Gun Co., Buffalo, N. Y., Colt's Repeating Fire Arms Co., Hartford, Conn., Lozier Mfg. Co., Toledo, O., and others. He served as foreman for two concerns. His specialties are gun work, designing and model work. Since coming to America in 1885 Mr. Monrad has acquired an experience equaled by few.

groove filed in a little on each side, and has a taper .010 to 1 inch, to fit the mouth of the thimble. After it has been hardened, ground, and lapped all over to a plug fit in the barrel, and with a driving fit on the thimble, break it apart so it can be placed in position when assembling. One end of the thimble is bored to fit the barrel, and at the bottom of this hole is threaded to receive the adjusting nut *d*. It is then placed on an arbor which has been turned in a chuck, and the center hole bored out, threaded to fit the rod, and chamfered out at the end to within 3-16 inch of the threaded part. The outside is shaped like an ordinary thimble with a graduation of 25 divisions. Speeder *g* has a tight fit in the thimble, and is turned down to ⅛ inch diameter, and milled its length by a 60 degree cutter. This gives a good grip and allows the thimble to be turned quickly.

The main body of the instrument, *h*, is made of tool steel. The lower end of the round portion is bored out in the center

so that the scriber will slide freely, but will have a good fit on the barrel. The upper end is formed into a split chuck, spring-tempered, which grips the barrel and holds it in position, while the lower part is threaded to receive the knurled cap *c*. This tightens the split chuck and serves to hold the part firmly in position on the barrel. In the lower end is fitted a round key *k* 1-16 inch diameter with the end bent at a right angle, whose purpose is to prevent the scriber from turning on the barrel. The point of the scriber is hardened and the upper and lower surfaces are parallel 0.2 inch apart. The cap *c* is made of mild steel, casehardened, knurled its entire made of 1-16 inch round Stubbs wire and bent at an angle of 90 degrees to fit the base.

Fig. 3 shows a 5-inch special, or disk micrometer which has proved very handy in measuring snap gages, slots, and thicknesses, and which may also be used as a height gage to ascertain the distance from a shoulder to the base. In measuring slots the outer sides of the disks are used and for thickness the inner sides. This form may also be used for setting tools on a planer or shaper. As shown in the cut, there are two sets of graduations on the rod, which enables the operator to see at a glance the measurement recorded either from the

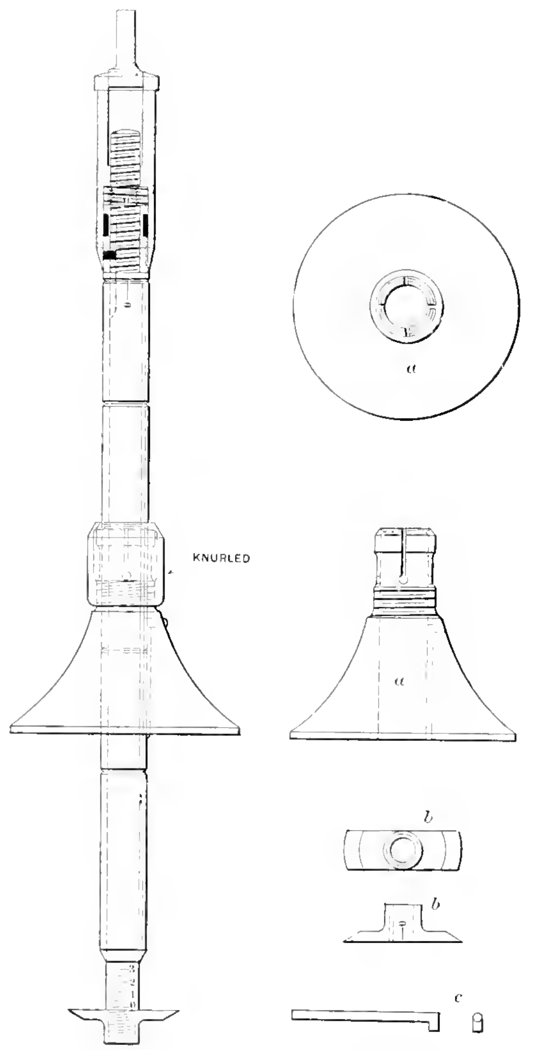

Fig. 2. Micrometer Tool used as a Scratch Gage.

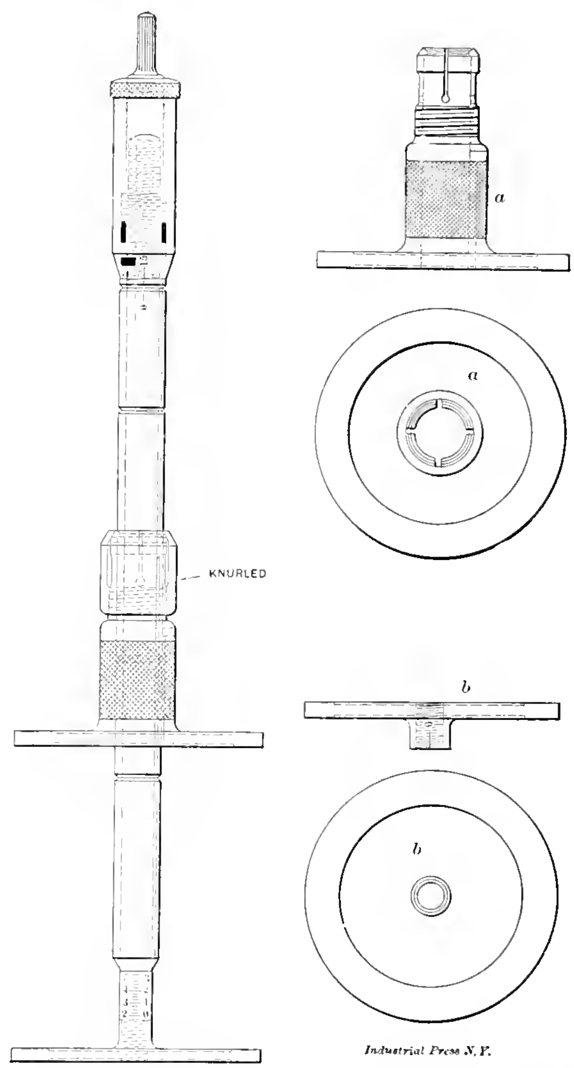

Fig. 3. Micrometer with Disk Attachments in place of the usual Jaws.

length on the outside, and fits the scriber chuck. The base block *i* is made of mild steel casehardened, and lapped at the surface. In the center it is tapped for 40 pitch thread to fit the rod, having a zero line to place it in the right position, and through the forward part of the block is a slot that allows the measuring or scribing jaw to come flush with the bottom of the base.

When ready to assemble the adjustment is very simple. Draw the zero line from the end 5/8 inch down on the barrel. When the tool is set to measure 1 inch correctly, draw the thimble over the split bushing, starting with the zero line at the end and continuing until in position.

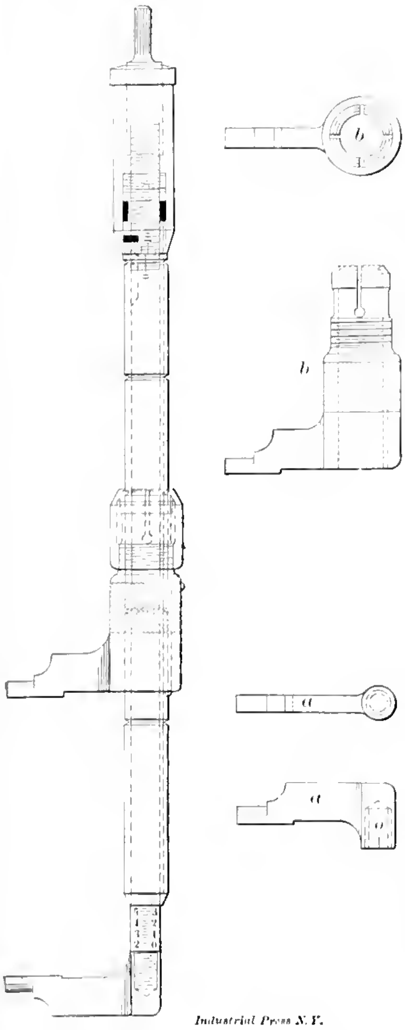
Fig. 2 shows the same tool used as a scratch gage, which may be done by changing two pieces, and in this form will be found very convenient on a job that cannot be handled with a surface gage. This simple device has saved a lot of time, when accurate scratch line is wanted, where other means had to be applied. In addition it can be used as a depth gage, by exchanging the scriber *b* for the shoe *a*, shown in Fig. 8. The scriber *b* is made of tool steel, hardened and ground on each side to an angle of 60 degrees, and may always be set in the right position by drawing it to the zero line. The base *a* is made of tool steel and the top end forms a spring-tempered split chuck, using the cap *c*, shown in Fig. 1. The key *c* is inside or outside of the measuring disks. Each of the disks is 0.10 inch thick, so that the range of the micrometers is .400 inch for inside when .600 inch for the outside.

The disk *a* is made 2 inches in diameter and disk part is hardened, ground, and lapped. Great care must be exercised in lapping so as to make it perfectly true and parallel. The upper end is spring-tempered and fitted to the cap described for the first form. Disk *b* is hardened, ground and lapped, fitted to the rod in the usual manner, and screwed to the zero line.

By use of the parts shown in Fig. 4 we have a 5-inch micrometer caliper square which is preferable to the vernier caliper. It has the great advantage over the vernier, that the reading may be readily discerned without straining the eyes, and the use of a magnifying glass is avoided. Its manipulation is as easy as that of a regular micrometer.

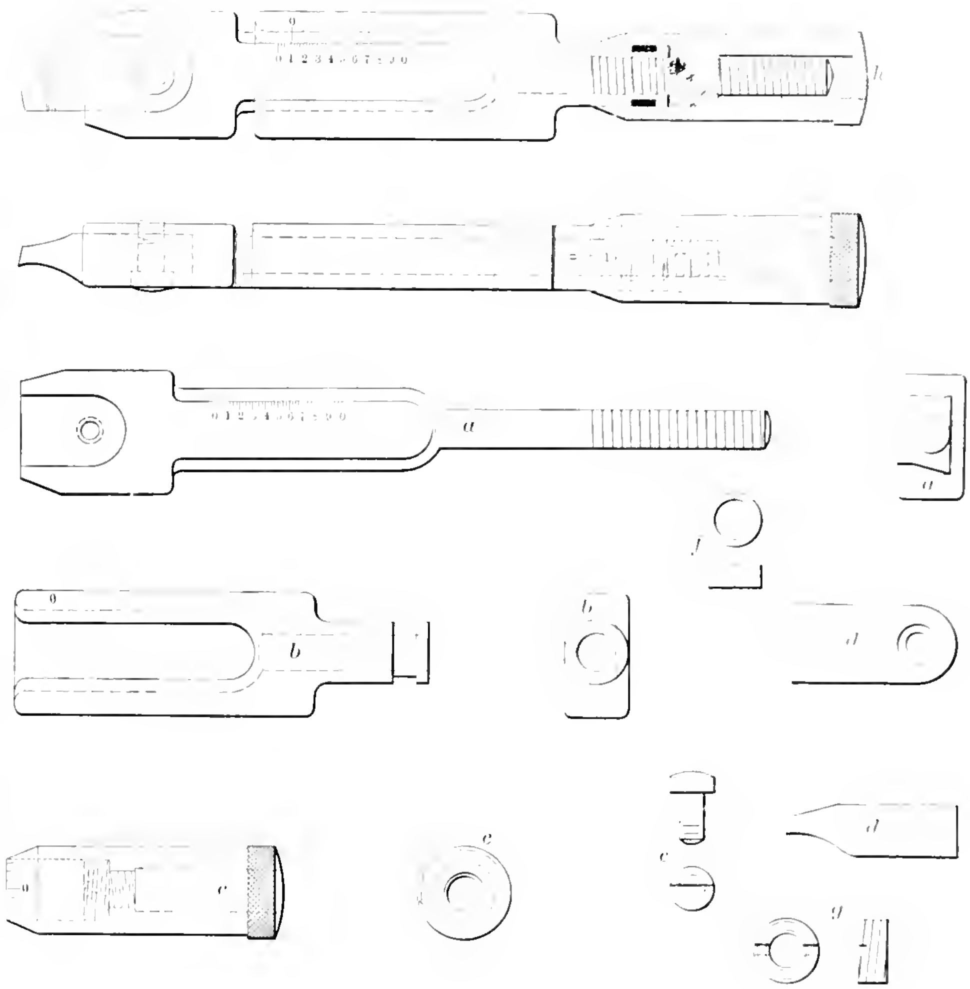
The jaw *a* is fitted to the rod in the usual way to zero line, and the end is hardened and lapped to a finish surface. The jaw *b* is made in a similar manner, and knurled in the middle for a grip, the top end being fitted to the knurled cap. This forms a very neat and light tool; but it must be carefully and accurately made to be of value.

Fig. 8 shows a 5-inch micrometer lathe stop, which is one of the most accurate and universal tools in use. How difficult



Industrial Press N. Y.

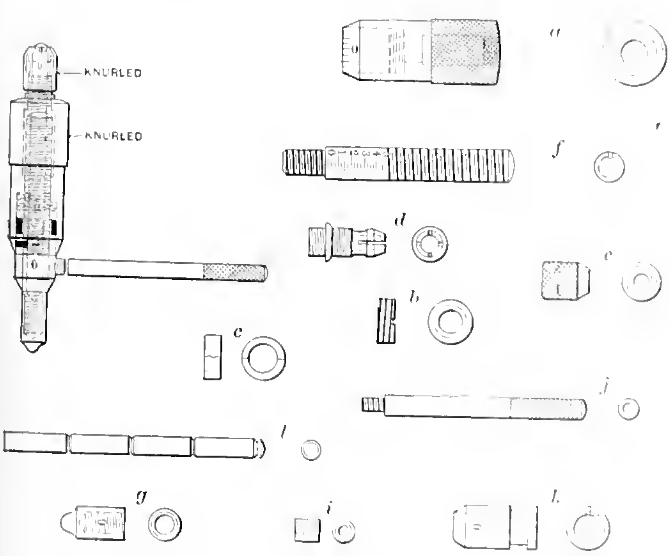
Fig. 4 Five-inch Micrometer Square.



Industrial Press N. Y.

Fig. 5. Micrometer Lathe Tool.

it often is to gage correctly a certain piece of work in the lathe or planer, especially when a distance of several inches is required, and frequently it becomes necessary to make a template or a length gage in order to get any halfway decent result. This tool "fills the bill" and does away with the "cut and try business." It can be used on either the right or left side and the holder is of so rigid a form that it does not show



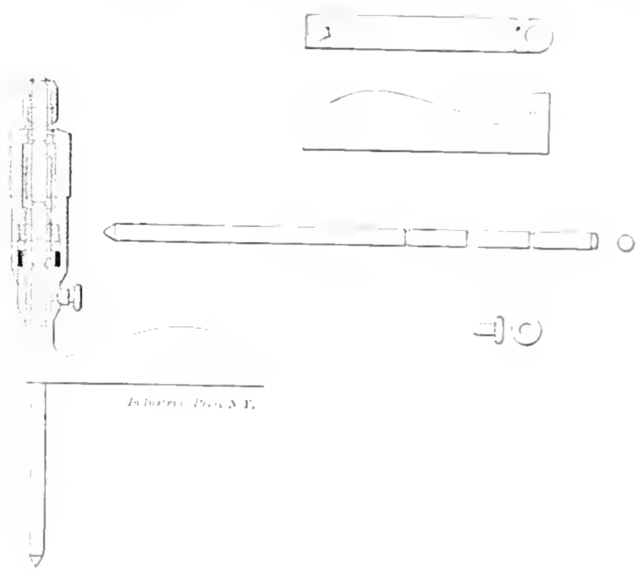
Industrial Press N. Y.

Fig. 6. Small Inside Micrometer.

the tendency to spring, that is a serious fault with some. It is made to fit any machine of modern make, being clamped either on the rib or the flat surface.

The C-shaped clamp *b* is beveled a little on the inside, for convenience in adjusting in place on the machine and on the side is formed the usual spring chuck which fits the cap before described. On the end of the rod is fitted the shoe *a*, hardened and lapped, and drawn to the zero line by a spanner wrench fitting in the hole *c*. Thus we have five very handy tools almost combined in one, only slight changes being required. They save a lot of labor and do not take up so much room in the tool chest, where there is usually insufficient space.

Fig. 5 shows a micrometer finishing tool for lathe or planer. Most of the modern machines are supplied with a micrometer



Industrial Press N. Y.

Fig. 7. Micrometer Depth Gage.

screw stop, but the old ones are not, and on such this tool will come handy. It is designed on the same principle as the others, and the tool points are interchangeable. By making them fit snugly on the sides, the screw *c* will hold them firmly in position.

Part *a* is the main body of the tool. On the end a 40 pitch thread is cut to fit the thimble, and the sides are dovetailed to fit the holder *b*. Near the middle of one side one inch of

space is graduated, the lines being .025 inch apart. On the other end is a recess with a tapped hole to secure the tool d. The holder b a sliding fit in a, and on one end is the zero mark, while the other is nicked down to receive the split bushing f. The thimble is made in the usual manner as also the adjusting nut g.

Fig. 6 shows a neat little inside micrometer, designed for internal and lineal measurements. It is useful for measuring cylinders, and rings, etc., as well as for setting calipers, comparing gages and measuring parallel surfaces. The micrometer screw in the head has ½ inch movement, and the device is so designed as to be in touch with the other tools described above. The thimble a is constructed in the usual way, except that the top is fitted to receive the spring-chuck d. The adjusting nut b is made in the usual manner to compensate for wear, and the split bushing c as before described. On the thimble is screwed the tempered split chuck d, with the

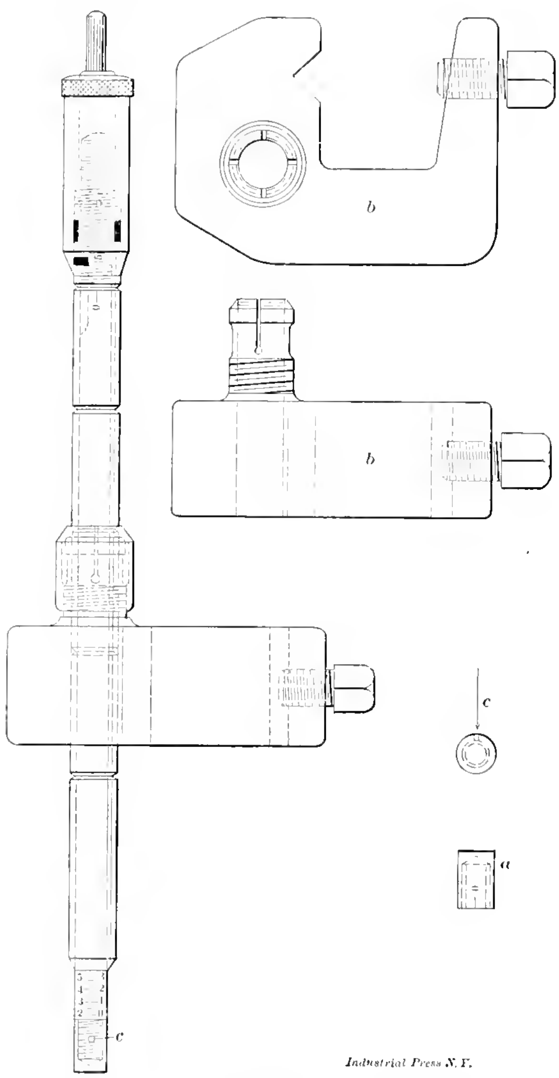


Fig. 8. Micrometer adapted for use as a Lathe Stop.

knurled cap e to clamp the rod in position. On the lower end of the screw f is fitted a shoe g which is shaped at the point like the rod. On the barrel k is soldered a bushing i which is tapped inside to receive the handle, thereby enabling one to take measurements in holes and other places where the micrometer could not otherwise be used. This handle may be exchanged for a thumbscrew, which may be used to lock the instrument after a measurement has been taken. Rods like that shown at l may be made of varying lengths.

Fig. 7 shows an instrument designed for measuring the depth of holes, grooves, or recessed parts, as well as gaging under a shoulder, or measuring the height of a small projection on a plane surface. The gage screw has a movement of ½ inch, and is encased and thus protected from dirt or injury. The measuring rod is graduated by a series of annular grooves ½ inch apart. The parts are the same as before and it is only necessary to unscrew the shoe, and replace with the base. Fig. 7, made in such a shape that it can be used in close shoulder work. This tool can be used as disk-gage, surface-gage, height-gage, etc., by placing the different parts in the split chuck and the machinist's needs may suggest various other uses to which these devices by slight changes may be made to apply.

* * *

THE DAVIS SELF-LOCKING CAM.

In the usual construction of mining stamps, used for crushing ore, the stamps are operated by double cams mounted upon a longitudinal horizontal shaft. These cams are made to give a free fall to the stamps, and are arranged on the shaft so that some are always lifting stamps while other stamps are falling, the reason, of course, being to equalize the driving power. Because of the shock and vibration it has been found very difficult, if not impossible, to keep these cams tight upon the driving shaft with any ordinary system of keying. Moreover, it is highly desirable that the cam can be easily removed as they wear out comparatively quickly and so have to be periodically renewed. For these reasons self-locking cams have found favor, the Blanton type being well-known. This is somewhat expensive in construction as special machinery is required to machine the locking surfaces which consist of a series of arcs arranged in sawtooth fashion. In the Davis self-locking cam, however, the construction is simpler.

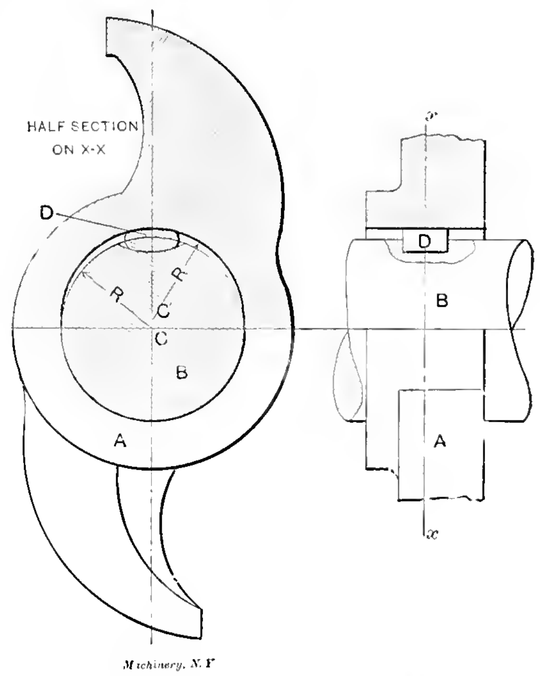

Fig. 1 Fig. 2.
Cam for Stamp Mills.

Referring to Figs. 1 and 2 which show side and end views with sections in each case, A is the cam, which, it will be observed, is double, that is, it lifts the stamp twice in a revolution; B is the shaft; and D is the key. After the cam has been bored to the radius R, it is set over and with the same radius an eccentric seat is bored in the middle of the bore and having a width about one-half that of the total length of the bore. This eccentric bore is shown in Fig. 1 by the radius R' drawn from the eccentric center C' and its width is indicated by the length of key in Fig. 2. A keyway is then cut through the bore somewhat wider than the key, and it is cut so that its bottom conforms to the arc of the eccentric bore. The key-seat in the shaft is milled with a cutter of the same radius as the shaft, and the key is made with its two working sides shaped to the common radius R. In assembling, the key is seated in the shaft and the cam is shoved on until the eccentric bore is directly over it; then a backward turn locks the cam on the shaft so that it can neither turn on the shaft nor slip endways. If the degree of eccentricity of the bore R' is correctly chosen the cam can be easily loosened by a blow on the point in the reverse direction.

* * *

An important ordinance has been passed by the Board of Aldermen of New York City, and is now in the Mayor's hands, requiring the use of fireproof wood in all buildings over 75 ft. in height and in all public buildings over 35 ft. in height.

LETTERS UPON PRACTICAL SUBJECTS.

A VACATION AND WHAT CAME OF IT.

Editor MACHINERY:

A friend of mine was telling me a while ago how he spent his vacation, and it was so interesting that I think that it will stand relating.

He was a toolmaker and he had worked steadily for over a year, and at the same time was taking a correspondence course in mechanical drawing. The hot weather was coming on and one night he came home and said to his roommate: "Bill, let's take a vacation." "Done," said Bill. "Where will we go?" "Denver," said Ed. "All right," replied Bill. And the next morning they "jacked up" their jobs, bought a first-class ticket for Denver and started.

They enjoyed the trip and arrived in Denver and took a room at a good hotel and the next morning started out to do the town. Ed. got a job at once in a small shop on the outskirts of the city engaged in tool and experimental work. His first job was making a die for a shoe heel. He had worked on the job about two or three days and was getting along first rate except he was handicapped for the want of tools, especially files. Ed. was working away using the stub end of a file next to the handle, which was the only place which had any cut left, when the foreman came along and said: "I've had all sorts of men working for me, but I believe that of the whole lot, you're the awkwardest hand with a file that I ever saw." They had a few words over it and the outcome of it was that Ed. got fired.

He went home to the hotel and was mad clean through. He, an A1 toolmaker and one of the best vise hands in St. Louis, had got fired out of that little one-horse shop because he did not know how to handle a file! He was still "chewing the rag" over it when Bill came home and he told him the whole story, and said: "That's the last day's work that I'll do in a machine shop for one year, for if I ain't got it in me to do something higher. I'll get along without."

The next morning he started out and made a tour of the draughting rooms and civil engineers' offices, and finally struck a place with a mining engineer at draughting, working under instructions and with the understanding that it was to be a short job only. He stayed there two months and finished the job; when he left he was given an extra week's salary in consideration of the good services rendered.

The next day after leaving the mining engineer's office he bought a camping outfit, including a woolen and a rubber blanket, packed them on his back and started up the line of a new railroad in course of construction, the name of which I am sorry to say I have forgotten. He got a lift of thirty miles on a gravel train and fifteen miles more on "shank's mare" brought him up with the tracklayers. He found that they were full handed and there was no show for a job there; but that the engineer of the surveying party, some thirty miles further up had sent back word he needed some axmen. That night he stayed in camp and was used finely, had a good supper and a clean bunk and the next morning shouldered his sack and started on.

Fifteen miles was the best that he could do in that day and that night he slept in the open, with a log for a pillow and the moonshine for a blanket. Getting an early start the next morning he came up with the surveying party about noon. He found the chief engineer and applied for a job. The chief looked him over, smiled and said: "You're a tenderfoot all right, but if you think you can learn to swing an ax I can give you a chance to try; the pay will be $30 a month."

Now, Ed. had been brought up on a farm and if there was any tool outside of a machine shop that he could handle well, it was an ax. After dinner he was given a good ax and started in. There was a good-natured grin on the faces of the crowd as the tenderfoot came out, and the first good-sized tree they came to, the boss, a big French Canadian, said: "You take him 'one side,' and 'take him one side' he did, and when the tree was down the boss said: "You one good man; I tink you have seen ax before."

That night the engineer came around and said: "We need an assistant to the transit man, and in the morning you take hold with him; the pay will be $45 a month." The next morning he started in with the transit man running the cross levels. He stayed at this two months, learning, as he said, more about angles than he ever knew before. The weather, getting too cold for comfort, he "jacked up" the job and left the engineer with mutual regret, and promise of $60 a month if he saw fit to come back in the spring.

He came back to Denver, put in a week of sight seeing and then back to St. Louis, where he struck a job as draughtsman in a mechanical engineer's office, and when I saw him had been there over a year, coming in at 8 o'clock in the morning and going out at 5, drawing a weekly salary instead of "pay" and wearing a boiled shirt with case hardened ends.

"And now," said he, "I've proved to myself that I can make a living outside of the shop, and I'm going back into it again as soon as I see a good chance. I may stand at the desk instead of the bench, but I'm not afraid but that I can fill the bill in either place."

Should this tale, as told by him stimulate any of the boys to take another step up the ladder, this will not have been written in vain, and they will have the best wishes of

A. P. PRESS.

THE PRACTICAL PERSPECTIVE.

Editor MACHINERY:

It is pretty safe to say that anyone who has ever made a drawing has wished at times to be able to show a piece in perspective; perhaps only a detail or possibly a whole machine or building, but the artistic or "true perspective" takes too much time and patience for the average draftsman. Men in the shop often express the wish, in language of varying intensity, that the drawing was made "so you could see what the thing really looks like." This is probably why many men like to work to "samples" rather than drawings.

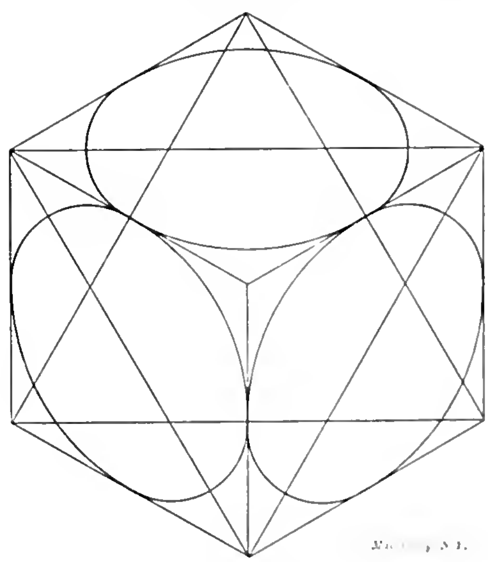

Fig. 1. Isometric Cube.

There seems to be only one practical way of using perspective, and that is what is called isometric projection. It was discovered or invented years ago, but has been about as hard to master as the true perspective and has not been made popular. In isometric projection lines which are normally horizontal are inclined 30 degrees from the horizontal in either direction, while vertical lines remain vertical. This makes a cube appear as a hexagon (see Fig. 1) and, as will be seen, makes the three visible sides "diamond" shape. These diamonds are the foundations for all circular work and as it is the circles which bother anyone in perspective drawing, a little attention to these will help make the matter clear.

All circles which lie in a horizontal plane and on which we look down when they are thrown into perspective, become ellipses in the upper diamond with the long axis horizontal. All circles or ends of shafts or tubes which run off to the left

have their ellipses in the right-hand diamond with the long axis, as shown. And all ends of round pieces which run off the right become ellipses in the left-hand diamonds. This holds true on all occasions and will help you out when you run up against something that seems hard to show or doesn't look quite right.

The wrench shown in Fig. 2 is an example of how often this works into sketches. With the handle going off to one side there is a great tendency to twist the ellipse around also—

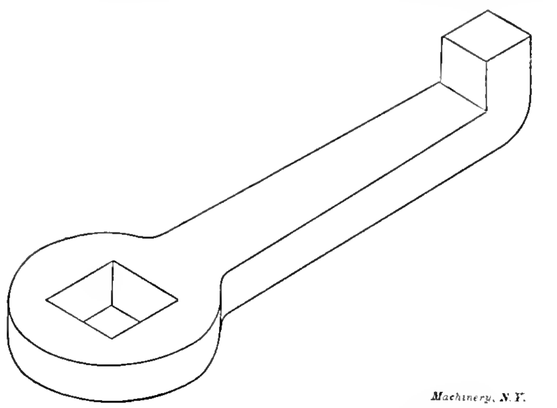

Fig. 2. Wrench in Isometric Projection.

seems as though it ought to be, but it is a top view and the ellipse remains as shown at the top of the square. To make this still more clear the spoked wheel in Fig. 3 is shown. Here the four spokes go in different directions but the central ellipse is horizontal just the same. This figure is made on a specially ruled paper so as to make it plain about the diamonds and to show how easy it is to draw with such guide lines. Where there are few curves the whole thing can be quickly done in freehand.

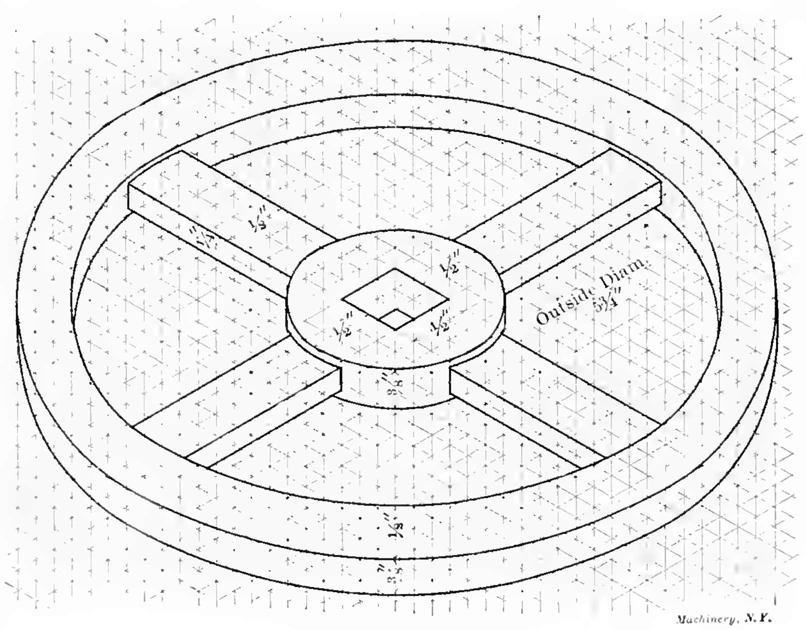

Fig. 3. Spoked Wheel Drawn on Isometric Paper.

Fig. 4 shows a rod end and gives an example of circles in the three positions. The broken end is in one position, the hole in the brass in a second, and the oil cup in a third. It might be thought that, as the rod is thrown up at an angle the oil cup circle should also be in that position, but such is not the case. A few trials will convince that this is right.

There is no question as to the value of this method for "assembly" drawings, even if details are made in the old way, but the details can be worked out in the same manner and are very easily understood. FRED H. COLVIN.

HIGH-SPEED STEEL IN THE MACHINE SHOP OF TO-DAY.

Editor MACHINERY:

This world is one of hustle and bustle, especially among us Americans. We are always looking around, trying to find a short cut to wealth. Now, how many of the manufacturing establishments of this country are really saving any money, in the way many of them handle the different brands of "high-speed steel"?

High speed steel has been before the manufacturing public for some time, but not until quite recently did it come into such general use and attract so much attention. It is, indeed, a great way to save money if handled by the people as it should be. It has great strength and can stand what no ordinary steel can stand. You can not pick up a mechanical journal to-day and not read of some of the marvels that have been accomplished with the "high speed steel." There is a great saving in time, but right here many close their eyes. Do they not save time at the expense of something more valuable by far? Right here starts the mistake.

A foreman in a machine shop will pick up a mechanical journal and read (if he reads one at all) of the great time saved by Blank Mfg. Co., of Somewhere. He will read it with amazement and perchance say to himself, "Well, now, is that possible? I will have to 'speed up' the men a little to keep in line with the rest of the world." He will come into the shop and start in on Tom. "Tom, throw that belt down on the high speed and put on a little heavier feed." So he will go around from one to the other. Then he struts around the shop with a self-satisfied grin on his face and tries to make the men feel that he is of some importance about the place. He thinks he has accomplished something of note. But has he? Did he, maybe, speed up his men more than their machines were capable of doing, and spoil the accuracy of the machine? Most of these tests are made on "high speed lathes," lathes that are especially constructed to stand the strain to which they are subjected. Lathes with long bearings, large driving belt, and heavy headstock spindle, and many other minor points that make them stronger than the average lathe. But you go into many shops and they are trying to make as good time on a lathe built fifteen years ago as they are on a modern lathe especially constructed for this work. They often succeed in making as good time on rough work, but when it comes down to accuracy of their job, then what do they have? You find that they have

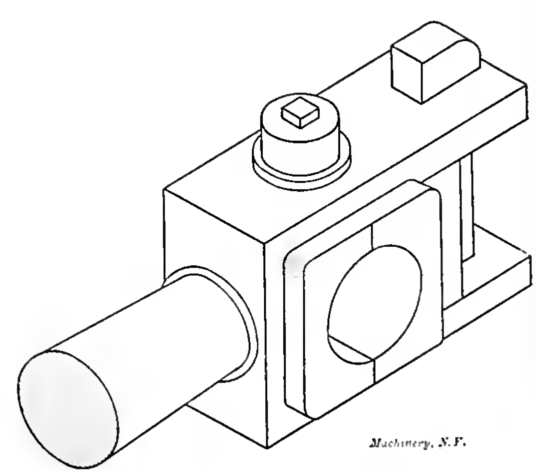

Fig. 4. Connecting-rod End.

sprung the lathe all out of shape; strained the leadscrew, and they have lost motion "to burn" all over the machine. You can not expect to compete in "hogging," with an old lathe as your "hog." This is not only the case with lathes, alone, but with all lines of machinery. The machinery in use to-day must be redesigned to meet the demands of the times.

If you broach this subject to many foremen and ask them how about the wear and tear on the machinery, they simply say that they do the work in so much better time that it makes up for this loss. But it does not, for the simple reason that they are straining every machine in the shop, and the work they do on the machines is not accurate. When it comes to assembling or when work goes to the vise hands, then they put in the time trying to make a job out of some fellow's "bum" work. But you can not do this and save time, so you see in this way you have a poorer lot of work turned out and a shop full of ruined machinery. You go into any shop in this

country that follows such methods and see if their force of vise hands has not increased faster than their force of machine hands, for the simple reason that they need more men to turn out the work in the same time, because the machine work is not properly done.

What is the natural consequences of such lax methods? Why in a short time your machinery does not represent the same standard that it once did, and your trade begins to fall off as a result.

Now to overcome this difficulty you must place a man in your shops at the head of affairs, that is practical, and can improve the methods of doing work, but not at the expense of the machine's accuracy. You want a man that can design special tools, etc., and in many little ways facilitate your progress. However, if you are able, financially, buy the best machinery and then try to keep abreast with the times, by employing skilled labor and employing the cheap labor for helpers. I do not think much of the management of a man that has to employ cheap labor to make a decent showing or profit for the business. I would not employ a foreman that is always trying to grind his men down to the very lowest wages.

The time is now at hand when a man must know a little about his business in a practical and theoretical way. If he does not, a man who does know steps in and takes his place, and he is pushed out in the cold. J. J. JENKINS

LATHE ATTACHMENT FOR TURNING TROLLEY WHEELS.

Editor MACHINERY:

The service required of trolley wheels, demands that they should be made of as hard a composition as can be machined at a reasonable rate of cost for the work. In the shop where this device for turning trolley wheels is used, this work was formerly done by the following method:

The hub in the casting had a cored hole which was first drilled out, and then reamed to size, the casting being held in a three-jaw chuck, and the work done in an engine lathe. One end of the hub was faced off, and the other end faced by a separate operation. After the hub was finished, the casting was then placed on an arbor, that fitted into the hole in the spindle of the lathe, and was held in position by a nut on the end of the arbor. A pointed lathe tool was then used to rough off the metal in the groove, the tool being made to follow as closely as possible the contour of the groove. After this operation was finished, a tool having the shape of the groove was used for finishing, it being held in the tool-post, the same as an ordinary lathe tool. The width of a trolley wheel is $1\frac{3}{8}$ inches, and the depth of the groove $\frac{3}{8}$ inch; from these dimensions it will be seen that the last tool had to take a cut that should have had a very substantial machine to do the work. Such was not the case, however, and the whole arrangement was very unsatisfactory. The margin of profit on this work is very small, and it will not pay to put in expensive machinery to do it, so the device described here was designed to do the work.

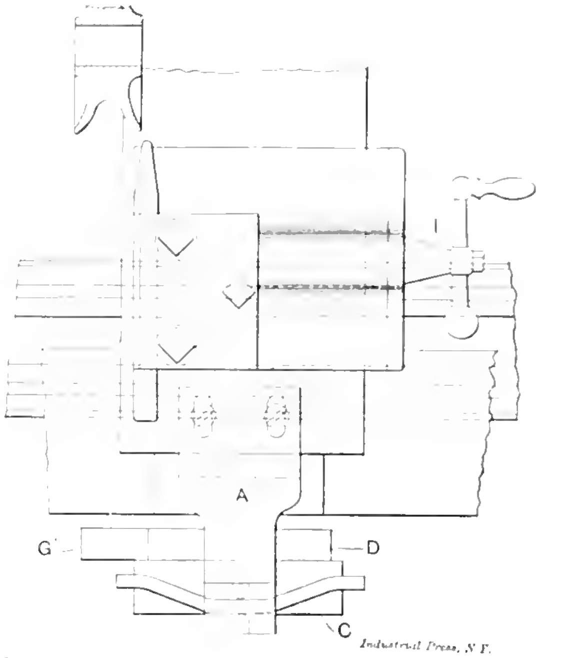

Fig. 2. Plan View of Attachment showing, also, the Tool and Work

The work of finishing the hub was transferred to a turret lathe, the casting being held in a two-jaw chuck, the jaws gripping it in the groove. The hole was bored, then reamed, and a tool having two cutters spaced the length of the hub, was then used for facing the hub; one cutter faced the side nearest the chuck and the other cutter the outside face. Thus the hub was finished with one chucking.

To turn the grooved part, the engine lathe before mentioned, was arranged to do the work with a round point tool, driven by a cam, so shaped as to give the curve desired. Fig. 1 shows a front view of the device with a portion of the apron of the lathe in sight. Fig. 3 shows a section of the device on the line x x, and also a portion of the lathe and some of the hidden parts of the feed mechanism. Fig. 2 is a top view, showing a portion of a trolley wheel in position and the tool

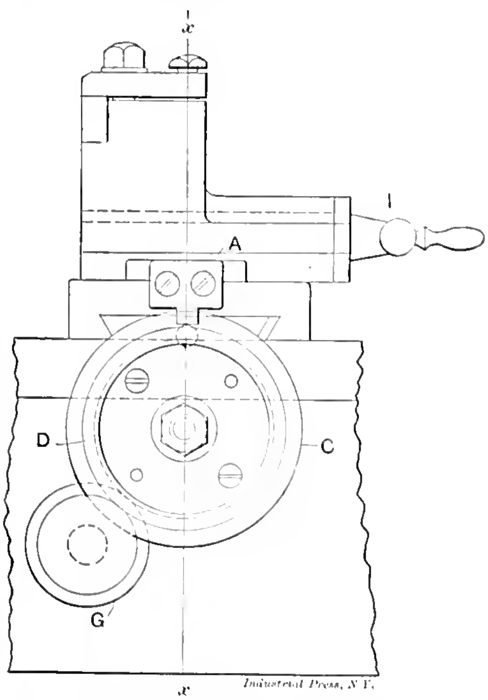

Fig. 1. Front View showing Circular Cam

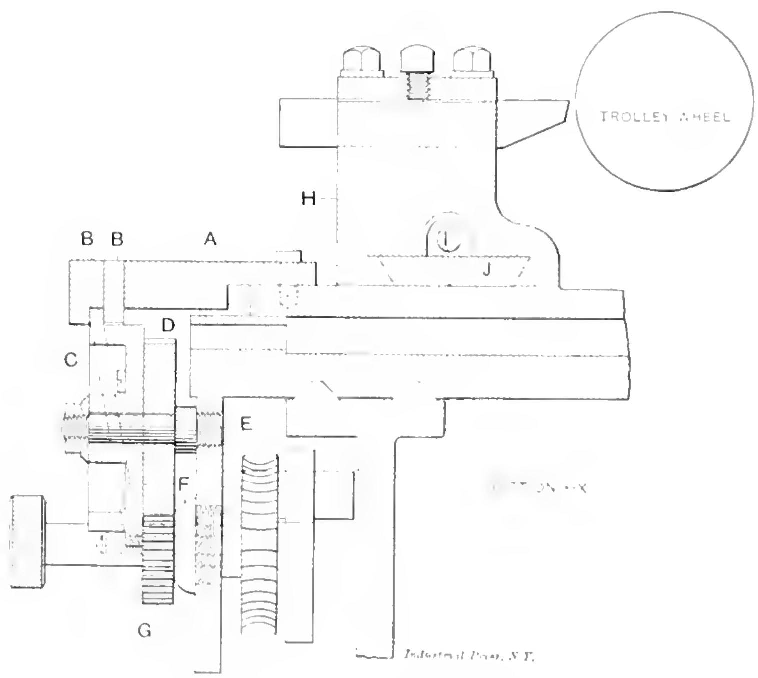

Fig. 3. Cross-section of Lathe Carriage and Cam Attachment

ready to take the cut. The cam *C* was fastened to a gear, and both revolved on a stud *E*, Fig. 3, which was screwed into the apron of the lathe. The sleeve *F* that supported the hub of the worm gear in the apron, was faced off to allow room for a gear *G*, the pitch diameter of which is shown. This gear was keyed to the hub of the worm gear, and, of course, revolved with it.

The cross-feed screw was removed and an extension, *A*, Figs. 1, 2 and 3, was fastened to the tool carriage in its place. Two hardened steel blocks, *B B*, Fig. 3, having carrying pins, were screwed and doweled to the extension. The pins of these blocks straddle the track of the cam. The cutting tool, of high-speed steel, was supported in a special holder *H*, whose

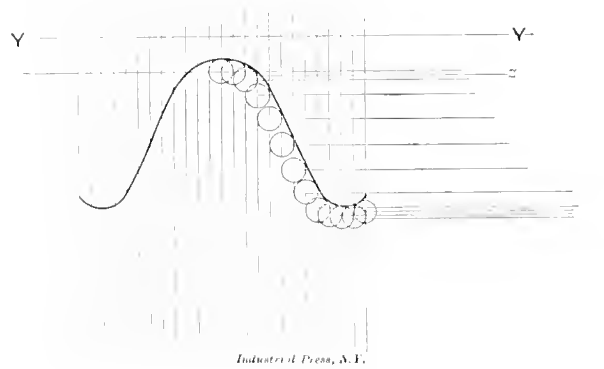

Fig. 4. Layout of Cam.

height was such as to bring the top edge of the tool to a point even with the lathe center. The holder *H* is adjustable laterally by the screw *I*, working in a nut which is fixed to the dovetail block *J*, Fig. 3. Adjustment for depth of cut is obtained by the slotted holes shown in the extension *A*, Fig. 2. This adjustment is but little used, the tools being ground and set to gage.

The construction of the lathe was such as to permit the adoption of this device, it having a feed reversing arrangement in the apron that, at the middle point, threw the gears out of mesh, and allowed the carriage to be run back freely after the cut was made. It was found that one turn of the worm gear gave an inch of movement of the tool carriage and as it was desired to have $1\frac{1}{2}$ inches movement to the carriage to one turn of the cam, the gears were arranged in the ratio of 1 to $1\frac{1}{2}$. The outside diameter of the cam track was made so as to give a circumference of 16 inches. This was done partly for the purpose of laying off the cam readily, and it may be of interest to some of your subscribers to read how this was done to give the curve desired.

This curve was taken from a sample wheel, to which a template was closely fitted and the curve was then plotted as in Fig. 4. Twenty-five vertical lines, giving 24 spaces of 1-16 inch each, were laid off on this curve, the middle line being in the center of the curve. The shape of the tool point was to be a semi-circle of 1-16 inch radius, and in order to obtain the curve the cam should make, circles $\frac{1}{8}$ inch diameter were drawn, the centers of which were in the vertical lines, and the sides just touching the curve. From the centers of the circles, horizontal lines were drawn, and a line *Y Y*, representing the back edge of the cam was drawn. The pattern for the cam was spaced on the face of the rim into 24 equal parts, giving a distance of $\frac{3}{4}$ inch for each space, or a ratio of distance of 12 to 1 of the cam and the curve. The width of the cam track was to be $\frac{3}{8}$ of an inch, so beginning at any one of these spaces and at the edge of the pattern, a circle $\frac{3}{8}$ inch in diameter was drawn. On both sides of this first circle and on the lines representing the spaces, two other circles of the same diameter were drawn, the distance from the edge of the pattern to the center of the circle being found by measuring the distance from the line *y-y* to the nearest line, *z*, drawn from the center of the circle representing the point of the tool in the diagram. This distance is quite small, and had to be measured carefully; in fact the whole diagram had to be laid out with great care. All the other center distances were found in the same manner as the last, and it only remained after this was done to draw lines from the edge of one circle, to the edge of the next circle, and so on around the pattern to complete the laying out of the track.

The whole device worked better than expected, the only weakness being the carrying pins *B B*, which wear faster than is desirable. The curve generated is so accurate that upon cutting a wheel into two parts the curved surfaces exactly matched. The strain on the lathe is reduced to a minimum and the work is rapidly done.

A simple device for truing the edge of the wheel was afterward added. This mechanism was supported by a bracket, fastened to the lathe head, and consisted of a tool carriage worked by a lever and carrying two tools, the whole device being on the back side of the lathe and out of the way.

Brooklyn, N. Y.

PROPOSED CHANGE GEAR DEVICE.

Editor Machinery:

As change gear devices seem to be the fashion about this time I offer the one shown in the cut as being a simple and effective method of getting a variety of positive speeds for tool feeds, screw cutting or machine drives. The drawing is almost self-explanatory. Gear *A* is the driving gear within which slides shaft *B*. Shaft *B* transmits its motion to gear *C* through the shaft containing two universal joints, *D* and *E*. Gear *C* is held in the forked rocker, *F*, sliding on a stationary rod, *G*. The rocker is held in its various positions by a spring catch acting in holes in the casing of the mechanism. Gear *C* may be brought into mesh successively with any one of the nest of gears on shaft *M* and so drives the shaft at corresponding speeds. For heavy service it might be better to have the diagonal shaft *H* made to telescope instead of having shaft *B* slide in the driving gear. *C′* and *H′* represent the position of *C* and *H* when driving the smallest gear on shaft *M*.

Simple Device for Securing Changes in Tool Feeds.

LABOR-SAVING SCHEME FOR MAKING DRAWINGS.

Editor MACHINERY:

There is always more or less interest taken in a new labor-saving device, and no one is generally able to judge the importance of such improvements better than the designer himself, but seldom does the designer think of improving his own situation by devising a quick method of making drawings.

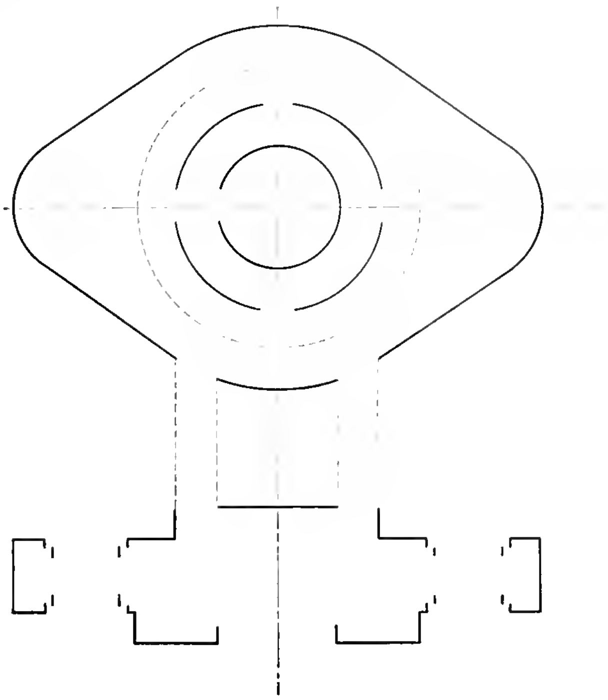

Fig. 1. Drawing Outlined by aid of a Templet.

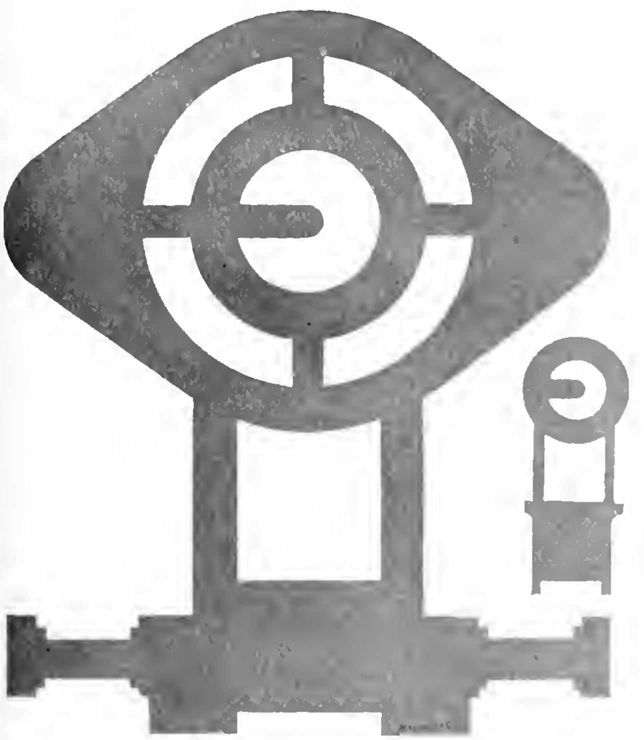

Fig 3. Templets used for making a large number of Drawings for Jigs.

A short time ago I developed a novel idea for making drawings of jigs for drilling glands and stuffing-boxes. The company I was working for had followed the practice of coring the stud holes in the glands, and after they were machined these glands were used as jigs for drilling the stuffing-box stud holes. The cored holes were not symmetrical, and could not be duplicated, so I was detailed to devise a cheap method of drilling these glands as they were to be cast blank henceforth. This style of gland jig may not be new, but I think the method of making the drawings has not been published.

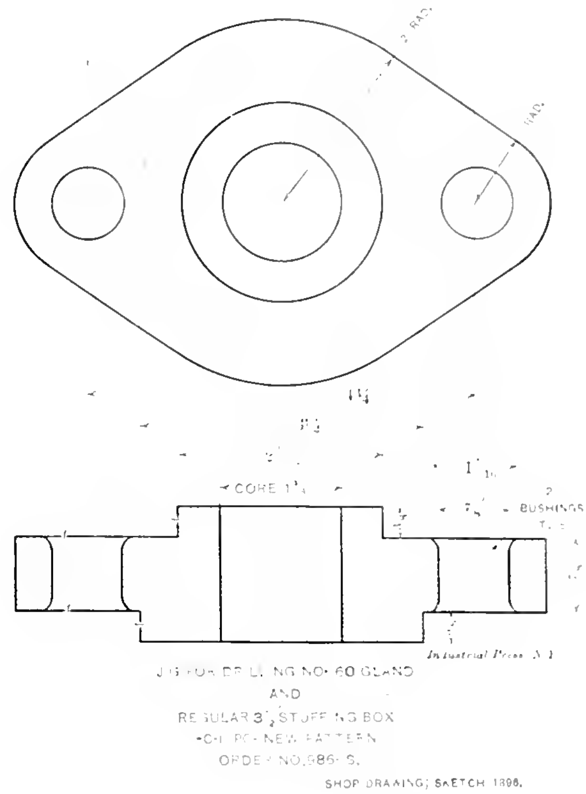

Fig. 2. Completed Drawing of Jig for Drilling Glands and Stuffing Boxes.

Fig. 2 shows the style of jig drawing with two counterbores, one for the gland on one side, and on the opposite side a counterbore for the stuffing box. In making this jig drawing I used the templet shown at Fig. 3. This was first drawn on cardboard and cut out as shown so that by tacking on a paper the outline could be made with a pencil as shown at Fig. 1, which is easily filled in to make it look like Fig. 2. The bushings in the jig are for drilling the gland. At the right in Fig. 3 is a templet for marking out a loose bushing shown in Fig. 4, first as marked out and second as finished. This bushing is used to put in jig for drilling the stud holes in stuffing-box head.

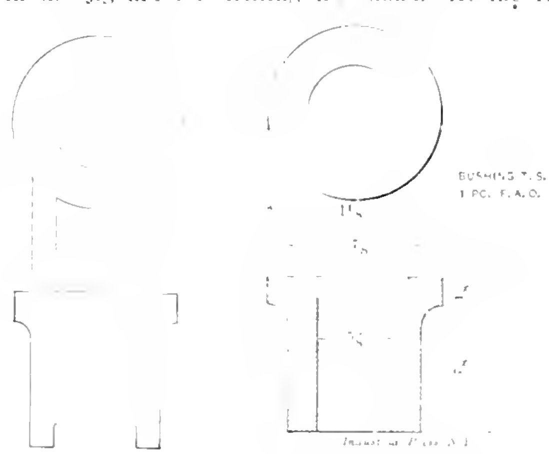

Fig. 4. Showing Drawing of Jig Bushings.

I found that by using carbon paper I could make four drawings at the same time, by placing four sheets of paper under the template with carbon paper in between each sheet. The pressure of the pencil would make an impression strong enough for my purpose. The figures of course I would leave out to be filled in according to the size desired of this style of gland. Some glands were round, some square, with from two

C. W. PUTNAM was born in Orange, Mass., June 8, 1862. He served his apprenticeship with the New Home Sewing Machine Co., Orange, Mass., and is now with the Deane Steam Pump Co., Holyoke, Mass., where he is department foreman and designer of jigs and tools. His experience has been mostly in sewing machine manufacture and the building of pumps, both of which he considers as his specialties. Mr. Putnam has contributed a number of articles to the technical press on laying out work.

to four holes to be drilled. There being nearly 500 regular glands of different sizes to make jigs for, this method of making the drawings proved a great success. The drawings were not inked in or made to scale but the figures told the story.

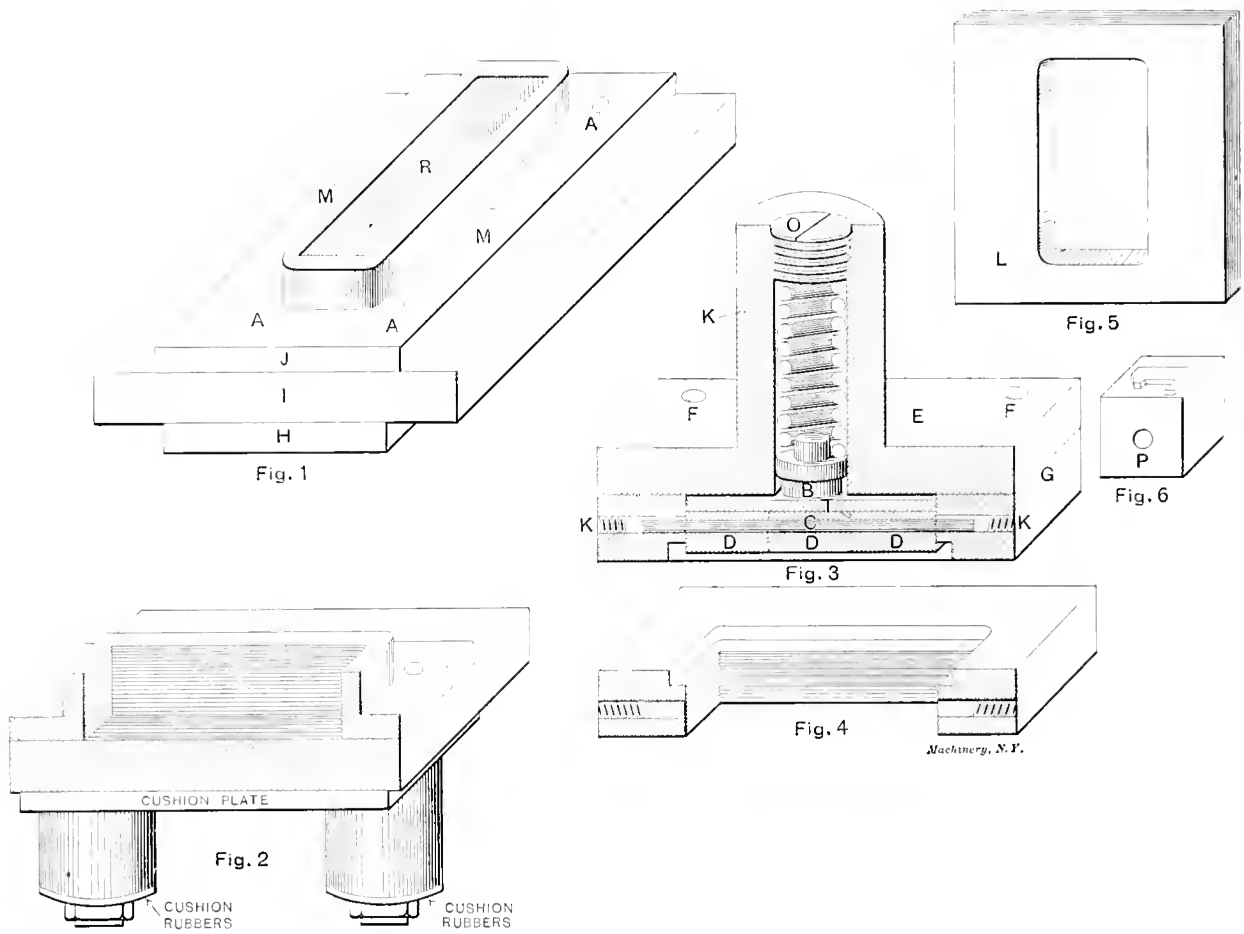
Holyoke, Mass. C. W. PUTNAM.

PUNCH AND DIE FOR MAKING NUMBER PLATES.

Editor MACHINERY:

The punch and die shown in Figs. 1 to 6 are for making number plates which are used to number stoves and to designate the different styles of a steel range made in our shop. I think it is quite a novel way of making number plates, and after I have described the die and its workings, I believe the readers of MACHINERY will agree with me, and I hope that it *I*, which is made to fit a 4-inch shoe, and held on the block *I* by the 5/8-inch fillister screws, *M*. *A* are cushion pin holes which work on the cushion plate *H*, to keep the metal from buckling while being formed. Fig. 2 shows a sectional view of Fig. 1 with the cushion rubbers in position. Fig. 5 shows the cushion ring, which is mortised out to the shape of the forming die, *J*, and sets on top of the four cushion pins, *A*. The metal is laid on top of the cushion ring, which projects above the top of the die about 1-16 inch, and as the ram descends it forces the cushion plate, *H*, down, and the tension of the cushion rubbers keeps the metal from buckling.

Fig. 3 shows a sectional view of the female part of the die. The upper half of the die *E* is made of cast-iron and a 3/4 inch hole is drilled through the shank for the spring *N*. Fig. 4 shows a sectional view of the lower half of the die, *G*, Fig. 3;



Views of Punch and Die for Stove Number Plates.

may be of some benefit to others who are engaged in this line of work.

J, Fig. 1, shows the forming die, and the number holder, as I call it, which is of hardened tool steel. The mortise *R* holds the number blocks, shown in Fig. 6, which are interchangeable, and is made to hold three blocks at a time. The number blocks are 11-16 inch × 11-16 inch, and are made of brass; by using two 11-32 inch pieces to make up for the third block, two numbers can be made on the number plate instead of three. The piece *J* is set on the cast-iron piece, it is made to conform to the shape of the forming die, *J*, Fig. 1, and is made twice the thickness of the metal larger. Fig. 3 shows the female number blocks, *D*, in position. These are held in place by the rod, *C*, the blocks having a hole 5-16 inch diameter drilled through them, as shown in Fig. 6, at *P*. The two screws, *K*, are to keep the rod *C* from coming out. These blocks act as a kicker, which accounts for the hole being drilled 5-16 inch in diameter, as the large size allows the blocks to work free and bottom on the upper half *E* or shank holder. The piece *T* is a loose piece laid on top of the blocks, *D*, so as to get even pressure on all of the blocks. The piece *B* rests on top of the piece *T*. As the width of the

Fig. 7. Number Plate as it leaves the Press.

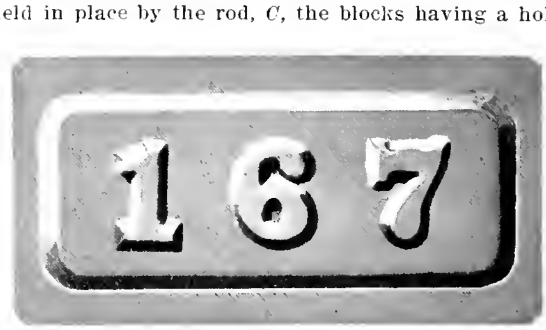


Fig 8. Plate after being Trimmed.

blocks is only 11-16 inch, I had to use this means of making an effective ejector, as the spring hole being ¾ inch in diameter it would not allow the spring to come in contact with the piece *T*. The lower half of the die *G* is fastened to the upper part by means of the four fillister screws, *F*. *O* is a tension plug and keeps the spring from coming out.

Fig. 9. From a Photograph of the Punch and Die.

One advantage of this die lies in having the numbers interchangeable; it only requires a few blocks, whereas if each number was all made in one, it would require a great many number blocks. Constructed this way it makes a very neat tool and produces just as good a work.

Lorain, Ohio. W. VAN ORMAN.

ADJUSTABLE HOLLOW MILL.

Editor MACHINERY:

I send below description of an adjustable hollow mill that can be used where the collar clamping device of the ordinary form is in the way. It was developed in our shops two years ago, and is the joint production of my foreman and myself.

Referring to Fig. 1, *A* is a machine steel shank fitted to the drill press or other machine in which it is to be used. It is threaded at *a* and the lower end is turned down so as to form

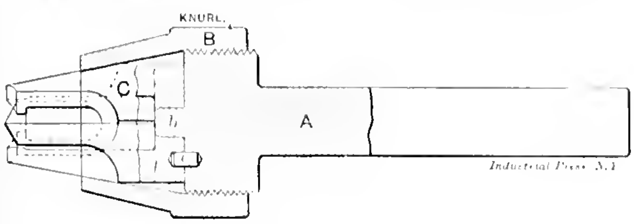

Fig. 1. Section of Hollow Mill.

the stud *b*. *B* is a collar or sleeve similar to those used on adjustable chucks for holding small drills. It is also of machine steel, is threaded to fit the shank *A*, and below the threaded portion is bored taper. *C* is the hollow mill of the ordinary split collar type, except that at the upper end it is bored to fit the stud *b* and a portion of the outside is turned taper to fit the collar or sleeve *B*. In the lower end of the shank *A* is inserted a driving pin *e*, which enters a hole *f* in the upper end of the mill *C*.

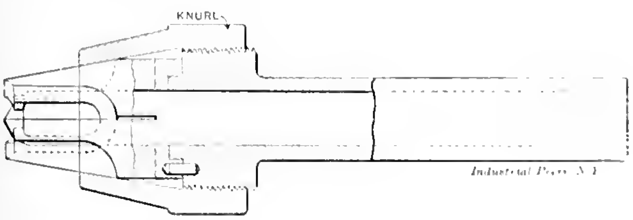

Fig 2. Hollow Mill for Long Work.

The above described tool can only be used for short work, but the modified form shown in Fig. 2 will take work of any length.

Our mills are made a trifle larger than the desired size and squeezed down by the taper collar *B*. This affords a delicate adjustment for size and at the same time keeps the teeth of the mill concentric with the shank. V. H. MARCELLUS.

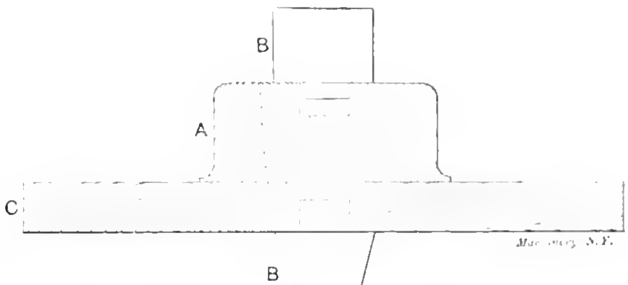
Belvidere, Ill.

PATTERNS FOR CHUCK PLATES.

Editor MACHINERY:

For a number of years we fitted up chuck plates in the same way that most other lathe builders did. That is, we hunted through all the patterns we had or our neighbors had at the foundry. After spending just about time enough to make a good pattern we tacked a couple of thicknesses of leather belt around the rim of one and used a hub that was a mile too big, but had about the right size core print, and trusted to luck to remember to turn the hub down a little. The principal variation from this method was when we found a hub about the right size but with a 2-inch print where we wanted a 1½-inch core set. The molder usually got it near enough the middle so that we could use it except when we were in a great hurry.

We finally rebelled and got out a set of patterns that worked well enough so that the other lathe builders were perfectly willing to borrow them. We turned up a set of hubs as at *A* in the cut, making the diameter of the hub about 1¾ times



Pattern for Chuck Plate.

the diameter of the nose of the spindle it was intended for. These hubs had a dowel made on one side 1 inch in diameter, as shown, and on the other side a corresponding hole. Sets of core prints were also made of sizes to correspond to the standard foundry stock cores and of a size to allow about ⅛ inch on a side to bore out before threading. These core prints were all made with 1-inch dowels, as shown, and were stamped plainly with their actual size and the size lathe for which they were intended. The hubs also were stamped with the lathe sizes. The plates *C* were made to suit the diameters of plate called for by the makers, whose chucks we were mostly using, and were stamped with their finishing sizes, that is, the size they were intended to finish to. The thickness of the plates varies from one-eighth of the diameter for small plates to one-twelfth for plates a foot or more in diameter.

A full set of hubs and core prints was made at once and a few of the most used sizes of plates. After that if a new size was called for it was a matter of only a very short time to get out a new plate. E. H. FISH.

Paxton, Mass.

ACCURATE JIG MAKING.

Editor MACHINERY:

Kindly allow me space for a few words regarding accurate jig making. I was somewhat surprised to note in the current issue of MACHINERY that Mr. J. R. Gordon prefers a drill press to either the milling machine or button method for accurately spacing holes. Undoubtedly brother Gordon failed to state how he overcame the following unquestionable chances of errors, and I will point out where the drill press is not allowable for jig making in watch or fine instrument factories. When writing the article on jig making in the July issue, I had in mind the method of spacing as advocated by Mr. Gordon; in fact, I described that same method applicable to the lathe in the January, 1904, issue of MACHINERY, but it is accurate only when holes are *bored*. Let us see how many chances for error are presented when employing the drill press plan of spacing. First, the bracket or arm, that is fastened to drill press and which holds the bushings used to guide the drills must be made perfectly accurate; that is, the hole in said bracket must align absolutely with center of drill spindle. Secondly, the bushings to guide drills must be made so that the hole is perfectly concentric with the outside. Third, the hole in bushing must fit perfectly the drill used. Fourth, the outside of bushing must fit perfectly the hole in bracket, to insure the hole in bushing remaining absolutely central with spindle when using bushings with different sized holes. Fifth, the spindle of drill press must be at right angles with table of press in every direction, a condition that is rarely met with in a drill press.

Mr. Gordon spots the holes using spacers made of drill rod. The bracket is removed and the holes drilled clear through the jig plate. But what assurance has he that the drill continued through the plate perfectly straight? None whatever; hence, chance for error No. 6. When drilling work fastened to face plate of lathe we always bore the hole to "true" same. Now, why will a sensitive drill press, that is more sensitive to "spring" than anything else, produce a hole that requires no boring? Seventh chance for an error is when the holes are opened up with a half-round center reamer having but one cutting point. Cast iron is full of grit and it requires but a small particle of grit to cause the center reamer to change its location. Eighth, and greatest chance is that of opening the holes with a larger drill. If one lip of drill is the least bit longer than the other it is therefore doing more work and tends to crowd the drill over to opposite side. Error No. 9 is when the hole is sized with a reamer. I repeat my statement made in August issue of MACHINERY, that when absolute accuracy is required, the hole must be bored. Error No. 10 is the personal one, caused by uneven tension on measuring instrument when making the drill rod spacers. True, the error in all cases may be very slight, but if there are, say, 20 holes in the jig, the multiplication of errors will amount to considerable. It is very doubtful if a jig, made in above stated manner, could be duplicated. When using the buttons for spacing as I described in the July issue there is but one chance of an error and that is the personal one caused by uneven tension on measuring instrument, due to the fact that the buttons are indicated and holes bored. Mr. Gordon meets this same personal error when making his spacers. I agree fully with Mr. Gordon as regards the condition of milling machines in most factories. But I stated very clearly that the milling machine method was applicable only to those being fitted with corrected screws and dials. Any manufacturer that holds accuracy in the tool room as the prime factor, and also expends $125 for three milling machine screws is very careful that a "cut meter" is not employed on that miller and reserves same for "Accurate Jig Making."

Gt. Barrington, Mass. FRANK E. SHAILOR.

SETTING FOR TURNING TAPERS.

Editor MACHINERY:

The following method for tapers may be of interest to some of the readers of MACHINERY; they have been of use to me many times:

When turning a rod to a certain given taper, or to fit a taper hole, if the taper is given, for instance, 5/8 inch taper per foot, and the piece is an odd length, say, 31 inches, instead of figuring the distance necessary for 31 inches of length I simply set the tool at a point 2 feet from the live center and adjust the cutting edge to a distance 5/8 inch from the work. This I usually do by taking a piece of 5/8-inch steel and set the tool so that it will pass between it and the work. I then set the tail center over so that the work will touch the tool. This gives the desired taper very easily, even if the rod is three or four feet in length.

If the hole to be fitted is, for instance, 5-32 inch taper to 3¼ inches in length, take, say, $8 \times 3\frac{1}{4}$ inches $= 26$ inches and $8 \times 5\text{-}32 = 1\frac{1}{4}$ inches. The distance necessary to throw the tailstock would be one-half of 1¼ or 5/8 inch measured from the end of the setting tool at a point 26 inches from the live center.

To bore a hole to a given taper with a compound rest I usually set a piece of shaft, rod or mandrel by this method and then adjusted the compound rest to the arbor with a tool set at the same height as the center for a guide. It is much easier than to cut and try, or to set to certain degrees by use of a bevel. I have worked in many small shops where the taper attachment was an unknown quantity and there the method just described is most valuable. J. T.

* * *

The air-lubricated journal, described by Mr. A. W. Cole in our issue of May, 1904, was designed and built by Prof. Albert Kingsbury and was used by him in his experiments on the theory of lubrication.

THE APPRENTICESHIP QUESTION.

The trade schools, night schools and the engineering shops do what they attempt to do all right, but do not fill the shop requirements. Boys become students in the trade schools because in many cases that is the best they can do. Learning to fit pieces of wood together in different shapes or in all shapes will not train a boy to be a carpenter and joiner, or patternmaker; chipping and filing, turning and planing, milling and drilling, and scraping will not make a machinist nor learning to make drawings of buildings make an architect.

Neither is it possible to make an architect in the way I believe it possible to make a machinist, patternmaker, molder, plumber, etc. They do not pretend to make architects in the trade schools any more than I would pretend to make mechanical engineers in the school of trades. They do come very near making brick masons at the Jewish school at New York by the trade school methods. That is to say that brick walls are built as they would be in a building by the students and then torn down to be built up in some other way by other students. Plumbing is taught similarly, that is, pipe can be screwed together and unscrewed to be used over, and lead pipe can be soldered and unsoldered, and for those two trades it is unquestionably a fairly good way.

But that way will not do very well for a foundry and not at all for patternmaking or machine work. In patternmaking the thing done must be good enough to use or it is practically a total loss and in a machine it is the same in the main. The different parts done in most of the college shops are simple exercises, pieces chipped and filed in some instructive form to drill the hand in special skill, and the work when done thrown into the scrap heap. Other exercises are in the use of the various machines, attention being directed to how the work is done, rather than to the ultimate use of the piece. Just whether this is the best method for the mechanical engineer it is not my purpose to discuss, but that such a method would not make draftsmen, patternmakers, molders and machinists, I am quite sure.

To make good foundrymen the boy must work where castings are made to be used and where the cost of the product is an important part considered, and this is the weak part of the college foundry. In the school pattern shop the cost of the work is much less likely to be considered than in the foundry or machine shop, as it is in all shops where the three are carried along together in the same establishment. In the new order of things where patternmakers are carrying on business and competing with each other the question of cost is brought down immensely by competition, and in many cases this is carried to such an extreme as to result in poor work, and one of the hardest things to teach patternmakers is to consider the ultimate use of the pattern. The poor patternmaker cannot make a pattern that needs to be good, good enough, and it is hard to get a patternmaker who is used to making good patterns to turn out a pattern from which only one or two castings are to be made, crude enough. In a patternmaking school this could easily be made a part of the training.

If one is to learn to be a machinist he must work where machines are made, and, too, where many kinds are made. To get this varied experience it takes the apprentice and young mechanic many years of time, and generally going from place to place. Whereas in a school this varied experience could not only be obtained at one place but in much less time.

In the ordinary shop, in fact in all shops, except in those cases such as Brown & Sharpe's, where a special instructor is employed, the apprentice has to acquire the trade by absorption, as it is no one's business to instruct him. He gains his knowledge by what he can see, and the bad habits, negligent and indifferent ways and methods are as easily absorbed as the good ones, and the progress at best is slow.

Where the whole business of the boy would be to learn and the primary business of the foreman to teach, and to teach the best known ways, a year or two's time would be added to the useful life of the man and the money value of this year or two's time saved would far more than pay the young man to

Paper read by Prof. John E. Sweet before the Syracuse Metal Trades Association, July 22, 1904.

work for nothing for three years than to be paid apprenticeship wages in the ordinary shop, though the primary trouble is, he cannot find the places to learn the trade even in the present indifferent way.

In reply to the prevalent notion that a boy cannot learn a trade in school, let us see if we can tell why the following plan would not work. Take a well-organized shop with all the tools and machines necessary to do various kinds of foundry, pattern and machine work, with drafting room, offices, etc., and I would add a school room, not particularly different otherwise from a regular shop except there shall be no dividends or taxes to pay. The running expenses for the first year would be insurance, coal, water, oil and engineer for power, material and general supplies, a small office force, foreman and instructors or journeymen, a sweeper and watchman and a very little in the way of helper, as that would be as in an ordinary shop, only much more largely so, done by the freshmen. Now the first year it would be too much to expect the enterprise to be self-sustaining, but the second year a change for the better could not help but show itself. Such of the boys as had not fallen out would have a year's experience and some of them would in certain ways be, by their superior opportunities, pretty good journeymen, and replace some of the hired journeymen of the year before. Some would have shown their ability for draftsmen, some office men, some foundrymen, some patternmakers and others machinists and likely some more drop out.

The third year still more of the employed help could be dispensed with, better and more difficult work intrusted to the students, those showing the ability set to doing the drawing and so learn the relation between the drawings, patterns and finished work. Some set at tool-making and those few that show the ability, inclination and have the means, started in the necessary preparatory work to enable them to enter the College of Mechanical Engineering. In this respect the school would become the sorting ground for the university.

The fourth year men would be enabled to fill nearly every place in the institution. The history of our times show that of those who learn the machinist's trade many make machinists, some make stationary engineers, some draftsmen, some clerks, some business men and some mechanical engineers, and this combination is exactly the combination that it takes with the patternmakers and founders to run a successful shop, and that is exactly what the successful school for apprentices has got to be.

The question naturally arises what is to be made to sell that will sell for enough to pay running expenses? At first such things as require the least expense for material and furnish the most work, as the work in the main will cost nothing, no matter how much of it is put upon a piece, if the piece will sell. Later better and better work could be done and as the final test will be the character of the men turned out, the best men can only be made by doing the best work. If better work is turned out than anywhere else, then the ordinary shops cannot complain that the school shop interferes with trades union labor.

As I have indicated a school room, that implies some school work that could be imparted in two hours a day, and of just the kind that would be of the greatest use to the mechanic or necessary to enter a technical school. Certain things such as writing, spelling, arithmetic and the civilities of life should be insisted upon, and beyond that such as the ability of the student seemed to justify.

When the school turns out men that there is a demand for, the reputation of the school would soon be such that the boys would covet the chance to be given admission and many parents willing to pay tuition fees, the same as at college. But after all would it pay dividends, taxes and insurance? No. Does it pay young men to go to college? Well, some it does and some it does not. Does it pay to go to school? Sometimes it does and sometimes it does not. Does it pay to learn a trade? Generally, and it is one of the best ways to keep men out of State's prison and the poorhouse.

But how is the fanciful school I have been describing to be brought about? It isn't in my time, but I hope in some of yours. Such changes before they materialize have to be harped upon by some man for about twenty years, then if he gets some one to help pick the harp strings with him the idea will grow, and in this case slowly, because it not only requires a change in sentiment, but money.

I can see no hope until the happy coincidence comes about by there being a good machine shop in the receivers' hands and the time when the glory of giving money to colleges, libraries and hospitals has grown stale, and the millionaire buys the shop, donates and endows it for the purpose.

What interest is all this to this association? First, to keep the supply of good workmen up to the demand, and second, to bring up a set of better educated men and further to fortify manufacturers against labor troubles.

It may be easily imagined that I am laying unnecessary stress upon the importance of the machine shop to our lives, but if we stop to consider one prominent fact it will be seen that we must have the machine shop or go back to primitive methods, as the machine shop is growing of more and more importance.

Everything is being done more and more by machinery and that means more and more shops to build them in. The technical schools are training engineers and men to lead, but it takes from ten to a hundred men to execute the work of an engineer, and nothing is being done, or certainly less and less is being done, to train them. Unless not only one but hundreds of such schools as I have described are provided, foreign workmen will find work in this country and promote idleness in our own young men.

If the old apprenticeship system is revived it can only be done by change in sentiment as to the relative value of an academic education and a trade. Whether it is of more value, and whether it is more likely to lead to happiness for one to know what has been done in the world or for one to know how to do something himself, will be the question. When a parent comes to the conclusion that he wants his son to learn a trade and is willing to pay the price, manufacturers will be willing to accept the money and give the boy a chance, or there will be money enough drifting the right way to establish the schools.

* * *

Compressed air is widely used on railways for cleaning the cushions, carpets, draperies, etc., of passenger cars, and it has been found far superior to the beater, broom and duster method. But it has one serious fault in common with the ordinary implements of cleaning in that it scatters the dust through the air, which, as soon as the disturbance has ceased, settles again upon the furnishings. For this reason the vacuum system of cleaning seems likely to supplant compressed air for railway car cleaning, and because of its great efficiency it is also likely to be largely employed for the annual or semi-annual "housecleaning" in hotels, private houses, etc. With the vacuum system everything is cleaned *in situ*, there being no need of taking down curtains or pulling up carpets. The dust is sucked out of them, even that which has penetrated carpets and lies on the floor beneath. The vacuum system, of course, requires a vacuum pump, or, in other words, an air-compressor in which the suction is the "business end" instead of the discharge pipe. For house-to-house work a portable plant is necessary, and the business has already reached the point of development in this country where the portable plants are being introduced. One recently built in New York consists of an inclosed electric automobile truck, in which is a three-cylinder gasoline engine connected to a small dynamo. This dynamo charges the storage batteries, from which current is drawn for running the truck and for operating the vacuum pump. This latter is in the back of the car and is driven by a small motor connected by a Renold chain drive. The pump is a vertical two-cylinder machine, having a capacity of about 400 cubic feet of free air per minute.

* * *

Three thousand employees will be required to operate the trains of the New York subway when it is opened next month, and most of them will require special instruction to qualify for the work. The arrangements for giving this instruction are so complete, that it is expected all the trains will be running on schedule time within an hour-and-a-half from the time the subway is opened to the public.

HOW AND WHY.

A DEPARTMENT INTENDED TO CONTAIN CORRECT ANSWERS TO PRACTICAL QUESTIONS OF GENERAL INTEREST.

Give all details and name and address. The latter are for our own convenience and will not be published.

We have received the following inquiries from our subscribers, which we are glad to submit to our readers as subjects upon which some among them may be able to supply information that will be of general interest:

1. W. C. J.—Will you kindly tell me how axes and hatchets are made, especially as to the way in which they are finished and tempered?

2. C. K.—Will you kindly inform me of the best prescription for thinning lard oil after it gets thick from using?

3. H. J. N.—Can you give me any information regarding the use of aluminum for gas or gasoline engine castings? Can it be used for cylinders, and, if so, of what composition should the alloy be? Also, can an aluminum mixture be used for the bedplate? The engine in question is for a gasoline launch to develop from 10 to 15 horse power.

4. B. and R.—Is there any means for protecting highly polished steel surfaces from rusting after soldering? We have tried several so-called anti-acid soldering solutions, but none of them prevented the subsequent rusting of the polished surfaces coming in contact with them.

5. "Connecticut" asks: Will you give me some idea in regard to making a straightener for brass wire 1-16 inch diameter? The wire has considerable spring in it. I have tried an eight-wheel straightening machine, but it does not accomplish the work desired. I do not want to mark the wire.

6. Inquirer: Can you give me information upon designing an 8, 10 or 12-tooth cast-iron sprocket wheel, for No. 32 malleable chain? I would like to have dimensions for the addendum, dedendum, thickness of tooth, clearance, etc.

Answers to Question 33.

The two following replies to the inquiry of C. W. B. for a solution or solder for soldering brass and steel together without rusting, have been received:

1.—Non-corrosive soldering fluid.—Grain alcohol, 3 pints; glycerine, ½ pound; chloride of zinc, ¼ pound. Glycerine to be well shaken or mixed with the alcohol before introducing chloride of zinc. After introducing the zinc to the alcohol-glycerine compound, mix thoroughly by shaking until the chloride is dissolved. Any combination of quantity may be used if the proportion is maintained.

2.—A saturated solution of chemically pure zinc chloride in best grain alcohol will give good results. It is equally good for copper.

About Sepia and Blue-print Paper.

We have two inquiries regarding sepia and blue-print papers. The first correspondent incloses a sample of sepia paper and asks, "Will you kindly advise me, if possible, as to what composes the solution used in making sepia printing paper? Also, whether there is any solution that can be used for making corrections on such paper?"

This inquiry was referred to our contributor, Mr. W. H. Sargent, chief draftsman of the Fairbanks Scale Works, St. Johnsbury, Vt., who replies as follows:

I regret that I cannot give you the formula for preparing "sepia paper" or "maduro paper" as it is sometimes called. It appears to me to be similar to "Kallitype" paper, described in the *Camera* for May, 1903 (The Camera Pub. Co., 114-120 So. 7th St., Philadelphia), also described in *The Photo Miniature* No. 47, Tennant & Ward, 287 Fourth Ave., N. Y. City. So much depends upon the selection of the paper and the preparation of the chemicals that the work of an amateur is likely to be unsatisfactory.

The sepia paper may be written upon with "Farmers' Solution," which consists of a few grains of red prussiate of potash (potass. ferryicyanide) with an equal amount of hyposulphite of soda. Pulverize the crystals and dissolve in an ounce of water. The proportions are not very exact—the stronger the solution the quicker it acts. The potash is very poisonous.

The second inquiry relates to making prints from, or reproducing blue-prints. As we have seen work of this character at the works of the New Britain Machine Co., New Britain, Conn., we submitted the inquiry to them and have the reply, which follows. These two inquiries and information given may, we trust, lead to information from other sources upon these subjects, which are of considerable interest to draftsmen.

With regard to reproducing blue-prints, we would state that we get out a considerable number of bulletin blue-prints consisting of part drawings and part type-written work. The foundation for these is a reversed blue-print made from a Vandyke process paper negative. This Vandyke process, as you undoubtedly know, is exploited by Eugene Dietzgen & Co., New York and Chicago. It was invented by a draftsman of ours, Mr. Schmelz, and gives a deep Vandyke brown background with white lines, and, of course, in reprinting from them with ferro prussiate paper, one gets blue lines with white background. A bulletin mailed you was made from a glass negative made by a wet process plate, by photographing a combined sheet of drawing and type-written work—the latter made with black record ribbon.

7. A. J. J. and others—We cannot understand the use of the expanding nozzle in the De Laval steam turbine. It would seem quite useless to generate steam of high pressure and then expand it idly before delivering it to the wheel. Why not use a straight nozzle and simply limit the boiler pressure in the first instance? 2. Why is it that steam when flowing through a straight nozzle superheats, while when flowing through a diverging nozzle, as that of the De Laval turbine, it condenses?

A.—It is necessary to expand the steam in order to get the full amount of work out of the steam that it is capable of performing. There is a large amount of stored heat energy in steam which can be converted into useful mechanical work even when the steam has been cut off entirely from the boiler; and it is this energy which is made use of by expanding the steam. In the case of a steam engine, steam is cut off in the early part of the stroke, but it continues to push the piston forward with a gradually lessening force, in virtue of its own intrinsic energy, which causes it to expand. In the case of a direct-acting pump, steam is admitted during the whole of the stroke. Practically considered, there is no expansion at all, with the result that this is one of the most wasteful forms of motors. In order to take full advantage of this expansive force in a steam nozzle the walls of the nozzle must diverge, as can be explained by reference to Figs. 1 and 2. It has been proven by many experiments that when a converging or straight nozzle is employed, like in Fig. 1, steam will expand in the nozzle to about 6-10 of the boiler pressure, under ordinary circumstances. This is true whether the boiler pressure is high or low. The result is that when the steam leaves the nozzle it at once drops the other 4-10 in pressure, and the jet of steam at once expands to a larger diameter, and its energy is dissipated in producing eddy currents, and in friction, instead of giving the steam velocity.

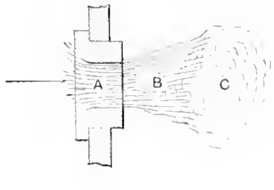


Fig. 1.

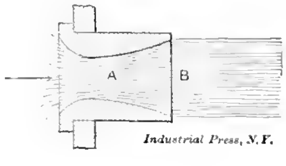

Fig. 2.

In Fig. 1 the pressure at A would be about 6-10 of the higher pressure, and at B is shown how the jet bulges out and how its energy is lost to a certain extent. Steam flowing through such a nozzle acquires a velocity of from 1,400 to 1,500 feet per second, this velocity being nearly constant for all pressures within certain limits. If, however, we attach a diverging mouthpiece to the nozzle, as in Fig. 2, having the area increase from A to B just sufficient to confine the steam so that it will be compelled to expand in the direction in which it is flowing, instead of radially, the energy will all be directed to giving velocity in the direction of flow, and the steam will issue in parallel lines at a much higher rate of velocity, which rate will increase with an increase in pressure in the boiler.

The reason the nozzle must diverge in order to produce this result is because steam at a low pressure has a greater volume

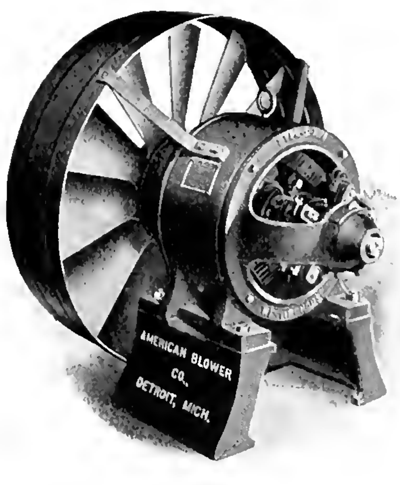
than steam at a high pressure; and consequently increasing room must be given it if the pressure is to drop within the confines of the nozzle. The flare of the nozzle is modified somewhat, however, by the fact that the velocity of the steam is rapidly increasing and consequently the steam gets out of the way faster toward the discharge end of the nozzle and the area at that point can be proportionately smaller than if this were not the case. Theoretically, the ratio of the areas at A and B, Fig. 2, should be directly as the specific volume of the steam at these two points (remembering that the volume at A must be for steam at 6-10 of the higher pressure) and inversely as the velocity of the steam at these points.

2. The answer to your second question must be evident from an examination of Figs. 1 and 2. In Fig. 1 the energy of the steam is dissipated in friction, and eddy currents, which produce heat and superheat the steam. With a diverging nozzle, however, the steam flows smoothly from the higher to the lower pressure, and all of its stored energy is converted into kinetic energy (the energy of motion). The high velocity of the steam in this case is the direct result of the expenditure of the stored energy in the steam, and inasmuch as this energy has been given up the steam has lost part of its heat and consequently has condensed.

* * *

VENTILATING BLOWER WITH MOTOR.

The American Blower Co., Detroit, Mich., have worked out a new design for diréct-connected disk fans, as shown in the accompanying illustration. The fan is a modification of the "A B C" fan of this company's make, which has been on the market for a long while and is in general use. The custom has previously been to attach the motor to the arms of the fan, but the excessive weight of the overhung motor has



sometimes been an objection. In the present combination the motor is placed on a substantial base, and the fan is supported by the motor frame by means of radial arms, as shown. The fan, which can readily be made very light in weight, is thus the overhung part of the apparatus. There are no bearings except those of the motor. The complete apparatus is compact and well adapted for ventilating purposes. The fan is equipped with Westinghouse motor.

* * *

IMPROVED DRAFT GAGE.

The importance of being able to tell the chimney draft at a glance is fully recognized, and the necessity of knowing the pressures maintained, where quantities of air are moved is becoming more apparent to ventilating engineers. In testing gas engines for their thermal efficiency, the pressure of the gas as well as the barometer readings must be accurately recorded if correct results are desired.

For such purposes an ordinary U-shaped glass tube has been used and the difference of the level of the liquid in the two legs taken as the pressure. Aside from the fact that one can seldom read closer than ¼ of an inch on account of the menisci varying with the direction of movement of the liquid and that one must take two readings and add or subtract to get the correct result and that the tube is fragile and often gets broken, the device gives good results.

In order to read closer than ¼ of an inch, a glass tube has been used in an inclined position, giving a 10-inch travel for 1-inch rise. This makes the readings finer but limits the range for practical purposes as a tube showing a difference of pressure of 6 inches would be five feet long.

To meet the requirements for a strong, direct-reading manometer that would give close results and could be used either as a portable instrument or could be attached to the gage board, an interesting draft gage has been brought out by Mr. C. E. Sargent, mechanical engineer, Chicago, and is for sale by Schaeffer & Budenberg, New York and Chicago.

It consists of a nickel-brass cylinder, closed at both ends, encircled with a spiral groove in which is wound a transparent flexible celluloid tube, the bottom end of which is cemented in and communicates with the interior of the brass chamber.

An extension of its lower head passes through the bracket, which supports the gage, yet allows it to be revolved at will, around its vertical axis. A small hose cock, to which a rubber tube can be attached, admits pressure through the top head of cylinder. Distilled water, usually colored, is put in the cylinder through this cock until the zero mark is reached on the scale.

Pressure will cause the level of the liquid to ascend in the tube and for every inch of vertical rise, it will travel around the cylinder, a distance of about 9 inches, which is divided into 100 equal parts. The angle of the tube is such that the plane of the minisci is radial, making close reading possible. The cylinder can be rotated so that the level of the liquid comes on the front side.

Rarefaction causes the liquid to descend, and by adjusting the cock, any degree of steadiness of the level in the tube may be obtained. The upper end of the tube is closed with a screwed brass plug and the inlet cock is shut when the gage is carried about, maintaining the liquid in place without danger of spilling.

As the tube is tough and elastic, it is not liable to be broken. The whole device is 3 inches diameter by about 12 inches long, and weighs about 3 pounds.

* * *

A large industrial plant for the manufacture of "fiberloid" has recently been put up at Indian Orchard, Mass., consisting of 20 brick buildings. Fiberloid is practically the same as celluloid, but it is made from a different base, by a somewhat different process. The base of celluloid is tissue paper, while fiberloid is made from fine cotton yarn or rovings. Collars, cuffs, combs, brushes and mirror backs are some of the products manufactured at this plant; also large sheets of fiberloid of various colors, from which are made various articles such as imitation tortoise shell combs. These goods were formerly manufactured by the dry process in which there was some danger from explosion, but in the new wet process they are said to be entirely safe. The plant is built in the latest design and most approved methods of modern mill construction, and covers a large area of ground. All the buildings are heated and ventilated by the Sturtevant fan system and not only is this system applied for heating and ventilating but also for special drying, cooling and exhausting arrangements. In the sheeter dry house there is a special Sturtevant drying apparatus for drying the sheets of fiberloid; in the sheeter room is a special cooling apparatus for maintaining an even cool temperature necessary in the process of manufacture, and a special ventilating equipment is installed in the rolling mill to keep the atmosphere pure and healthy. The equipment of this extensive plant illustrates some of the various uses to which the fan is now applied.

* * *

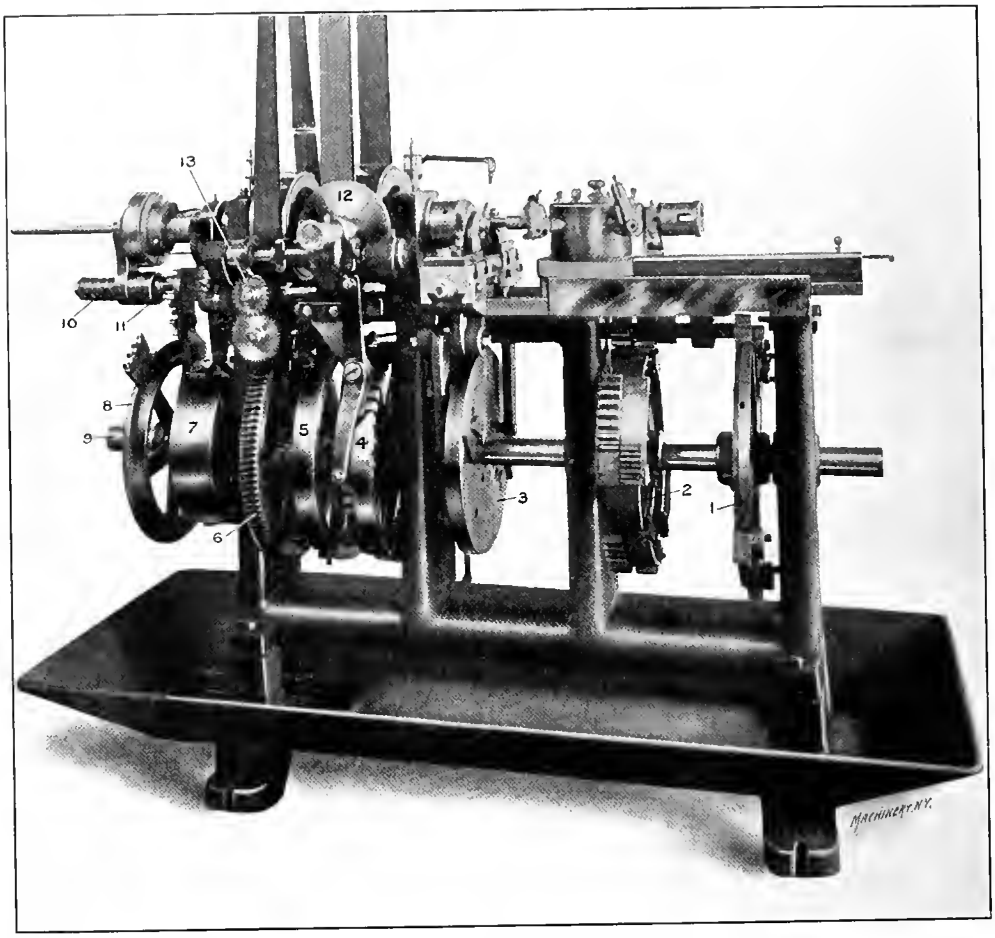
The staterooms of the steamships *Minnesota* and *Dakota*, now nearly completed at New London, Conn., for the Pacific trade, are to be heated with electric heaters, similar to the electric heaters used in trolley cars. These vessels are designed primarily for freight purposes, but provide unusually attractive accommodations for such passengers as are carried and the electrical equipment is said to be the most complete ever placed on shipboard.

NEW TOOLS OF THE MONTH.

A RECORD OF NEW TOOLS AND APPLIANCES FOR MACHINE SHOP USE.

NEW AUTOMATIC SCREW MACHINE.

A new universal automatic screw machine, the invention of J. P. Lavigne, master mechanic of the Detroit Lubricator Co., Detroit, Mich., is shown in the accompanying illustration. The construction of the machine is such that any one can set it up for any piece of work, by means of the instructions furnished, as the adjustments are not at all complicated. It will produce any class of work without requiring any parts such as cam faces, which heretofore have frequently had to be designed for the work to be performed.



The Lavigne Automatic Screw Machine.

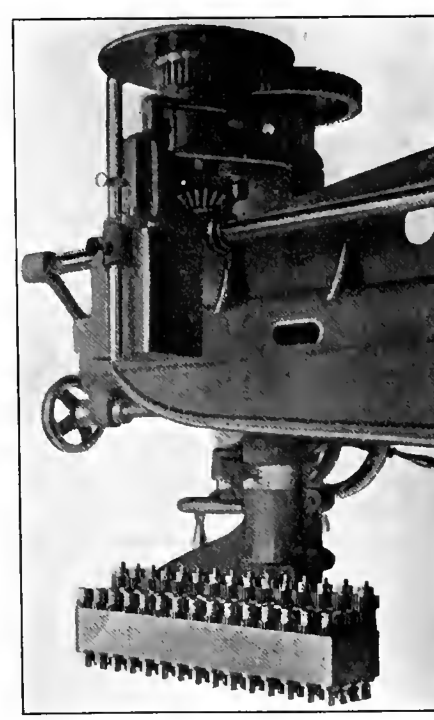
The machine is driven by two belts running on pulleys which are loose on the main spindle. One of these belts is simply for the reversal of the spindle, while the other one drives it in a forward direction while the tools are cutting and also furnishes power for rotating the cam shaft marked 9 in the engraving. Power is transmitted to the cam shaft through the friction disk 12 which runs in contact with a leather surface on the forward belt pulley. This friction disk is carried by a sleeve on a short horizontal shaft which it drives by means of a worm and worm wheel, and thence transmits power to the cam shaft 9 by the train of gears 13, which finally give motion to the wormwheel 6. Inasmuch as the timing of the different parts of the machine is governed entirely by the speed of this cam shaft, it is desirable to have means for adapting this speed to the different requirements. This is accomplished by two speed devices. One of these consists of a set of differential back gears attached to the shaft which drives the wormwheel 6, and the other, of arrangements for moving the friction disk 12 longitudinally on its shaft, which gives a smaller but gradual variation in the driving speed. The friction disk is moved by a lever which derives its motion from cams attached to wheel 4, and which can be so adjusted by means of slots in the face of the wheel as to give any desired motion to the disk at any time during the revolution of the shaft.

The differential back gears are operated by a clutch. This clutch is thrown in or out by cams clamped to one side of the wheel 5. The clamps are also attached to the other side of this wheel for operating the clutch connecting one or the other of the two main belt pulleys with the lathe spindle. The type of cam used on wheel 5 is used throughout the machine wherever possible, since it is easily attached and can easily be adjusted to any position. The chuck for holding the stock is operated by cams on the wheel 7, and the device for feeding the bar of stock through the spindle is operated by toothed segments on the wheel 8. At 10 is a coarse pitch screw, the rotation of which moves the stock-feeding device. On the right-hand end of this screw is pinion 11 and below it is an intermediate pinion. These are so located that one of the segments clamped to wheel 8 will mesh directly with the pinion attached to screw 10, and the other segment will mesh with the intermediate pinion turning the screw in the opposite direction and thus moving the feed device back to position where it is ready for again feeding the stock forward.

Now going to the other end of the cam shaft we find wheel 1 for moving the turret-locking bolt in or out of position by means of cams clamped to the periphery of the wheel. At 2 is a wheel carrying two sets of segments designed to mesh with pinions which rotate a screw visible under the turret, causing a nut on the screw to travel back and forth and thus operate the turret-turning mechanism. The distance that the turret is turned at any time is governed by the length of the segment on wheel 2. At 3 are two disks clamped together, which carry cams for operating the tool slides. These disks can be adjusted relatively to one another by twisting slightly upon the shaft, so as to bring the two tools into position where they will operate on the stock simultaneously.

MULTIPLE DRILLING ATTACHMENT.

The Mueller Machine Tool Co., Cincinnati, O., have brought out a new drilling device



Multiple Drilling Attachment for Radial Drills.

which we show herewith, to be applied to a radial drill. This device permits 60 holes to be drilled at the same time by operating the usual feeding levers.

The main casting, or head, is clamped to the machine sleeve, which is raised and lowered by means of its rack and pinion. The radial spindle runs loose in this head, and, by means of teeth cut on the spindle next to the sleeve, drives the sixth gear in the first row of 15 spindles, which mesh together. These spindles have 1½ inch centers, and each of them drives three others in rows at right angles to the first row. Their centers are 1⅛ inches in order to allow the teeth of their gears to pass each other as they run in opposite directions. Thus 30 right- and 30 left-hand drills are used to do the drilling. With the aid of a graduated dial on the cross screw, and a table having its adjustment at right angles to the radial arm, thousands of holes can be drilled with accuracy, down to ¼ inch center distances.

SHAPER INDEX CENTERS.

The three photographs herewith, illustrating index centers for shapers, tell their own story and require but little description. They are manufactured by the Stockbridge Machine Co.

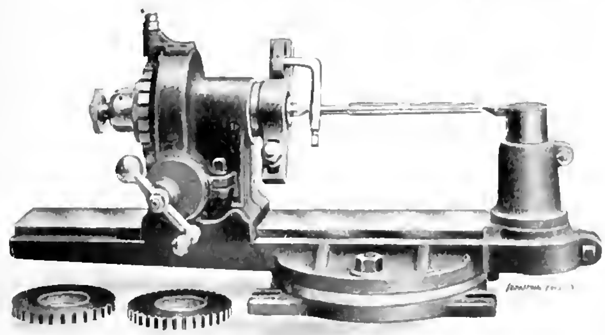


Fig. 1. Holding a Taper Reamer.

Worcester, Mass., the manufacturers of the Stockbridge shaper, and possess several points of novelty and usefulness that are original with this design.

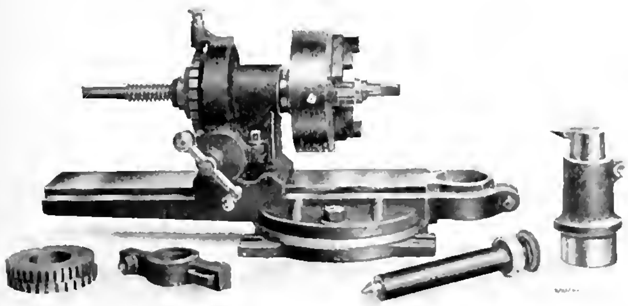

Fig. 2. Holding a Rod which Passes through the Spindle.

The illustration, Fig. 1, shows a taper reamer in position between the centers, and it will be noted that the tail center is raised sufficiently to bring the upper edge of the reamer parallel with the plane in which the shaper tool travels. Fig.

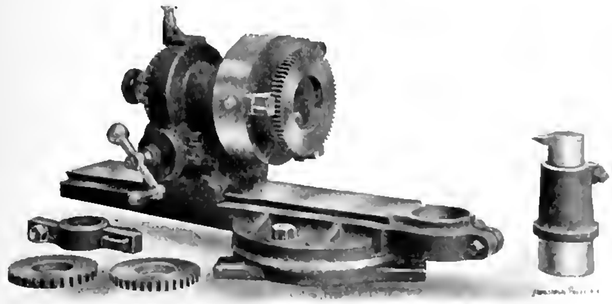

Fig 3.

2 shows the tailstock removed and the chuck attached in place of the dog holder. The spindle is also removed and a rod run through and held in the chuck, for squaring off the end. Fig. 3 shows a gear held in the chuck for the purpose of having the ratchet teeth cut.

The index centers swing 10 inches and take between centers 14½ inches. The hole in the spindle is 1 3-16 inches in diameter. It will be seen that the centers are designed to be used with a graduated base, such as is supplied with the Stockbridge shaper, but they can, of course, be used without this base by simply bolting directly to the shaper table.

NEW BENCH-STRAIGHTENING PRESS.

A bench-straightening press has been brought out by the Springfield Machine Tool Co., Springfield, O., which is of larger size than this company have heretofore made. The screw used in straightening the work is provided both with a hand wheel and a hand lever, the former being used for small work and the latter where considerable power is necessary. The hand wheel also permits adjusting the screw from large to small work, and *vice versa*, with rapidity. The centering heads are fitted upon a cold-rolled shaft 1½ inches in diameter, and have a capacity of 6½ inches diameter, with 40 inches between centers. Any length of shaft, however, may be straightened with this press, if occasion requires.

NEW UNIVERSAL JOINT.

The Boston Gear Works, Boston, Mass., have recently applied for a patent on an improved solid-ball universal joint coupling which they are now offering as a joint of unusually good design from the fact that it is strong and has no projecting parts. It is perfectly safe for the operator of the machine to stand close to one of these joints when running, as there is no possibility of his clothing catching.

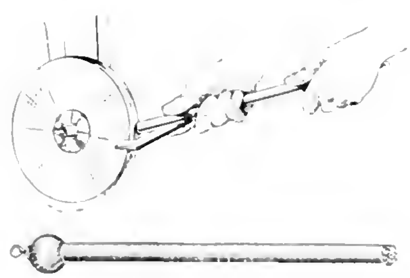
The bearing surface of the rubbing parts is also unusually large, so that it should be a durable joint. The only space inside the joint which is open is used for holding a lubricant,

A Ball Universal Joint.

which thoroughly lubricates the inside bearings. The opening of the oil well is closed by a screw. It is to be noted that this joint has a spherical bearing of large area directly on the ball, which latter is hardened and ground to exact dimensions. The joints are made with hub diameters of ½ inch to 4 inches and are manufactured in two styles: One for extra heavy duty and for angles up to 15 degrees measured from a straight line; the other style is not so strong but works up to angles of 30 degrees.

THE "SEMI-DIMOND" TOOL.

An emery wheel dresser manufactured by the International Specialty Co., 35 Holden Avenue, Detroit, Mich., is designed to take the place of the expensive black diamond. This is a most efficient tool for the purpose, and the makers write us that it will do the work of truing and shaping emery wheels



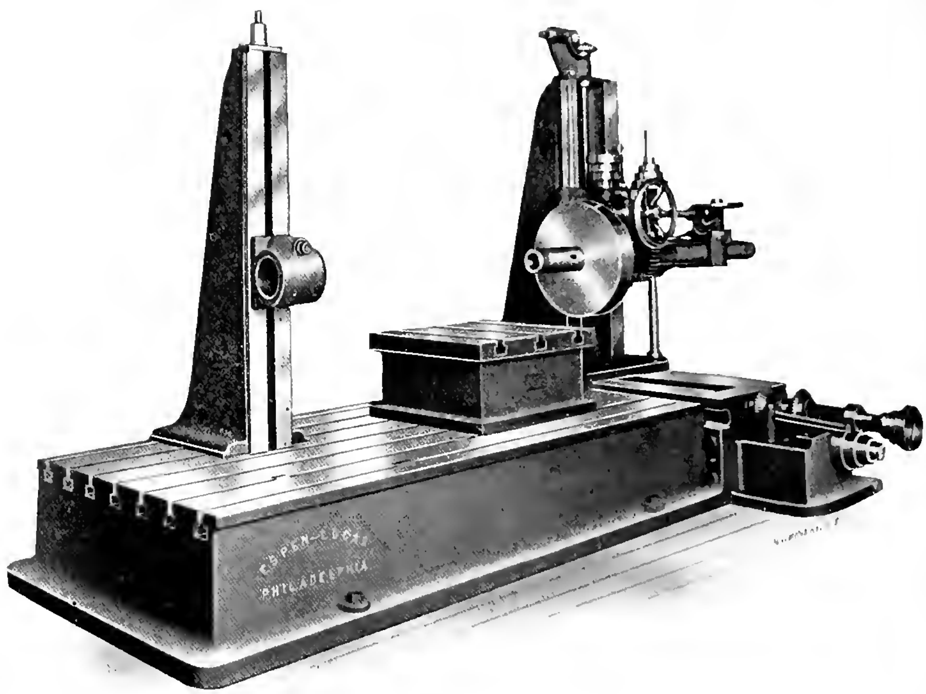
A New Emery Wheel Dresser

in as satisfactory a manner as the diamond dresser. The "Semi-Dimond" dresser is a steel tube filled with the hardest abrasive that can be obtained, which presents new cutting edges the entire length of the tube and as long as it lasts, which is from three to five years, with ordinary use. The

dresser is not recommended for water grinders or very hard wheels, although it can be used on such if necessary. Its efficiency is best demonstrated on grades up to medium hard.

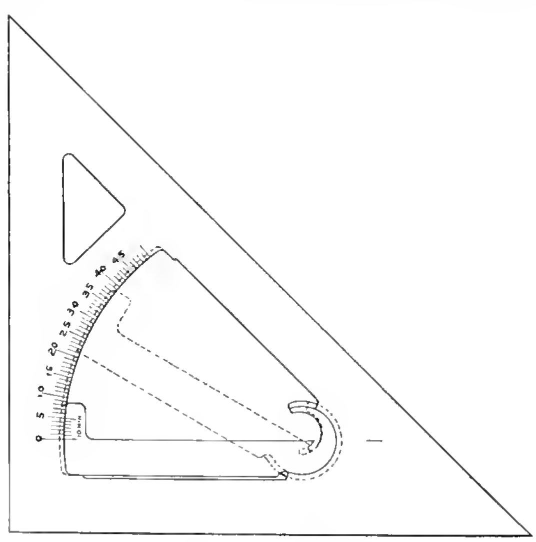
ESPEN-LUCAS HORIZONTAL FLOOR BORING, MILLING AND DRILLING MACHINE.

This new horizontal floor boring, milling and drilling machine has been designed by the Espen-Lucas Machine Works, of Philadelphia. This tool, while it conforms in its principal features to the more expensive and larger machines, is able to do the boring and a large amount of the milling heretofore necessarily done on the long milling machine. It covers an extra wide range and a great variety of work, being applicable to all kinds of boring, tapping, reaming and various kinds of milling, such as key-seating long, heavy shafting, etc. It can be used for face milling with a rotary cutter head like a rotary planer, and will do end milling and can be used for cotter drilling and cutting key-seats with an end mill. Large castings can be placed on the platen and work finished without removing the casting.



Horizontal Boring and Milling Machine.

The spindle, which is made of hammered crucible steel, is four inches in diameter and feeds through a gun metal sleeve. The boring bar has twenty inches of feed and has a No. 6 Morse taper hole in the end, also pin hole for retaining the bars and milling tools in place. The head has vertical adjustment of thirty inches and can be securely clamped in any position for milling. The column carrying the spindle head has automatic feed and quick return in both directions, giving forty-two inches of horizontal movement to the spindle head for milling. The spindle has feed in either direction for boring and counterboring both ends of cylinders. The machine, among other things, takes the place of the old style boring machine, where the work had to be adjusted to the spindle instead of the spindle being adjusted to the work, and, in this case, also relieves the milling machine of some of the large work, which would require a larger tool. The spindle is geared powerfully for heavy work and with ample power for drilling. It has a five-step cone which gives it eighty changes of feed and twenty changes of speed. The gearing is made of steel, cut from the solid and the bearings are all lined with bronze. The machine can be built with plain or compound table, or with both. The platen is forty-two inches by eighty-four inches, well ribbed to carry large and heavy work, the tail support being built with or without horizontal adjustment. Accurately adjusting screws and micrometer adjusting dials are also attached, if required. The countershaft is so arranged that spindle can be run in either direction. Length and width of table, also length of movements in all directions can be increased to suit requirements.



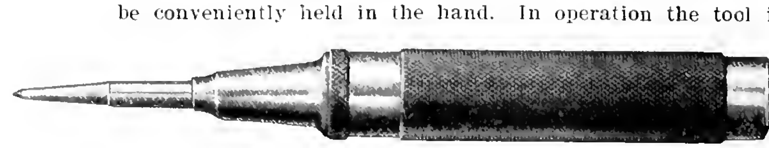
Celluloid Protractor Triangle.

A NEW PROTRACTOR TRIANGLE.

The accompanying illustration shows a draftsman's triangle, with a protractor combined, which is apparently an unusually useful tool, especially for rapid detailing. The tool is a 45-degree triangle, made in two sizes, 6 and 9 inches. It is of celluloid and the protractor arm is sprung into position, fitting snugly in V-grooves in the opening cut out of the triangle for the purpose. Just enough spring is given to the arm to maintain sufficient friction, so that it will stay in any position and yet can be moved readily. This arm has a vernier reading to 10 minutes, so that it can be set with sufficient accuracy for most requirements. When set at the 30-degree divisions the triangle becomes a convenient 30—60-degree triangle. One of the advantages of the construction is that lines which make a slight angle with the vertical and horizontal lines of the drawing, such as screw threads, for example, can be conveniently drawn by the use of a T-square and one of these triangles. It is made by the Triangle Protractor Co., Worcester, Mass.

BROWN & SHARPE AUTOMATIC CENTER PUNCH.

An automatic center punch has been brought out by the Brown & Sharpe Mfg. Co., Providence, R. I., which is entirely new in its design, combining features that make it much more convenient and accurate for laying out work to be machined or drilled than the ordinary center punch and hammer. The tool is self-contained, the striking mechanism being enclosed in the knurled handle, which is of such size and form as to be conveniently held in the hand. In operation the tool is similar to the automatic hammer used by dentists and with which readers of MACHINERY who have had occasion to resort to the dentist chair are probably familiar.



Brown & Sharpe Automatic Center Punch.

In operation the point of the punch is placed at the point where the prick punch mark is desired, the handle is pushed down, which compresses the spring, and at the proper point the spring is released and causes the striking mechanism to deliver the blow. The tool is about $5\frac{1}{4}$ inches long by $\frac{5}{8}$

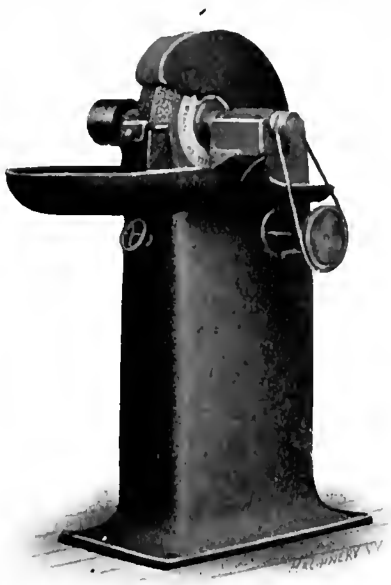
inch in diameter. In designing it every care has been taken to combine lightness and simplicity with durability. The various parts are proportioned to withstand the most severe usage to which a tool of this character should be subjected.

When following a line or establishing a point by the intersection of lines, one hand can be free to guide the point or hold the magnifying glass and, after the point is located, it is not apt to slip and lose the setting, as just a downward pressure of the handle releases the striking block and makes the impression.

Another advantage appreciated by mechanics is that the punch marks are all of uniform depth and, therefore, more easily and accurately followed than when of varying depths.

AUBURN TOOL GRINDER.

A new tool grinder, shown herewith, is manufactured by E. F. Allen & Co., successors to George J. Ridley, Auburn, N. Y., manufacturers of the Auburn tool grinders. In this machine the water tank is located inside of base and below the touch of the grinding wheel. A disk located in a separate apartment revolves with sufficient speed to throw water up and onto the wheel. Water is admitted to the disk chamber by means of a special valve which is regulated by a hand-wheel in front of the machine. The rest is solid and substantial and



Auburn Tool Grinder.

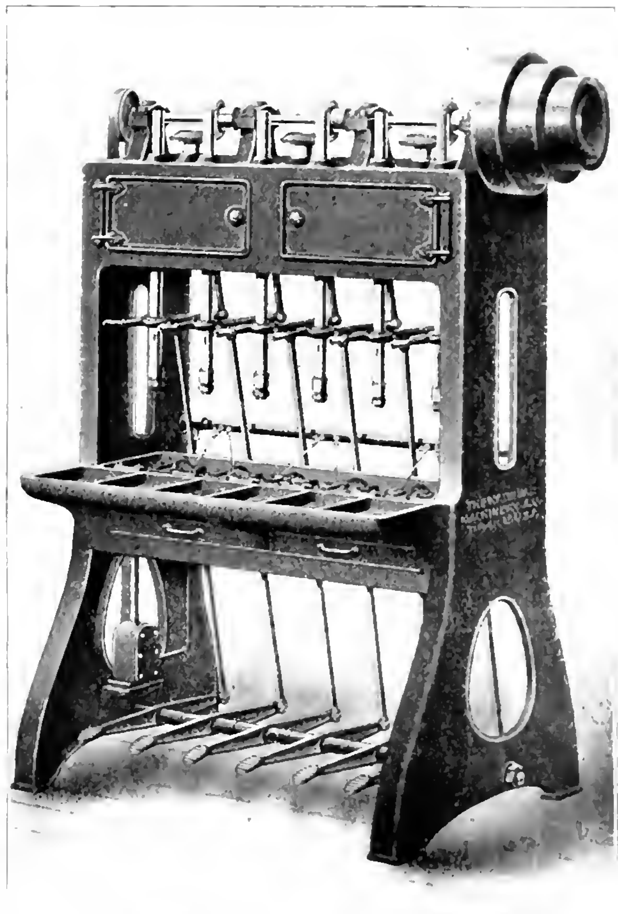
is high above any obstructions so that the tool may be held in any desired position. The wheel is covered with a hood provided with an adjustable water guard. It will be seen from this description that the machine possesses several advantages in being free from levers, treadles, pump, pipes or other devices liable to get out of order or to be adjusted or operated each time the machine is used. It is automatic in action. When the machine is at rest the grinding wheel cannot be left soaking in the water, which is a very desirable feature.

THE "NATIONAL" NUT TAPPER.

The accompanying illustration shows a nut tapper recently placed on the market by the National Machinery Co., Tiffin, O. This machine is compact, simple and easily operated, and is intended for tapping small nuts in large quantities. Special attention has been given to the convenience of the operator, so that he may take full advantage of the high tapping speeds to which it is designed to run.

Each tap spindle is equipped with both a foot treadle and a hand lever, the latter to be used in starting the tap, should the operator allow it to become dull. Tap sockets are so designed that taps can be removed or inserted while the machine is running at full speed, but any spindle may be stopped independently of the others merely by lifting its hand lever to the highest point. Nuts with either right or left-hand threads can be tapped with equal facility.

All gears are cut from solid stock, and are inclosed in a housing which protects the gears from dirt and the attendant from being caught in the gears. The rotary pump, shown near the bottom of the machine forces oil in jets against each tap, lubricating it, cooling it, and washing away the chips. The oil and chips drain into two iron drawers with screen bottoms. The screen retains the chips, but the oil filters through and returns to the pump.

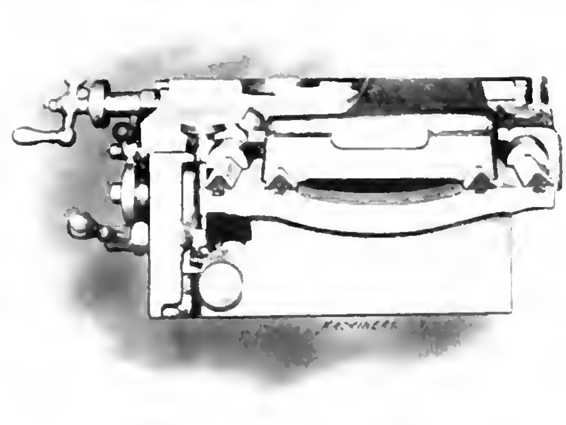


National Machinery Company's Nut Tapper.

All joints are machined, making each part rigid and true. All bearings are scraped, and adjustments for taking up wear are provided at all necessary points. All parts are machined to standard size, and repairs are interchangeable. The regular equipment includes six taps and tap sockets of any size within the capacity of the machine.

OSGOOD LATHE WAYS.

Some two years ago we called attention to a patent which had been issued upon steel lathe and planer ways which were to be inserted in the bed of the lathe, or table of the planer, in place of the usual cast-iron ways which are part of the casting itself. The use of these ways has now been developed so



Osgood Hardened Steel Lathe Ways

that they have been placed on the market by J. L. Osgood, 121-131 Erie County Bank Building, Buffalo N. Y. The application of these ways to a lathe is shown in the accompanying illustration. They are of cold-drawn, very high-carbon

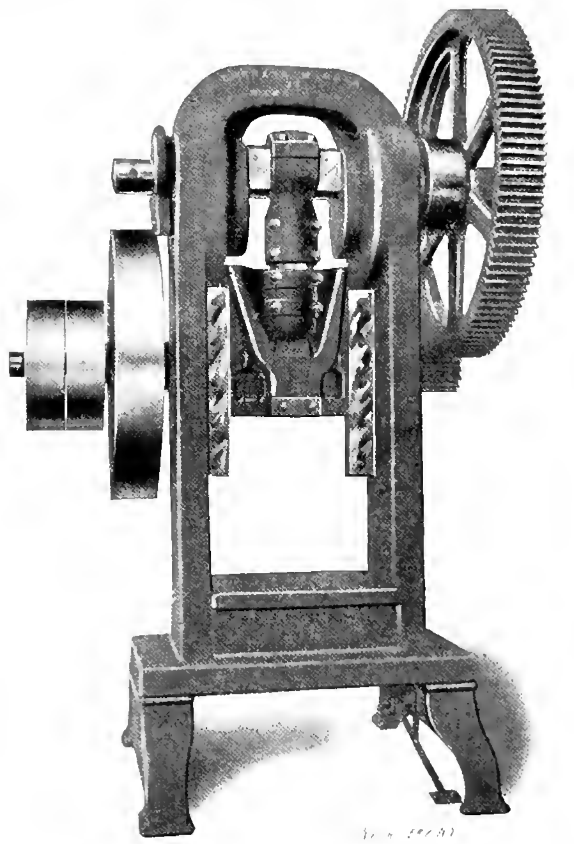
steel, and are smooth, true and bright, can be furnished in any lengths, with dimensions within limits of 0.002 inch.

In the circular supplying information upon these guides it states that they will not dent, grind or cut, and have a hardened surface which reduces friction and prevents wear. They will stand heavy strain and high-speed tool steel without showing signs of wear.

These guides are either sold separately or lathes will be supplied fitted with them, as desired. They are also well adapted for the repair of old lathes having guides which are defective. They are made in 9 sizes, ranging from 13-16 inch wide for 10 and 11-inch lathes up to 2½ inches wide for 48-inch lathes. The sides of the guides make angles of 45 degrees with the horizontal.

HEAVY STAMPING AND FORMING PRESS.

The illustration herewith shows a new press that has been brought out by the Perkins Machine Co., Warren, Mass., with improvements especially adapting it for heavy stamping and forming. The press has an 8-inch stroke of plunger, the plunger ways being set off center, so that the center of the plunger overhangs a distance of from 4 to 5 inches. By this



New Perkins Press.

construction the press can be so adjusted that the ram will travel up above the lower ends of the guides and the guides will not interfere with the punch, which has heavy strippers and spring bolts. The adjustment of the plunger can be effected quickly by a slight turn of the screw, which latter has a right- and left-hand thread.

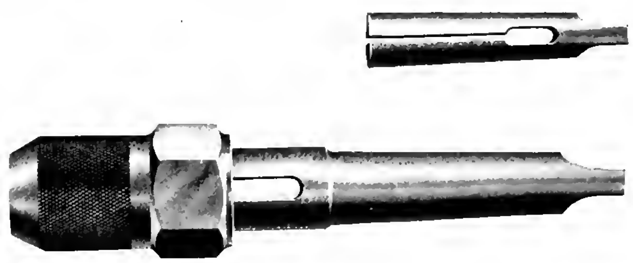
DRILL CHUCK FOR TAPER SHANK DRILLS.

The National Twist Drill and Tool Co., 21st and Standish Streets, Detroit, Mich., have placed a drill chuck on the market designed especially for holding taper shank drills. It will hold any such drills securely, even after the tang has been broken off.

The body of the chuck is bored out to form a taper socket, and is split so that it can be compressed slightly by a taper sleeve, which screws on the outside of the chuck. For smaller size drills split taper collets are used and for drills having the Graham grooved shank a special collet is provided, not shown in the engraving.

It will be evident that the construction is such as to enable the chuck to bear firmly against the whole taper surface of the drill shank, making practically one solid body of the drill, the collet and the chuck.

The chuck is made in several sizes, to accommodate a wide



National Twist Drill Holder.

range of drill sizes. The parts of the chuck are interchangeable, and new collets can be ordered at any time. The chuck is made of tool steel, properly hardened.

* * *

FRESH FROM THE PRESS.

BOILER CONSTRUCTION, by Frank B. Kleinhans. 421 pages, 5½x7¾ inches, illustrated with 334 line cuts and half-tones, and five large plates. Published by the Derry-Collard Co., 256 Broadway, New York. Price, $3.00.

This work is essentially one for the working boilermaker, being "a practical explanation of the best modern methods of boiler construction from the laying out of sheets to the completed boiler." It is confined to the problems of construction involved in the locomotive type, the inference being that any boilermaker who is competent to handle the difficult construction required in modern American locomotive boilers, should be amply competent to cope with the simpler construction of stationary and marine types. The work logically begins, of course, with the laying out of the sheets, taking up in order gusset sheet development, development of irregular shaped sheet, laying out of dome sheet, dome base, first course, laying out first course sheet, front tube sheet, smokebox sheet, etc. Following the section or chapter on laying out which covers nearly 60 pages, are sections on flanging, forging, punching, shearing, bending, machining parts, under which general head comes drilling, turning and boring, tapping and reaming, planing, milling, etc. The important subject of riveting is comprehensively treated, following which are boiler details including under this head stay bolts, crown stays, crown bar bolts, crown bars, etc. A specially valuable feature of the book is the numerous half-tone illustrations of modern boiler shop tools, but the practical boilermaker will doubtless more appreciate the fine line cuts from actual working drawings with which the different sections are copiously illustrated. The work is what we believe to be one of the most practical and comprehensive mechanical books ever published. No expense has been spared to make the illustrations the best obtainable. Mr. Kleinhans, the author of the work, is well known to our readers as a clear and logical writer on problems in theoretical and constructive mechanics. He has had a wide practical experience, including service with the Baldwin Locomotive Works where the larger part of the data for this work was collected. The book is handsomely bound in drab cloth with a symbol on the front cover representing the tubesheet of a boiler. For some reason the imprint of the title was omitted from the back which we believe was a mistake when the convenience of being able to select a book from a row on a library shelf by inspecting the titles on the back, is considered. This, however, in no way detracts from the general excellence of the work —would that there were more like it.

MANUFACTURERS' NOTES.

MR. GEORGE K. WILLAND, formerly secretary of the Washburn shops, Worcester Polytechnic Institute, recently tendered his resignation, to take effect August 1. Mr. Willand has been connected with the Institute for the past 10 years, but is now to enter in the manufacturing business in Worcester.

THE STANDARD ENGINEERING CO., Elwood City, Pa., makers of bolt threaders and pipe threading and cutting machines have appointed Mr. A. Schaefer their New York sales manager, with office at 150 Nassau Street.

THE CINCINNATI MACHINE TOOL CO., Cincinnati, O., have now completely moved their plant and are located in their new quarters at Spring Grove Avenue and Townsend Street, which plant is particularly designed for the building of upright drills. They state they will be glad to show interested parties through at any time.

THE FOOTE BROS. GEAR & MACHINE CO., at Chicago, Ill., have succeeded the firm of James & Foote, whose good will and plant they have recently purchased, excepting bills receivable and bills payable. They will continue the old business at their permanent location 24-30 So. Clinton St., Chicago, Ill.

THE INGERSOLL-SERGEANT DRILL CO., New York, have received an order from the O'Rourke Engineering & Construction Co., who have the contract for building the Pennsylvania tunnel under the Hudson, for two Central compressed air power plants to be located at New York City and at Weehawken, N. J. This order includes eight 36-inch stroke Corliss air compressors each of 3,890 cubic feet capacity.

HENRY R. WORTHINGTON CO. are distributing a small map showing the location of their old works in South Brooklyn, their offices in New York and their new works at Harrison, N. J. The new plant occupies a 34-acre tract, has 18 acres of floor space and will accommodate 6,000 workmen. It is said to be the largest industrial plant near New York, and embraces the latest improvements in engineering production.

THE PERKINS MACHINE CO., Warren, Mass., who recently moved from South Boston to a larger factory at their present location, Warren, report that owing to the large orders which they are receiving they are still running day and night to execute same. They have been obliged to add another crane to their equipment, the addition being a large Pawling & Harnishfeger three-motor electric traveling crane, of the latest model.

NEW TRADE LITERATURE.

Manufacturers and others sending catalogues for notice are requested to address them to the Editor of MACHINERY, so that they can be kept separate from catalogues sent us for other purposes

THE ECK DYNAMO & MOTOR WORKS, Belleville, N. J. Bulletins No. 34 and 35 of the "Eck" small motors for direct current, with price list.

MACHINERY.

October, 1904.

THE DE LAVAL STEAM TURBINE COMPANY.

THEIR WORKS AND PRODUCT, WITH SKETCH OF DE LAVAL, THE INVENTOR.

Carl Gustaf P. De Laval, the Swedish Inventor.

The works of the De Laval Steam Turbine Co., Trenton, N. J., were built in 1901 and occupy a unique position among the machine shops of the country in that they were the first shops in America to be devoted exclusively to the manufacture of steam turbines. The buildings embody the most modern ideas, and in design follow out certain desirable features of construction of the parent shops at Stockholm, Sweden, where the original De Laval Company is located. Besides the American and Swedish companies there are also the French De Laval Company (Societe de Laval), located at Paris, and the English company (Greenwood & Batley), at Leeds, England, so that the American works are one of a system of factories engaged in the manufacture of steam turbines and turbine machinery, under the De Laval patents, in different parts of the world.

Since the works were first put into operation at Trenton, the methods of manufacture have been systematized until the point has been reached where the quality of product, both in the matter of finish and accuracy of the individual piece and in the interchangeability of parts, is to be classed with the best work of our leading machine tool shops. This fact alone places the De Laval Company in a unique position among concerns manufacturing steam machinery, for up to the advent of the steam turbine it has not been thought necessary, or even possible, to manufacture parts of steam engines or other prime movers of corresponding sizes on the strictly interchangeable plan. In a subsequent article something will be told about the interesting methods of manufacture carried on at this plant, and the special machinery in use.

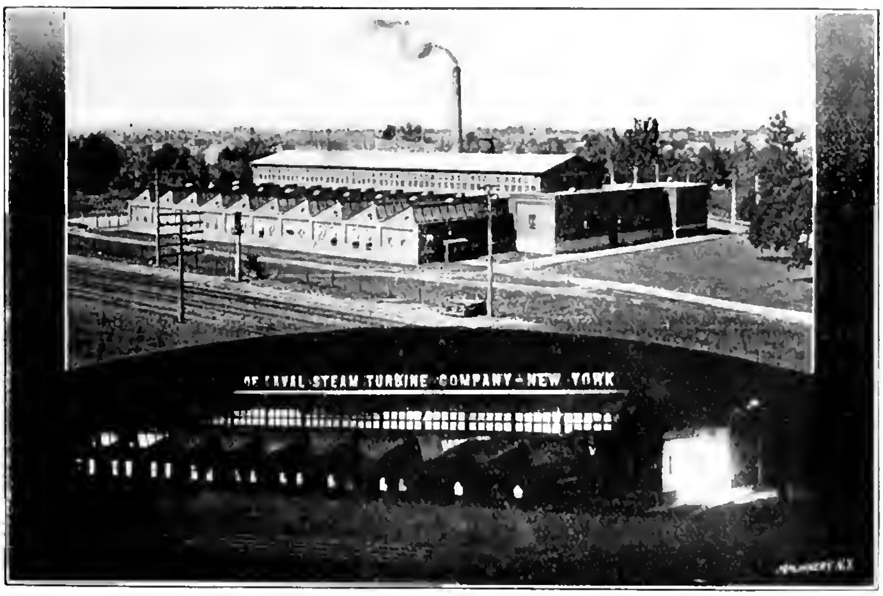


Fig 1. The Plant of the De Laval Steam Turbine Company, Trenton, N J., by day and by night. The main building is nearly a square structure, 200 by 210 feet, with a high crane shop running through the center and sections on either side lighted by saw-tooth roof At night the roof sign is lighted by reflected incandescent light generated by a turbine unit. This turbine is started after the plant is shut down at night and runs for four hours on the steam pressure remaining in the boilers, without additional firing. Steam is thus utilized which would ordinarily be lost at night by radiation.

The De Laval steam turbine must run at such extremely high speeds and, in order to compete with the steam engine, must be so reliable for constant service day in and day out, that it is absolutely necessary to have materials and workmanship as nearly faultless as possible. In fact, it is probably because of the possibility of securing uniformly high-grade materials and superior machine work that the turbine has proven its reliability under constant and severe service; for without these it would not be feasible to run a turbine wheel at 30,000 revolutions or more a minute, nor gears at a peripheral speed of eight or ten thousand feet a minute. The foreign De Laval companies have in operation about 3,000 on land and about 500 on shipboard, making more of this type than of all other foreign turbines combined; although it has not been considered advisable to construct the De Laval turbine in sizes larger than 200 K. W. capacity, so that the total horse power of these machines would be smaller in proportion than of the others. The first turbine built by the American company was in the fall of 1901, since which time over 400 have been completed, aggregating about 39,000 horse power.

Dr. Gustaf De Laval.

The original De Laval steam turbine is the invention of Dr. Gustaf De Laval, the famous Swedish scientist whose portrait appears on this page. Dr. De Laval was born at Blasenborg, Sweden, in 1845. He was educated at the University of Upsala, Sweden, and the technical University of Stockholm, where he graduated with highest honors in 1866. He was then employed with the Stora Kopparberg Mining Co., but believing his training not sufficient he decided to take a special course of several years' duration in physics and mathematics, at the University of Upsala, where he received the degree of Doctor of Philosophy. He again entered the service of the mining company and became interested in the erection of a plant for the manufacture of sulphur. Later he entered the service of the Kloster Iron Works, Germany, as mechanical engineer, and shortly afterward made his first two inventions—one relative to a new strainer, which was to effect a more perfect separation of air in Bessemer converters, and the other a crucible for galvanizing purposes. He experimented on centrifugal machinery and this led to his first ideas in connection with the centrifugal cream separators, which he believed would become of enormous importance to the agricultural and dairy industry if developed and perfected. His judgment in this has proven to be correct. The results of his efforts, in the dairy industry throughout the world, easily place him among the great inventors who have reduced the labors of mankind by their work. As the Kloster Iron Co. did not appreciate the importance of this invention he resigned and returned to Stockholm with the determination to thoroughly develop his cream separator ideas. These ideas were so radical that they met with considerable opposition, but he finally produced a commercially successful machine, and although it has since been modified the general principles have remained the same. Over 600,000 De Laval cream sep-

arators are in service to-day throughout the world; the American Separator Company making the cream separators has an extensive plant at Poughkeepsie, N. Y.

Dr. De Laval also perfected other useful inventions in connection with dairy apparatus, one of which was the "lactometer," by which the percentage of butter fat in milk could be determined in a simple manner, and the use of which modified the method of paying for milk, by dairy companies. Formerly milk had been paid for either by the quantity of milk itself or by the quantity of cream, without regard to the quantity of butter which the milk was capable of producing. The field of activity of the inventor, however, was not confined solely to agricultural machinery, for Dr. De Laval established a factory for stamping out utensils in steel, which resulted in a large and profitable industry, and he also devoted considerable time to experiments with a new type of steamboat.

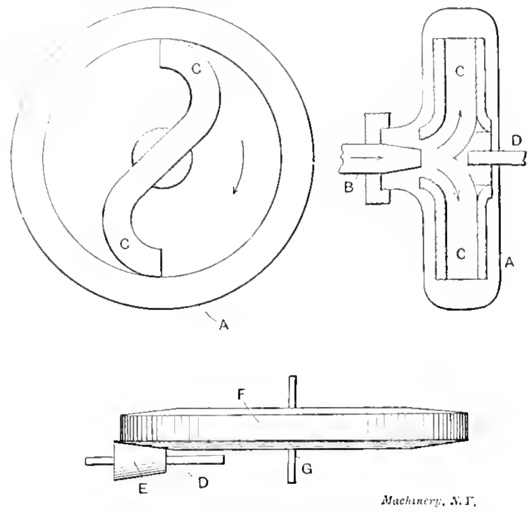

Fig. 2. The first De Laval Turbine.

In the manufacture of his separator he conceived the idea of a steam turbine as an ideal motor for driving the separator, which must itself run at extremely high speeds, and from this has grown the De Laval steam turbine industry.

About 1882 Dr. De Laval invented his first steam turbine, which was on the principle of the Hero engine. This is illustrated diagrammatically in Fig. 2. Steam (or other fluid) entered the casing *A* by nozzle *B* and passed the curved hollow arms *C C*, formed like the buckets of an outward-flow hydraulic turbine, and the passage of steam along them caused them to rotate shaft *D*. This shaft drove another at a slower speed by friction wheels, the requisite pressure between friction surfaces being obtained by the axial thrust of the turbine wheel. The first commercially practical De Laval turbine was built in 1883 and used for driving a cream separator, to which it was direct-connected. It was of the reaction type, along the lines described above, but its efficiency was low on account of the imperfect expansion of the steam. Five years later, in 1888, he invented and used the diverging expansion nozzle in which the steam was completely expanded, and which mainly is responsible for the efficiency of the De Laval turbine. He had experimented with a steam nozzle for sand blast purposes as far back as 1870 but did not hit upon the idea of the diverging nozzle until the later date. The complete expansion of the steam in the diverging nozzle necessitated considerably higher wheel velocities than he had used before, and in order to overcome the great difficulty in balancing a wheel accurately enough to revolve around its center of gravity at a peripheral velocity sometimes as high as 1,850 feet per second, without causing destructive side pressure upon the bearings, he adopted the flexible shaft which, with the diverging nozzle, is employed in the De Laval turbine of to-day. These characteristic features, as shown in Fig. 3, have become so identified with the De Laval turbine that a representation of them is used as a trade mark by the company.

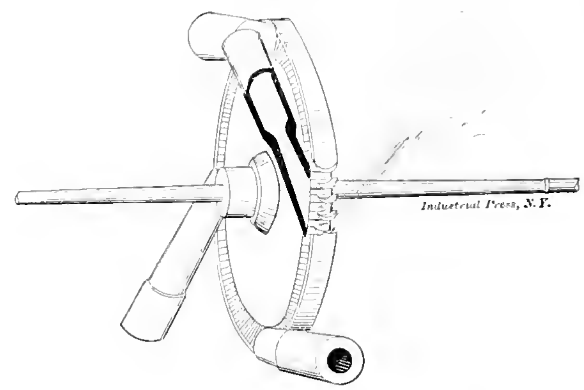

Fig. 3. The Main Elements of the present Turbine.

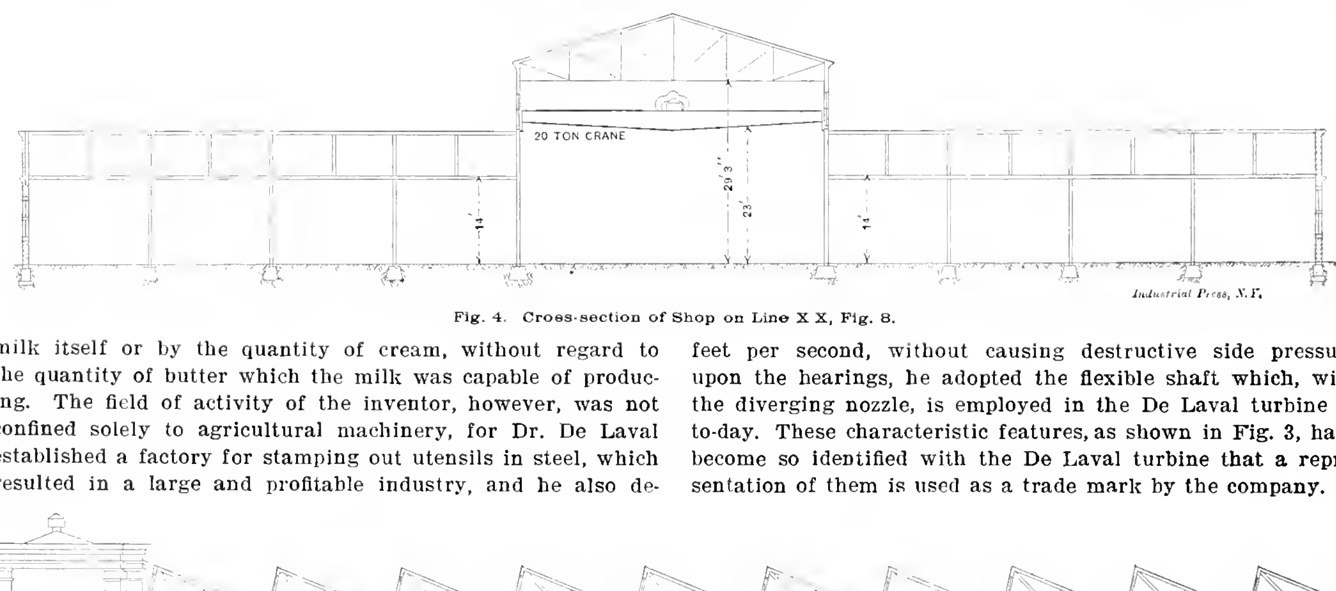

Fig. 4. Cross-section of Shop on Line X X, Fig. 8.

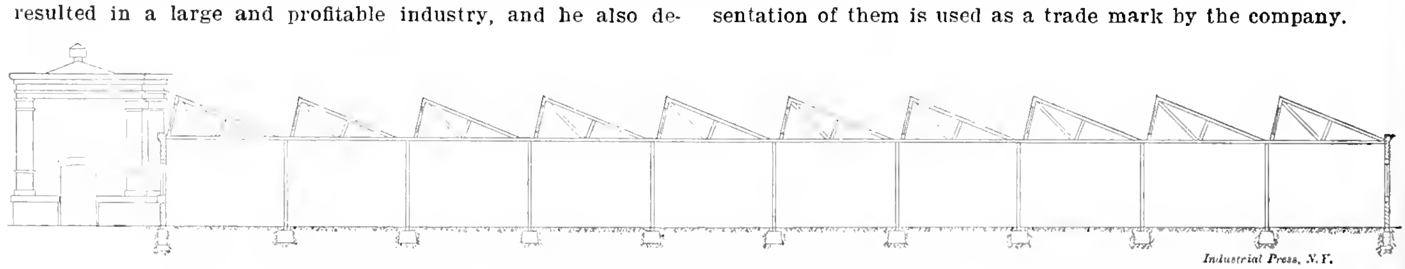

Fig. 5. Cross-section on Line Y Y, Fig. 8.

Dr. De Laval has had many distinguished honors bestowed on him by scientific and other societies and he has also served his government in various public capacities.

The De Laval Shops.

The shops at Trenton are located just outside the city limits, directly on the New York division of the Pennsylvania

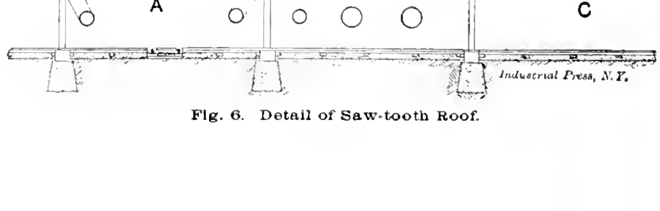

Fig. 6. Detail of Saw-tooth Roof.

Fig. 7. Side Elevation of the De Laval Works. Engine and Boiler House at the Right.

Railroad. The plot of ground contains about 10 acres and is large enough to allow an extension of about 900 feet in the length of the building, which is now 200 feet long. As stated, the buildings are of the saw-tooth type with a center crane shop 51 feet wide. The plan of the works is shown in Fig. 8 and cross-sections of the shops in Figs. 4, 5 and 6. Fig. 4 is a section taken on the line *X X*, in which the crane shop appears at the center; and the saw-tooth roof sections are shown in longitudinal section at either side. Fig. 5 is a section on the line *Y Y*, and in Fig. 6 is a detail of the saw-tooth roof construction, in which is indicated the location of one of the traveling hand cranes by which work is brought to the machine tools. The positions of the shafting are also indicated. The shop is served by two sidings from the railroad and also by its own individual shop tracks for transferring castings and completed machines from one part of the works to another. At present the offices and drawing rooms are located at *A*, Fig. 8, in one corner of the shop building, but an office building at the front of the shop is contemplated, as indicated in the plan.

The side view of the works, Fig. 7, shows the relative proportions of the main shop and the lower sections, as well as the location of the engine house, testing laboratory, etc.

Power is supplied by a steam turbine unit of 200 K. W. capacity built in Sweden, which has been in constant service almost without interruption since its installation, and the spiral gears and pinion and other parts, such as bearings, show no perceptible wear. The works are electrically driven, the smaller tools by the group system and the larger ones by individual motors. An interesting feature is the testing room, shown at *F* in Fig. 12. Here all turbine units are tested before shipping. The testing room is equipped with a large water rheostat, the water tanks being placed outside the building, after the usual custom, and there are also two

tanks beneath the floor of the testing room, to enable the centrifugal pumps, which form an important part of the products of the company, to be readily tested. The illustration *F*, Fig. 12, was taken while Prof. Denton, of Stevens Institute of Technology and Mr. Wm. Kent, consulting engineer, were conducting a trial of centrifugal pumps referred to later.

In the first illustration, showing the plant by day and by night, the illuminated sign is a conspicuous feature of the view, at night. This sign is painted a light cream color and is visible at night by reflected light by means of incandescent lamps. The lamps are placed in a reflector at the top of the letters, and three or four feet in front of same. It is interesting to note that the sign is lighted at practically no cost; that is, the boiler plant which has a capacity of 500 H. P. with a steam pressure of 200 pounds per square inch was found to be sufficiently large to operate a 30 H. P., 20 K. W. turbine dynamo running at about 70 pounds of steam pressure for four hours each night, practically without firing. One of these units was therefore installed, and the steam used for operating it after the close of the shops is merely that which was formerly wasted by morning through radiation, etc. All that is necessary is to place about 15 or 20 shovelfuls of coal on the grate at 10 o'clock at night. The lights are turned on at 7 o'clock and shut off at 11, after which the fires are banked the same as was formerly done after shutting down the shop. The machine is looked after by the regular watchman and therefore does not cost anything for attendance.

Electric Generating Sets.

The essential features of the DeLaval turbine are familiar to many of our readers; and, in any case, as it is proposed to enter into a detailed description of the construction in a subsequent article it will not be necessary to give more than passing notice to its features in the present article.

First to be noted in the turbine are the bucket wheel, flexible shaft, and the ring of nozzles, as mentioned above. The wheel rotates in a steel casing and the shaft is supported in bearings outside of the casing and also by a type of spherical stuffing box in the walls, to prevent the passage of steam or air around the shaft.

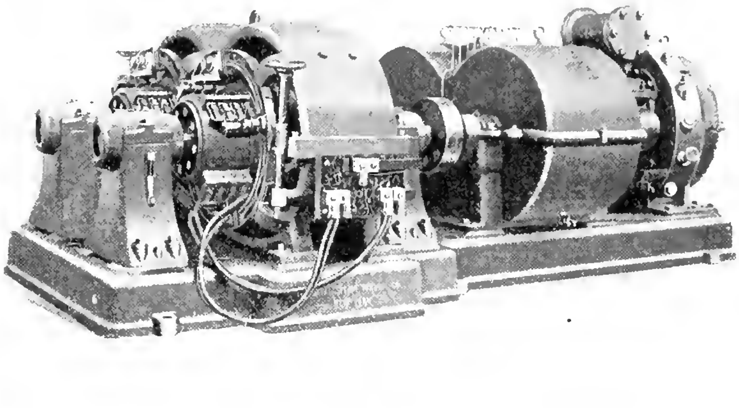

Fig. 9. Electric Generating Set, with Double Direct-current Bullock Generators.

On one end of the flexible shaft is a small spiral pinion which, in the smaller sizes, meshes with a single large spiral gear, and the larger sizes with two gears placed one on each side of the pinion. This latter arrangement balances the thrust of the gear transmission and also has other advantages for electrical generating and for driving compound pumps, as will shortly be explained. The turbine wheel rotates at speeds ranging from 10,000 to 30,000 revolutions per minute, and the smaller sizes have run up to 50,000 revolutions per minute, or more, under test. The gear shafts are reduced in speed so as to rotate at from 900 to 3,000 revolutions per minute, according to the size of the machine, which has been found satisfactory for dynamo driving and unusually well adapted for centrifugal pumps and blowers.

De Laval turbines find their widest application in connection with electrical generators. The turbines and generators are mounted as one unit on a single bedplate, and are all tested under full load before leaving the factory. At present the electric generating units are built in sizes of from 7 to 300 brake horse power, or 4-6/10 to 200 kilowatts. Up to 55 horse power, the De Laval turbine is built with the single large gear driven by the pinion on the turbine shaft; and in sizes above 55 horse power where the two-gear transmission is used, with two generators mounted side by side, as in the illustration Fig. 9. These larger sizes are especially

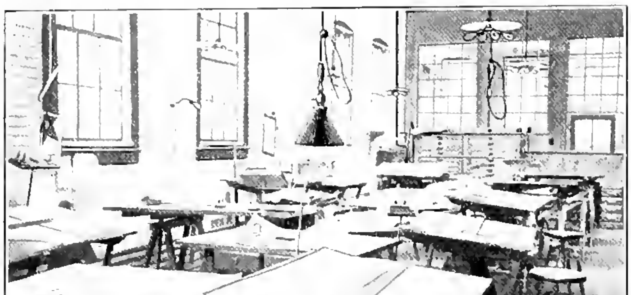

Fig. 11. Drawing Room.

adapted for factory purposes as they can be used either on a two- or three-wire system, running two voltages from the same unit, so that the motors distributed throughout the factory can be operated at one voltage and the lights at another. Thus, if 125-volt generators are supplied the lighting circuit would be connected in parallel, giving 125 volts for this purpose, and the motor circuit in series giving 250 volts. Owing to the short distance between the shaft centers it is possible to combine what would otherwise be two separate generator frames into one, at the same time leaving two openings in which the armatures revolve. The novelty of the arrangement is confined solely to its mechanical construction, and the dual generator is really nothing more than two generators separate in all their functions, but with their frames combined in a single casting.

When it comes to applying the turbine to alternating current generators provision must be made for rotors of larger diameter than the armature of the direct-current machines. Accordingly the generators, instead of being side by side are placed one in advance of the other. The size of the generator castings, therefore, is limited only by the condition that the frame of the machine nearest the turbine shall not come in contact with the driving shaft which passes by it to the generator furthest from the turbine. With this arrangement there is ample room for the alternating current machines when operated at the speeds of the geared shafts. The alternating current set makes a neat and compact unit, and the generators run at a high enough speed so that the exciter

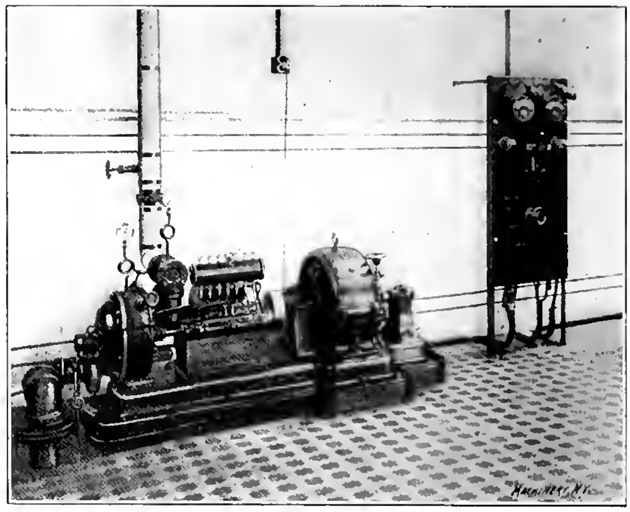

Fig 10. Thirty H. P. Generating Set in Power Plant for Lighting the Sign on Roof of Building (Fig. 1)

can be connected directly with the end of one of the gear shafts, thus dispensing with a belt connection.

Application to Centrifugal Pumps.

One of the successful uses of the De Laval turbine is in the operation of centrifugal pumps. This has not been considered as efficient as the plunger pump, mainly because of the low speed and imperfect design of such apparatus, and it has also been adapted only to low lifts. As the De Laval Steam Turbine Company were building high-speed turbines, however, which ran at speeds almost exactly the same as would be required to produce maximum efficiency in centrifugal pumps adapted to the different sizes of turbines, it was decided to design a series of pumps, of improved mechanical construction, which would admit of the high speeds necessary, and which would also enable the pumps to work against high heads. These pumps are supplied in connection with the turbines, or independently, to be driven by electric motor, when it is desired to locate the pump apart from the prime mover. The smaller units consist of a single pump, just as the small generator units have a single generator; but the larger units have two pumps driven by the double-gear turbine, one pump being connected to each gear shaft, permitting their operation in parallel for low pressure, and in series when high lifts are desired. Standard sets are built in sizes from 7 to 300 horse power for all heads up to 300 feet, handling from 90 to 26,000 gallons per minute. Lately a high-pressure centrifugal has been developed with the forcing pump having a runner of very small diameter

attached to the turbine shaft and rotating at the extremely high speed of that shaft. The centrifugal force developed by the runner under these conditions makes it possible to pump against heads of 600 to 1,000 feet, and to use the pump for boiler feeding. A runner operating at such high speed, however, would force out the water more rapidly than it could draw it in by suction, or under atmospheric pressure only, and hence the pressure pump is flooded with water at sufficient pressure to ensure an adequate supply, by a pump on the geared shaft.

The pump case, the lower half of which, together with the runner and shaft, is shown in Fig. 15, [illegible] through the center of the main bearing so that [illegible] is removed a thorough examination may be made [illegible] the working parts or any of the pipe connections. [illegible] centrifugal pumps the packing about the shaft serve[illegible] as a bearing and soon becomes worn, but in this machine the bearings are entirely independent of the shaft packing and are of the ring-oiling type. The lubricant thus cannot enter the pump chamber, which is important where a liquid would be damaged by the oil. Where hot water is to be handled flax packing is used, and where cold water is pumped

a cupped leather packing is employed, which is set out by the water pressure and prevents leakage of both water and air.

Water is drawn into the lower part of the pump casing and enters the runner at its center and is thrown outward through the runner in a radial direction by centrifugal force. The suction pipe connects with the portions of the casing

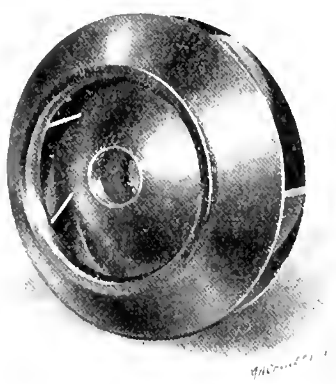

Fig. 14 Runner of Centrifugal Pump.

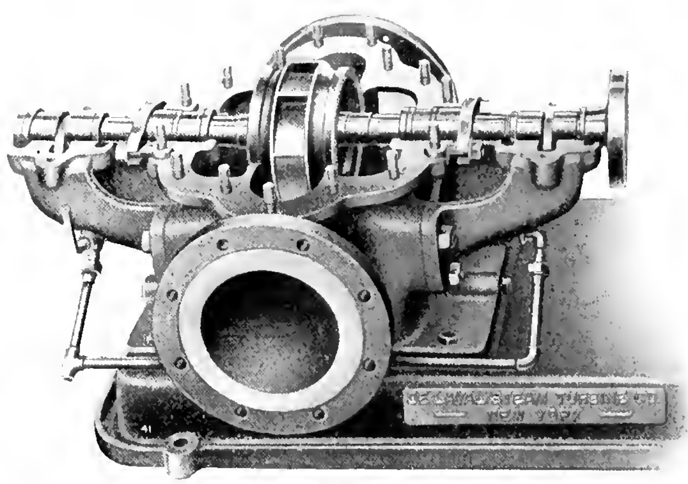

Fig. 15. Centrifugal Pump with top of Casing Removed

located at each side of the runner, Fig. 15, and the discharge pipe connects with the central portion in which the runner itself is located. The suction and discharge chambers are separated by vertical webs in the pump casing, bored to fit the cylindrical ends of the runner, as clearly indicated in Fig. 15. The liquid must therefore flow into and through the runner in order to pass from the suction into the discharge chambers. A channel cored in the casing runs from the high-pressure chamber to the packing glands and sets out the packings, as mentioned above. The outside of the packing is subjected only to the pressure of the suction chambers. The shaft is made of steel and provided with brass protecting sleeves at the packings and which also extend inward so as to prevent the steel shaft coming in contact with the liquid to be pumped. The runners are usually of bronze so that pumps may be used for corrosive liquids.

The development of centrifugal pumps at these works, and in connection with the De Laval turbine, it may be said, is only one instance where the centrifugal pump appears to be gaining ground over its older rival. Centrifugal pumps are used for general pumping conditions such as water works, irrigation, condenser circulation, boiler feeding, pumping pulp, sewage, heavy oils, etc. As constructed by the De Laval Company they give excellent satisfaction in handling liquids containing grit, because the only part to wear are the runners, the brass sleeves and the bearings; and as all the parts are interchangeable and easily accessible, any of them can be replaced on short notice. Such pumps have the advantage of absence of valves and water hammers, freedom from accidents due to breaks in pipe lines or losses in pressure, and the possibility of limiting the maximum obtainable pressure to any desired amount, by simply regulating the speed of

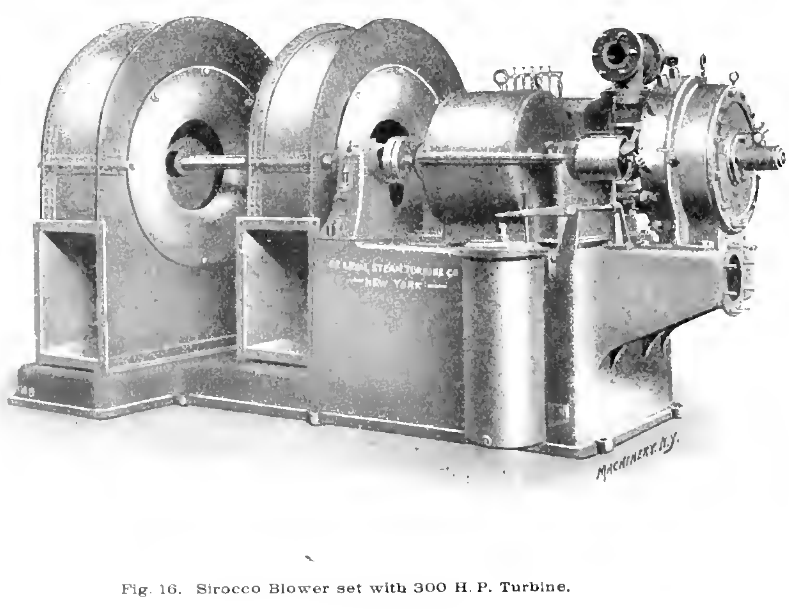

Fig. 16. Sirocco Blower set with 300 H. P. Turbine.

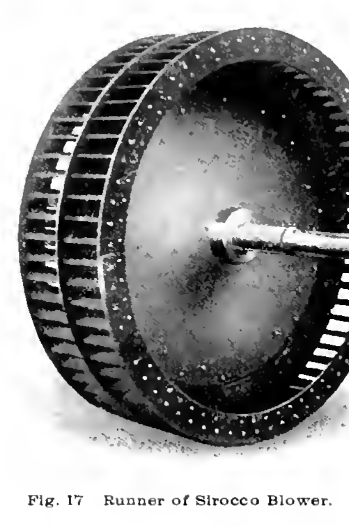

Fig. 17 Runner of Sirocco Blower.

rotation, thus insuring safety of parts of pump and pipe line.

Three centrifugal pumps were recently tested by Prof. Denton and Mr. Wm. Kent at the De Laval testing laboratory, and the results were summarized in the August number of MACHINERY. No. 1 was a single-stage machine designed to lift 1,700 gallons of water per minute against a head of 100 feet. It was driven by a 55 horse power turbine with a speed reduction of 10 to 1, and was found to require a maximum of 44½ horse power. The efficiency of the pump to the brake horse power of the turbine ranges from .743 to .756; the duty about 61,000,000 foot pounds per 1,000 pounds of steam, and the steam consumption per brake horse power about 24.25 pounds per brake horse power hour. No. 2 pump was driven by electric motor and showed similar results to the above. The third pump was a two-stage machine designed to lift 250 gallons per minute against a head of 700 feet with a large runner turning at the rate of 2,050 revolutions per minute and the small one at the rate of 20,500 revolutions per minute. This was one of the new high-pressure pumps with a small runner connected directly to the turbine shaft. The duty in million foot pounds ranges from 41.55 at a head of 494 feet to 48.88 at a head of 781 feet.

Blower Sets.

Another field where the De Laval turbine is well adapted is for direct connection to blowers for water pressures between 4 and 21 inches. The high velocity of the turbine makes it feasible to use such blower units for locations and pressures where the positive acting impeller blowers have been employed. The turbine is used in connection with blowers of the Sturtevant and Sirocco type. When directly connected to the blowers, the whole forms a compact unit, and eliminates the trouble from tight belts and heated bearings met with in attempting to use blowers for high pressures. A Sirocco blower set is illustrated in Fig. 16, and in Fig. 17 is a runner for one of these blowers. The blades of the runner are narrow and ranged around the circumference. They are concave and the runner rotates so that the concave sides lead. The theory of the blower is the reverse of the theory of a turbine water wheel; that is, the escaping air is the reverse in direction and corresponds in velocity to the jet of water which impinges against the blades of a turbine and like the jet of water has a higher velocity than either of the other components forming the parallelogram of forces acting at the edge of the blades. The air therefore has an augmented velocity with this type of runner at the point of escape which makes this type compact for a given capacity. The Sirocco blower is well adapted for the double-shaft turbine because it is of smaller diameter for a given capacity than the ordinary type; and by arranging the two blowers as in Fig 16 so they overlap in a manner similar to the arrangement of the alternating current generating set mentioned above, there is room for blowers of the required diameter for the speed at which the geared turbine shafts run. At the front of the bedplate, Fig. 16, there will be noticed a vertical cylinder, which is a regulator connected with the governor for varying the speed of the turbine slightly in order to maintain a constant air pressure. This cylinder is connected with the discharge ducts of the blowers and contains a weighted plunger which balances the air pressure underneath.

* * *

The serial articles "A Review of Steam Turbine Patents," and "Variable-speed Motors," the latter by Mr. Baxter, are omitted from this number of the paper, but will appear in the November issue.

* * *

What should prove an important discovery, if practicable, is that of a Philadelphia inventor for alloying copper with iron. Mr. Darling believes that he has discovered a process whereby a perfectly homogeneous alloy of copper and iron can be made in varying proportions up to 85 per cent. iron. An oxide of iron, either hematite or black oxide, is used, and if, for instance, a fifty per cent. alloy is wanted, three parts of oxide are mixed with one part of calcium carbide for the iron constituent; eighteen parts of this iron constituent are used with eight parts of copper. The copper is first melted in a crucible and the iron oxide mixture is slowly added a little at a time as the temperature is gradually increased.

TOOL STEEL FORGING AND TEMPERING.

Air hardening or special steel is a combination of various metals in various proportions with iron and carbon. These alloys give steel the power of holding an edge at a temperature, say, of 600 F. when the cutting edge of carbon steel is ruined. Various modes of treatment are specified or given as directions by the manufacturers, but by experiment the toolsmith occasionally treats the steel in a different manner, and gets better results. As to treatment most of these steels require the point to be slightly fused before cooling and grinding. This we would imagine turns the cement carbon to hardening carbon, and brings the outer surface up to the hardness of chilled cast iron, when under the influence of the air blast. Tools made from this steel should have short points and the steel should be of the largest section that can be used with the least possible clearance so as to conduct the heat away as rapidly as possible.

Air hardening is generally used for rough work where surplus metal has to be removed at a rapid rate and should be ground on wet grinders. Several brands of this special steel are almost unworkable or rather unforgeable. This class is not brought up to a weld at the point for the purpose of hardening, but is cooled in air blast; other brands again can be forged at the same heat as ordinary tool steel. These last are more economical to use, for when they are too short they can be drawn out for smaller work. The high prices being taken into consideration the unworkable grades are almost valueless when too short. By unworkable is meant those kinds that are used without forging, being cut off and shaped on an emery grinder. We must also bear in mind that since air-hardening steel deteriorates in heating and working at the forge, this process cannot be carried on as often as with carbon steel.

Carbon or tool steel holds a finer edge than the air-hardening variety and can be forged or worked into any shape required, and will always be used for tools required for exact work and tools urged by impact. There should be about three grades, the first for taps, milling cutters, reamers and screw-cutting dies, also for special tools used in tool making lathes; the next grade for machinists' chisels, cold sets, hammers, button sets, hot chisels, punches for machines, shear blades, etc.; the next grade for flatters, swedges, dies for working hot metals, bolt heading and forging machines. These latter can be made from open hearth steel.

Where there is a furnace for heating tools and a pyrometer to gage the heat, the tool question is reduced to a science. What is wanted is a good grade of steel for the tool required, then there is no danger of a poor tool. In making tools we must take into consideration the cost of such tools; first the cost of the steel in the bar; second, the making of the tools. A third consideration is the endurance of the tool, and taken in connection with the rate at which the tool can work determines very largely its economy. In most cases the wear and the cost of redressing and regrinding is less for tools made of high grade than of low grade steel, so that it is generally cheaper to make all tools of a good grade of steel than an inferior grade. We would remind you that at all times in forging and tempering tools it is necessary to have a good clean fire with plenty of suitable fuel between the tuyere iron and the tool to prevent the cold blast coming in contact with the tool, and to avoid too high a heat as there are more tools spoiled by overheating than otherwise.

In annealing it is impossible to avoid a slight lowering of the percentage of carbon on the surface of the annealed metal; the decarbonization takes place to a depth of 1-16 to 1/8 inch. In every case where the finished article, such as dies or cutters, is to be hardened this partially decarbonized skin should be removed before the steel is machined to finished size or shape, so sufficient stock must be allowed for this purpose when forged.

There is one great evil that is hard to overcome, *i. e.*, the many brands of steel that will accumulate in the average steel room. The tool smith may expect to find from six to ten different brands of steel, with the labels defaced, con-

* Abstract of report submitted by Mr. R. H. Henderson to the Twelfth Annual Convention of the National Railroad Blacksmiths' Association at Indianapolis, August 18, 1904.

sequently he is at a loss to know what he is using. When in doubt we know of no better way than to follow the recommendation of the committee on the treatment of high carbon steel of the eighth annual report as follows: Select the nearest size steel required for the tool you wish to make, draw the same down to a point. If this can be done without fracture you may assume the quality is good. The lowest heat that will give the desired hardness is the best, and if on breaking the point you find that the steel has a finer grain than the original bar the question of quality and temper is cheaply settled. This simple test will repay the cost many times over. If the steel manufacturers would brand their steel on the ends of the bars with their brands, also the number on each bar to denote its carbon temper—5, 6, 7 denoting 50, 60, 70 per cent. of carbon, respectively, the practice would greatly reduce the number of poor tools. When this practice is followed the tool-smith should stamp each tool where practicable with the corresponding number on the bar so that in redressing and tempering those tools they will know just what grade of steel they were handling and can govern themselves accordingly.

* * *

FROM MR. BLAKE.

Editor MACHINERY:

In reference to the articles in the last number by Messrs. Graham and Myers, in criticism of C. F. Blake's article in a previous issue upon "Beams and Planes Eccentrically Loaded and Severally Supported," we have the following communication from Mr. Blake:

"I should explain that my article was not sent as a finished, scientific treatise of the subject, but only as *one* attempt to solve a difficult problem, about which nothing could be found in a well-equipped engineering library; and I thought it time to make this explanation when the discussion I hoped for was brought out. For my own benefit I wish to see more light on the subject.

"The problem arose when we had a built-up frame of structural shapes, supported at several points and loaded at a known point: Required the reactions at supports. It was discussed by several designers and engineers, with the result as I gave it. During the discussion the claim was made that the problem was indeterminate, but that did not satisfy us, since the same reactions, if measured, would appear at each application of the load, and these reactions we wished to find, because we were up against an actual case in iron and steel, and not engaged in a fine-haired scientific discussion.

"While therefore agreeing with Mr. Graham that 'only three points are required to support a plane,' we had to look conditions in the face and could not dismiss the subject by saying that 'if more are used the division of the load is arbitrary,' because if placed by an arbitrary system, that system was not of our making, and we had to find the reactions existing, not those resulting from some arbitrary arrangement of our own. We realized that the method is only absolutely correct with a perfectly rigid body, but found no way of introducing a correction for deflections, short of a very arbitrary way, which might or might not (probably not), be in accordance with the way that nature had distributed the reactions in our particular frame. We tried, as suggested by Mr. Myers, to avoid the construction that gave rise to our troubles, but could not do so. I think Mr. Graham has not entirely made out his point in distributing the reactions. He says the particular four-armed spider shown is not in equilibrium about rectangular axes, but does not tell us where to place the origin of these axes, nor the direction of the same. Now it seems to me that the geometrical center of gravity of the supports is a point that must be recognized, and it logically becomes the origin of these rectangular axes. The direction of the axes is determined by the direction of the line joining the center of gravity of the load with the geometrical center of gravity of the supports. At any rate, as far as he goes up to this point, I have as much right to claim these as the rectangular axes as any other, and I think I am right in so doing. If this point is granted, then his spider would not be in equilibrium, while mine would. Later he *assumes* the origin at B with O B as direction, but why? It is unfortunate that I chose a four-armed spider as my illustration, since it gives Mr. Graham an opportunity to divide the load in a manner seemingly impossible with a spider of uneven number of arms, and I should like to ask him to extend his method to a spider having five arms. Mr. Graham's treatment of the subject after he has obtained his reactions seems particularly good, and is a point worth bringing out.

"I should like to see a thorough discussion of this problem, and if any can throw light upon it, I hope they will do so.

"C. F. BLAKE."

* * *

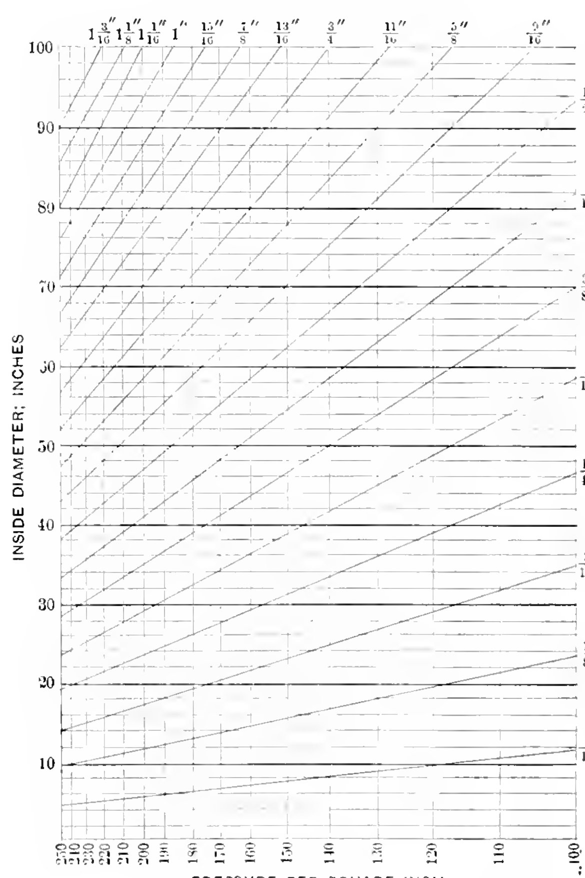
One of the useful applications of the electric motor is the operation of large valves. In the modern steam plant many of the valves are of such large size that if manually operated, two men often must be employed, and the closing or opening is slow. When electrically operated all the important valves can be wired so as to be under the immediate control of one operator. In emergencies a fraction of a minute lost in the closing of a main steam valve may mean all the difference between a trifling accident and an appalling disaster. A little wrinkle in the application of the motor to large valves, as practiced by one large electrical concern, is arranging the reducing gearing so that the motor can attain full speed before the valve begins to open. In this way a hammer blow is struck that does not fail to "crack" the valve disk loose from its seat; if the valve were made to open with the starting of the motor, frequently its torque would be insufficient to start it loose, although ample for opening it after the initial movement had been accomplished.

* * *

BOILER SHELL CHART.

The accompanying chart, contributed by Mr. A. A. Kellogg, of Green Island, N. Y., gives a graphical means of finding the thickness of boiler shell material for the cylindrical portion of locomotive or other type boilers, when the diameter and

TO FIND THICKNESS OF SHEET FOR ANY GIVEN BOILER DIAMETER: FROM INSIDE DIMENSION OF BOILER READ OVER TO RATED STEAM PRESSURE AND USE THICKNESS SHOWN BY NEAREST DIAGONAL.



steam pressure are known. It is laid out to give a nominal factor of safety of 6, with steel plate having an ultimate tensile strength of 55,000 pounds per square inch of section. The ordinates or verticals represent boiler diameters, in

inches, and the abscissæ or horizontals, the boiler pressures, in pounds. By tracing the horizontal line from any given diameter to its intersection with the vertical for the given boiler pressure, the thickness of steel plate required may be read directly at the upper end of the nearest diagonal. For example, what thickness of plate should be used for a boiler shell 80 inches diameter, carrying a pressure of 160 pounds per square inch? The intersection of the 80-inch diameter horizontal and the 160-pound vertical coincides with the diagonal representing 11-16-inch plate, which is the thickness required. Of course, steel-plate of this thickness and 55,000 pounds tensile strength would not make a boiler having a factor of 6, for the reason that the longitudinal seam is necessarily weaker than the solid plate, but such seams are now easily made over 80 per cent. efficiency, so that we can safely count on a factor of 5, which is the one commonly accepted.

* * *

THE PRACTICAL INSPECTOR.

E. N. PERCY.

E. N. Percy.

The inspector's duty is to represent his employer, and see that his employer's conditions are complied with in the most approved manner. The engineering inspector holds a responsible position, and should be, and usually is, a man of long experience and sterling character. Whether he is inspecting materials, construction, plants in operation, or steamships, he must be a specialist in his particular line in order to properly represent his employer.

Inspection begins with the raw product. Pig iron is tested by chemistry and with the microscope. It is broken, that the inspector may observe its texture, and crystallization; also, that he may note the amount of free graphite and carbon sprinkled through it. For first-class castings he should not pass any pigs full of dirt or slag. The proper mixtures of the various irons for a given class of castings must be personally seen to on any large or important work. In the manufacture of steel for forgings, castings or tools, the blistering or puddling processes are noted, and the inspector sees that all coupons for chemical and physical tests are cut actually from the rails or billets or sections they represent, and that said coupons suffer no subsequent "doctoring," tempering or annealing.

In all Bessemerized steel, he will see the blow at the converter, note that it is oxidized clean, until all colors disappear and white flame appears. He will have coupons made on important castings, and have buttons for chemical analysis cast from the same blow. He must see that these button molds are not filled with slag, or melted clay or flux instead of steel. He should also see that large castings are properly cooled, so as to have the least possible internal strain. With rolled sections, forgings and plate work, there are apt to be laminations, where scale or carbon has interfered with the welding of the different parts of a section.

Copper pig requires only the most superficial inspection, as it never contains visible impurities. Chemical analysis may show traces of silver or gold, which can do no harm. If, however, it is found to contain zinc or tin, it should not be used near salt water, without certain precautions to prevent galvanic corrosion. Tin, zinc, antimony and lead can be accepted as generally sold unless required especially pure for some particular reason. Commercially pure metal, while answering most purposes, may cost many times as much if required chemically pure.

The inspection of crude oil is a specialty not to be treated here, except as a fuel; but of its finished products in the lubricating line, we will speak later. An oil which has a specific gravity of .926 at 60 degrees F. and a flash point of 260 degrees F. will burn nicely with a little warming, and be perfectly safe. The flash point should not be below 180 degrees or better, 200 degrees. Beaumont oil, by one analysis contains 83.26 per cent. of carbon, 12.41 per cent. of hydrogen and 3.8 per cent. of oxygen. This may be considered a very rich oil and will give 19.481 B. T. U. per pound. To test for flash point, warm up a thimbleful with a thermometer in it, and note at what temperature it can be lit with a match. This should be done very quickly, or the more volatile gases will ignite first, giving an imperfect result.

To select good coal, wherever it may come from, choose the hard, shiny lumps, whose dust shines like diamonds when dry, and do not select mushy, soft, dull coal that smells of bitumen or heavy oil.

Next, after raw products, the inspector has to deal with the finished, or partially finished article. All castings require careful inspection. Look in all angles and fillets for cracks. If the iron suddenly changes thickness, test with hammer to see if the iron sounds strained. Note if workmanship is good, and if it is properly annealed or chilled, as the case may be. See that the iron has run well together at all points. Sometimes the iron will "freeze" and not come up well somewhere. There are often stream lines in cases where the iron has run, but was cool, and welded imperfectly. The casting should be of even thickness where intended. If a very tall casting, the head of iron is apt to compress the sand at the bottom and make the iron thicker there. Also, the cores will sometimes shift, or float. If chaplets are permitted, they should be tapped, to see if loose. They should be properly calked, if leaky, and should be so inserted that their edges are covered and hidden by the metal. Chaplets should be tested very carefully. The writer has in mind an over-zealous inspector who tapped on a chaplet until it was so loose it could not be fixed, and in removing it, the casting was ruined. The casting was worth many hundred dollars. Bronze and brass castings are apt to leak in cases where one crucible is poured in, and then another, and so on, where the casting is large enough to require several crucibles of material. The joining lines of these "pours" can always be seen. They may assume the appearance of a thin scale, and such "scale" on bronze castings should be very carefully examined.

Ribs and ties should be carefully tapped with a light hammer to ascertain any difference in tension. Spongy spots should be carefully considered in regard to their location, etc. If, as is an excellent plan, the more important castings are tested by hydrostatic pressure, they should be tested at about 50 per cent. more than their maximum working pressure. Wherever a fine sweat appears, that part should be marked with chalk, and pened inside until it leaks no more. Should the leaks be numerous, and fine streams of water appear in many places, and the casting show signs of distress, it must be rejected. No internal shellacing, oiling, or plugging should be allowed previous to the test. Some builders resort to many tricks in these tests. They use heavy oil instead of water, because it will not come through defective iron so easily. They cut out defective parts of castings, and insert plugs. One worthy ran the pump pipe straight through the casting to the gage prominently displayed on top. He filled the casting with water, pumped up the gage and called the inspector. The inspector thought the gage was remarkably responsive to the pump, and called an investigation. The worthy gentleman explained that "he meant to put a hole in the pipe, but forgot to." The inspector should always see that there is a "hole in the pipe."

Castings should be carefully measured, tested for roundness or straightness, and their squareness to other parts of machinery noted. Forgings are inspected for flaws, cracks, imperfect welds, burns, temper, springiness, and the coupons tested for strength. Each large forging should have two coupons taken from it—one for bending test, and one for tensile—and the inspector must see that these are not subjected to any treatment subsequent to their removal from the forg-

E. N. PERCY was for a time employed in the machine shops of the Vance Mill & Lumber Co., and then attended the Lick Technical School for three terms, taking the mechanical and scientific studies. For two years he went to sea as a junior engineer, then for two years he was with the Geo. E. Dow Pumping Engine Company as designer. He also worked for one year, as designer, for the Union Iron Works. Since then he has been inspector of machinery for the United States Government. Some of his more important work has been in connection with designs for the steamship *Whittier*, and the battleship *Ohio*; for the San Francisco Gas and Electric Co.'s plant; and some hydraulic work.

ing. Plates should be examined for laminations, cracks, blisters, buckles, thickness, scale, and general condition. Plates are apt to show cracks around punched rivet holes, or sheared edges. A blister should be drilled into, and, if merely a buckle, it can be planed out, but if laminations filled with scale show up, the plate must be rejected, unless the blister can be cut out. If plates are pickled, tempered, or put through any other process, it should be carefully noted, as more depends upon plates, and they carry greater loads in comparison to their capacity, than any other material of engineering.

The inspector himself should see all bronzes and babbitts for important castings compounded and melted. He will be present when the larger bearings are fitted, and note the oil grooves and holes and provisions for lubrication.

Coupons from forgings, castings, and plates for bending tests, shall be ½ x 1 inch by 8 or 10 inches in length. They can be bent in any hydraulic press to a radius whose length shall be determined by the qualities the metal should have. Coupons for tensile strength of iron castings and steel are round, ½ inch diameter by 3 inches long, with enlarged screw ends for testing machine. At 1 inch each side of the middle a center punch mark will be made. From these, the elongation after rupture can be measured. The reduction of area is also noted, and the number of pounds to break the coupon. This latter is changed by computation to pounds per square inch.

Boiler and machine steel run about 65,000 pounds per square inch. Nickel steel runs from 95,000 to 105,000 pounds per square inch, with 25 per cent. elongation, and 15 per cent. reduction of area. The requirements for steel change continually, and the inspector must obtain this from experience, study, instructions or specifications.

An inspector of foundations must see that the piling is full length, and driven without splintering, that the spring mat, rubble and cement are of the proper kind, that the cement contractor places the foundation bolts according to the template, and that the template is according to the engine. The foundation should be dry, and the flywheel or armature pit should have an accessible trap to sewer, with stairs down to it, if possible.

Probably the most important duty given to an inspector is the inspection of an elevator or a steam boiler, because they concern human lives. For a new boiler, it is merely filled with water, pumped up, and tested at 30 to 50 per cent. of excess pressure. If no rivets or seams leak, and stays and tubes are all sound, the boiler is emptied, and the inspector enters to sound the stays, to see that the calking tools have not grooved the plates, and that the boiler is free from mud and oil. The first time a boiler is steamed up, he sees that no oil or grease gets in from the condenser during the trial; that all rivet holes are drilled, not punched; that holes for tubes all flare properly, and that no cracked, split, or crooked tubes are used. The calking must be done by *upsetting* the corner of the plate, *not* by *splitting*. The grate bars must be suited to the coal they will burn, and of such shape that they will not warp. The boiler must be well supported, and accurately aligned. Brickwork should never take any of the boiler weight. The safety valve must be tried, its seat inspected, the weight or spring set, tested, locked and a key given to the proper party. In an old boiler, additional inspection as follows is required. 1st. Internal, for corrosion, scale, loose stays, burns, pockets, mud and thickness of metal.

2d. External, for rust, strength of supports, thickness of metal, ends of tubes, interior of furnaces and stacks. Water gages must be inspected and tested, also gage cocks. The steam gage must be calibrated, and there should be at least two ways of feeding the boiler.

3d. For all special requirements of the employer whom the inspector represents.

To inspect an elevator, first note the condition of the cables—how many ends are sticking out, how worn it is, how its terminals are secured, and how many there are. Then the sheaves should be carefully inspected. Any sheave that has a piece of the flange gone, larger than half the section of the cable, should be condemned as dangerous.

Sheave bearings and axles come next; then the motive power. If rams, see that all work smoothly. Look at the cup leathers, note if they are new, and if there are plenty on each ram. If electric, look at the worm gears, or screw, and see that neither wears too much in one place. Engineers are very apt to set up the driving nut so tight on the worn part of the screw, that when the nut reaches the newer part of screw, the ball bearings are crushed, and the elevator locked between floors.

The regulating devices must also be carefully inspected. See that the ropes are not worn, that the rheostats swing easily, and, in the case of a hydraulic plant, note the condition of the regulating valves, that they move easily, and that the main valves do not leak. The governor should be set properly, and given a thorough test at full speed.

The pumps or dynamos should be inspected to ascertain their condition and means of regulation. The air chambers, compensators, shock plungers, etc., should be carefully looked after. All elbows and tees carrying high pressure water must be thoroughly tested with a prick punch and hammer to see if the high velocity has cut them dangerously thin.

The safety appliances must be tried as nearly as possible under actual conditions. With air-cushion machines, they should at least once a year be dropped from the top of the building to test the cushion. It is not advisable for the inspector to ride during this test, but he might invite the maker of the elevator to do so.

The inspection of wood for engineering purposes is a specialty belonging to the expert lumberman, but an inspector can assure himself that it is of good quality, straight grained and free from knots. If it is chosen for lagging, he need look but for beauty alone.

He must learn to know the good and bad qualities of paint, varnish, oil, lubricants, glass, packing, tools, rubber, pumps, stokers, auxiliary machinery and all supplies for the engineer. This comes only from experience and wide reading.

The inspector is made use of and employed by insurance companies, buyers of machinery, steel companies, governments, navies, and all who buy or build machinery.

* * *

One of the strange features of mining is the existence of subterranean fires that have raged in abandoned coal mines for many years. One of these burning mines is the Greenwood Colliery, near Wilkesbarre, Pa. It has been burning for nearly fifty years and, so far, has resisted all attempts to quench it. Flooding with water is not effective, partly because the burning vein is above the natural water level, but largely because the imprisoned air and gas prevent the water reaching the fire. A determined effort is now to be made by the company to quench the fire, and drill holes have been bored, through which water charged with culm will be pumped in in vast quantities. The culm fills the vacant spaces of the mine, although the water may escape, and being wet it smothers out the fire. It also hardens in time, forming a mass practically as a solid vein of coal, and in this way the roof is supported so as to prevent the cave-ins which are a disastrous feature of these subterranean fires, especially in settled sections.

* * *

Referring to the model of the new quadruple-screw Cunard steamers exhibited at the Louisiana Purchase Exposition a correspondent of the *Scientific American* says: "Of course the model that attracts the most attention is that of the new 25-knot, 40,000-ton turbine steamers. . . . For reasons which can well be understood in this age of keen competition, the company has not seen fit to place upon the placard of this model any of the dimensions, etc." Certainly not! If the company had been so unwise as to put those dimensions on a placard where all the public could have seen them, every Tom, Dick and Harry would be building 25-knot turbine steamers and thus put the old established steamship companies out of business! As a matter of fact there is a lot of popular nonsense believed about business secrecy and the value of ideas. Ideas and knowledge are of little value unless they have the backing of capital and business push.

The index for Volume X of MACHINERY, (1903-4) is now ready and a copy of it will be sent to any subscriber requesting same. In writing please state whether the Index for the Shop Edition or the Engineering Edition is desired.

ESTIMATING COST, WITH EXAMPLES ILLUSTRATING APPLICATION OF METHOD.

JAMES A. PRATT.

James A. Pratt.

In the March issue of your journal I note an inquiry for methods of estimating cost, and offer the following as a good method, provided one has a knowledge of the work from the shop standpoint. If not he can hardly expect to do much in the way of estimating, in spite of the fact that many practical shop men are not good judges of time required to perfrom work.

The complete estimate of the cost of a machine will require an examination in detail into the cost of all the separate items such as patterns, castings, forgings, steel or brass rods, bolts, screws, etc., the various machining operations, and finally the cost of running the shop, offices and other fixed charges. If a number of similar machines are to be built, the cost of the patterns will not be so prominent an item as where only one is to be put up, in which case it may form a large percentage of the total cost. The estimating of the cost of patterns will require the cost of lumber and all other materials which enter into the construction of both patterns and core boxes as well as the cost of labor; and a knowledge of the men and their ability, as well as the machines that are available is of importance to the one making the estimate. He must also have a knowledge of pattern work, and should be able to decide as to the most economical methods in this line. Each operation must be gone over carefully in the mind, such as sawing, turning, planing, trimming, gluing, filleting, etc., and the more minute the examination the more accurate will be the estimate. It will be a good idea to note whether the methods in mind when making the estimate are being carried out in the shop; and if slower ones are used a change should be made, for it requires eternal vigilance on these points to keep a shop up to date.

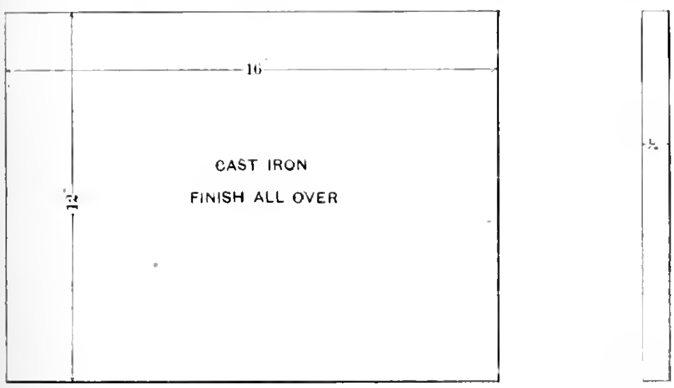

Fig. 1.

Next to the patterns will come the castings, and of these we will require as many sets as there are machines to be built. The weight of castings must be calculated and is readily obtained from the drawings by dividing each part into simple geometrical form, getting their volumes and from this estimating the weight. Almost all machine parts can be divided into a combination of forms of this sort and easily computed. This may be done in several ways by approximate methods, which save time and give results near enough for all practical purposes. Methods of estimating weights would, I think, be a subject well worthy of attention from contributors, but nothing of that sort is here offered, as the object of this article is confined to methods of estimating cost. After calculating the weight of the castings about 10 or 15 per cent. should be added for errors, finishing, etc.

On machine work the same process is followed as in the pattern estimate; that is, each operation must be gone over in detail, such as drilling, turning, boring, tapping, planing, etc., as well as a consideration of the time it will take to set a piece on a machine. Of all these except the setting a very accurate estimate may be obtained by calculating. Take turning a certain portion, for example. We know the surface speed that may be run, as well as the feed per revolution and the length of the piece, so can easily calculate how many chips will be taken to finish; hence, by a little figuring we may get a satisfactory result. The same is true of all other machine operations, but when we come to the setting up it must be entirely a matter of judgment.

A very important thing in working up an estimate, especially of machine work, is to see what special tools are available, and whether or not any new ones must be made; for if so, these must be reckoned in with the job, since it is desirable to clear a profit over all expenses. If a new tool to be made is one which can be used for general work after the job is done, we may be a little lenient and permit a part of the cost to be entered against the shop equipment; but the job directly in hand should bear the brunt of the burden of new special tools. Each tool should be considered as working at its maximum rate, and the work placed on each machine to the best advantage; that is, a job which can be done most advantageously on a turret lathe should not be put on an engine lathe, and one which can be placed to best advantage on a horizontal boring mill should not be put on an upright. At the present time the high speed steels should be considered, as a marked economy may be effected on all machine operations by their use; and wherever forged tools are used the high speed steels have a clear advantage.

If each operation is followed in detail, it is a comparatively easy matter to get the time on a job, and too much stress cannot be laid on the importance of going minutely through the making of every part of a machine, and assigning a certain time for each operation. The conditions under which the work will be done should not be assumed too favorable, as more or less time will be spent in looking for bolts, waiting at the tool room, reading drawings, and attending to the machine, all of which things increase the time but do not advance the work. The possibility of accidents should be considered also. I am aware that in some shops estimates are made, and the liability of accidents not considered, but such losses, when they occur, are charged against the profits. I think this should be considered as part of the cost of a job, as when we have made our estimate on the basis outlined the profit will come in as a clear item, and not mixed with any other considerations. The amount added for these things may be a very small percentage of the total cost, since it is covered by a number of jobs, all of which help to carry this burden.

After estimates on patterns, castings, and machine work have been made, take up shop expenses, such as rent, taxes, insurance, supplies, as well as the non-productive labor which must be employed. The running expense of the shop for a day is easily determined, and such an amount should be added as will permit the job in hand to bear its just share of the shop expense. The profit may now be added as a clean quantity, since everything has been considered by itself; and it is quite important that it be so viewed, since if it has to cover items not individually considered, one is very apt not to make it large enough, and the contract becomes a losing deal. In the above notes I have assumed that the machine has never before been built in the shop and that the estimate is being made directly from the drawings.

As an illustration, let us estimate cost of pattern, castings, and machine work on three planed bench plates, as shown in Fig. 1. The pattern will probably be made up of a main body and two end pieces, dowelled and screwed together. It is assumed that 1-inch stock is at hand from which to make the pattern.

James A. Pratt was born at Chelsea, Mass., April 6, 1873. He was graduated from school at 16, and entered a business office for two years. He then went to the Providence Engineering Works as apprentice and served four years. During this time, under the direction of a tutor, he took the regular course in mechanical engineering as offered at Brown University. His experience has covered the building of engines in the shop; erecting on the road; machine tools; special machinery; and jigs, fixtures and fine tools. At present he is instructor in machine work and mechanical drawing at the Sockanosset School for Boys, Howard, R. I. Mr. Pratt is a senior member of the Providence Association of Mechanical Engineers, and has contributed to several technical journals.

Getting out and sawing lumber	10 min.
Trimming ends	5 min.
Getting out end pieces and placing same	20 min.
Finishing pattern	15 min.
Surfacing cuts on different pieces	10 min.
Total working time	60 min.

This allows for actual working time only, but there will be more or less time indirectly spent which we must consider. To cover this, call total time on the whole job one hour and thirty minutes, which at 28 cents per hour equals 42 cents.

Next come the castings, of which three will be required. Proper allowance having been made in the pattern for shrinkage and finish, each plate will be $12\frac{1}{4}$ inches $\times$ $16\frac{1}{4}$ inches $\times$ $\frac{3}{4}$ inch. Taking $\frac{1}{4}$ pound as the weight of one cubic inch of cast iron, which is sufficiently accurate in this case, the calculation of the weight is readily made as follows:

$12\frac{1}{4}'' \times 16\frac{1}{4}'' \times \frac{3}{4}'' \times 3 \times \frac{1}{4}$ lb. = weight of three plates or $\frac{49''}{4} \times \frac{65''}{4} \times \frac{3''}{4} \times 3 \times \frac{1}{4}$ " $= \frac{28665}{256} = 112$ lbs —say 115 lbs., which at 2 cents per lb. will cost $2.30

Considering now the machine work. We have a plate $12\frac{1}{4}$ inches wide, $16\frac{1}{4}$ inches long and $\frac{3}{4}$ inch thick to reduce to $12 \times 16 \times \frac{1}{2}$. Assume that we take one rough and one finish cut with a roughing feed of 1-16 inch and a finishing feed of $\frac{1}{2}$.

Since plate is $12\frac{1}{2}$ inches wide and we take 1-16 inch at each cut we will need $12\frac{1}{2}$ inches $\div$ 1-16 inch, i. e., 200 cuts, and as each cut is 16 inches long the planer bed must travel $200 \times 16 = 3,200$ inches to get over the surface once. It must also travel the same distance for the return.

Speed of planer on cut 24 feet per minute = 288 inches.

Return of planer 48 feet per minute = 576 inches.

Hence we have need for cuts $\frac{3,200 \text{ inches}}{288 \text{ inches}}$ or 11.10 minutes and as the return speed is double the forward—one half as much time will be required for the return. Let us call the time for the cut 12 minutes and for the return 6 minutes. Now the planer will take some time to reverse at each end of stroke and for this we will allow 7 minutes. Cutting on sides of plate will require 3 minutes, with two minutes each for reverse and return, making 7 minutes for sides. Cuts on ends of plate will take one minute each for reverse and return, or three minutes for the ends, which makes a total for roughing cuts on one face and all sides, of thirty-five minutes; and as we have this on three plates, 105 minutes will be required for roughing one face and all sides and ends. We must also surface the other face of the plates at 19 minutes each, which makes 57 minutes more, or for roughing cuts throughout, 162 minutes. For finish cuts on all faces and ends we have, using the same method of figuring surface, but $\frac{1}{2}$-inch feed—33 minutes, which makes the total time 195 minutes, or 3 hours 15 minutes, which we will call $3\frac{1}{2}$ hours. For setting the first plate in the planer we will allow as follows: Getting and placing rib piece, 10 minutes; setting work, 10 minutes; clamping down, 15 minutes—a total of 35 minutes. For the other two plates we will allow 20 minutes each, as they will go quicker, which makes a total of 75 minutes for all three. For the second face we will allow 15 minutes, and for the ends and sides 45 minutes, which gives a total for setting, for all the roughing cuts, of 2 hours and 15 minutes.

Coming now to the setting for finishing cut we will make allowances as follows: Removing step plate and clamps and resetting plate, 12 minutes; getting bolts and clamping first plate, 17 minutes; for the other two plates, 10 minutes; for the second face, 15 minutes; a total of 54 minutes—say, one hour. Then we will allow for grinding and setting tools, and adjusting feeds, two hours; and finally for cleaning machine one half hour. This makes 5 hours and 45 minutes for setting grinding tools, etc., which we will call 6 hours. With the $3\frac{1}{2}$ hours for the cutting time we now have $9\frac{1}{2}$ hours. Adding for attention to machine, risk, etc., say, 5 per cent., and we have a trifle less than ten hours.

This assumes that the workman does not stop for any purpose whatever, but is constantly at work. As this is not possible, we may safely add one hour for time spent indirectly on the job, which gives us a total estimated time of 11 hours, which at 28 cents per hour is $3.08, making a total estimated cost of $5.80.

The actual time required to run this job off was 11 hours 25 minutes, showing that I was short on my estimate, but as two of the plates came from the foundry chilled, considerable time was lost in getting the work started, three tools being spoiled and one broken before work was really begun.

The average price for such jobbing work is 50 cents per hour for patternmaker and machinist, and for castings $3\frac{1}{2}$ cents per pound. Calculating on this basis, our estimate would stand as follows:

Patternmaker, 1 hour 30 minutes, at 50 cents	$ .75
Machinist, 11 hours, at 50 cents	5.50
115 pounds castings, at $3\frac{1}{2}$ cents	4.02
	$10.27
Estimated cost	$5.80
Leaving a surplus of	4.47

from which must still be deducted the proportionate part of the general shop expense before referred to, before we get down to the net profit.

As a second illustration of cost estimating, let us take up the cone pulley shown in Fig. 2. The pattern on this job was solid and the core box of the skeleton type. The core box is shown in Fig. 3 in order to make clear the references to it.

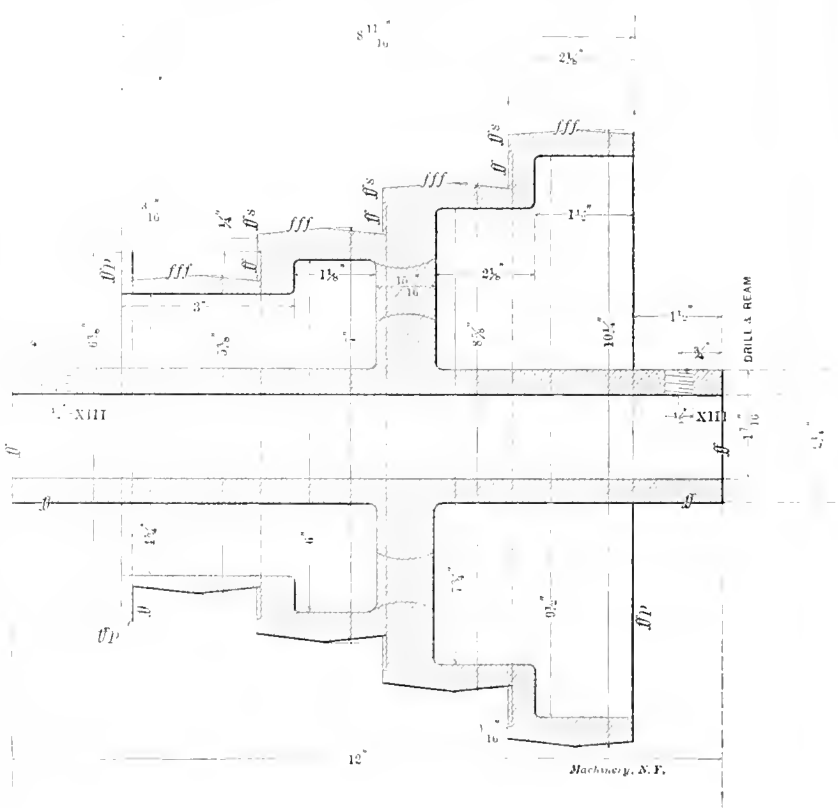

Fig. 2.

The pattern will be made up of a series of disks of $\frac{3}{4}$-inch stock glued together and turned, and large core prints $1\frac{3}{8}$ inches thick must be placed at each end. The flange shown in the drawing is left loose on the pattern for convenience in drawing the pattern from the sand. Estimated by items as below we have:

Getting out and sawing stock for pattern complete	60 min.
Planing up stock	45 min.
Laying out and bandsawing	60 min.
Gluing up	25 min.
Turning small core prints	20 min.
Turning pattern and sanding	60 min.
Placing prints and finishing pattern	20 min.
	290 min.

Total time on pattern, 4 hours 50 minutes.

Indirect time, ½ hour, making 5 hours 20 minutes—say 5½ hours.

Core Boxes.

The small core will be a "stock core," and no core box will be needed. The core for the larger part we will make of the skeleton type and sweep up in four quarters, these being afterward pasted together for use in the mold. Again estimating by items we have:

Getting out sides complete	107 min.
Getting out and attaching ends	25 min.
Getting out and placing barrel	20 min.
Getting out two shoulder pieces	30 min.
Doweling shoulder pieces and baffle board	40 min.
Getting out baffle	25 min.
Shellac	15 min.
Striko board	20 min.
Total	282 min.

Total time on core box complete, 4 hours 42 minutes.

Total time on pattern, 5 hours 30 minutes.

Total, 10 hours 12 minutes.

To cover indirect time, call estimate on pattern and core box 11 hours.

The next thing for consideration is the weight of the casting. We will take the hub as a cylinder 12 inches long, 2½ inches diameter, with 1¼-inch hole through it—44 cubic inches; the central web as a ring 7¾ inches diameter, ⅞ inch thick, and 2½-inch hole—37 cubic inches; the small step as a ring 5½ inches diameter, 3 inches long and a 5-inch hole—11.50 cubic inches, etc., using the same method in getting the whole volume, viz., divide it into a series of rings and get the volume. Adding these together and multiplying by .25 pounds (the weight of a cubic inch of cast iron) the calculated weight is 46 pounds. Add 10 per cent. for errors and variation, and we have approximately 51 pounds. The actual weight of this casting was 52 pounds.

In connection with the machine work, the first thing to be done is to look over the machines in the shop and see if any special tools are needed. This is very important, as at times work may be taken up which is larger than a machine can conveniently handle, and it will be necessary to make some alterations. We find nothing of this sort to be done on this particular piece, but we will need a long arbor, which we will charge entirely to the job. Those who wish might take part of the cost of the arbor off, since it can be used for other purposes after this particular piece of work is done.

Finding we have an arbor 1⅝ inches diameter and 16½ inches long, we will turn it down for this job. Being already centered we will not have to allow for that, so the time will be as follows: The coarsest feed of the lathe to be used is 1-100 inch per revolution, and we will take two roughing cuts with the lathe running 130 R. P. M.

The lathe must make 1,650 revolutions in going the length of the arbor and will take $\frac{1650}{130} = 13$ minutes for each of two roughing cuts, making:

Roughing time	26 min.
Finishing chip at 160 R. P. M.	11 min.
Filing and fitting	45 min.
	82 min.

Total 1 hour 22 minutes. Call this 1 hour 30 minutes.

Coming to the machine work on core, we have drilling at 94 R. P. M., surface speed 35 feet per minute. Piece is 1 7-16 inches diameter = 23-16; 23-16 × 3.14 = 4.5 inches circumference. As the surface speed is 35 feet or 420 inches per minute, and as a point on the circumference travels 4.5 inch at each revolution, we must make $\frac{420}{4.5} = 94$ R. P. M. Feed 1-32 inch per revolution will need 32 revolutions to go 1 inch, and for 12 inches, the length of the hub, we need 12 × 32, or 384 revolutions to go through the hub once, and it will take $\frac{384}{90}$ = 4 + minutes. Call this 5 minutes for roughing and 5 minutes for finishing, we have 10 minutes. This is provided casting comes soft and homogeneous. It may come hard with blow holes, causing grinding of drills, etc., and to cover these possibilities we call

Time	20 min.
Squaring down cone faces	25 min
Squaring inside of flange face	10 min.
Spotting down to crown size on cone steps	24 min
Turning cone steps 2½ inches long, feed 1-100 inch per revolution, will need 213 revolutions at 22 R. P. M., and will take	10 min.
Three chips on each step, and assume all steps same size, we would need about 120 minutes; but we can speed up on smaller steps and may call	
Time	100 min.
Undercutting on cone faces	30 min.
Squaring and turning left side of hub and flange	15 min.
Scraping, filing and polishing	85 min
Drilling and tapping for setscrews	20 min

The above deals only with the actual cutting time. We must now take into account the setting and grinding of tools and other incidentals.

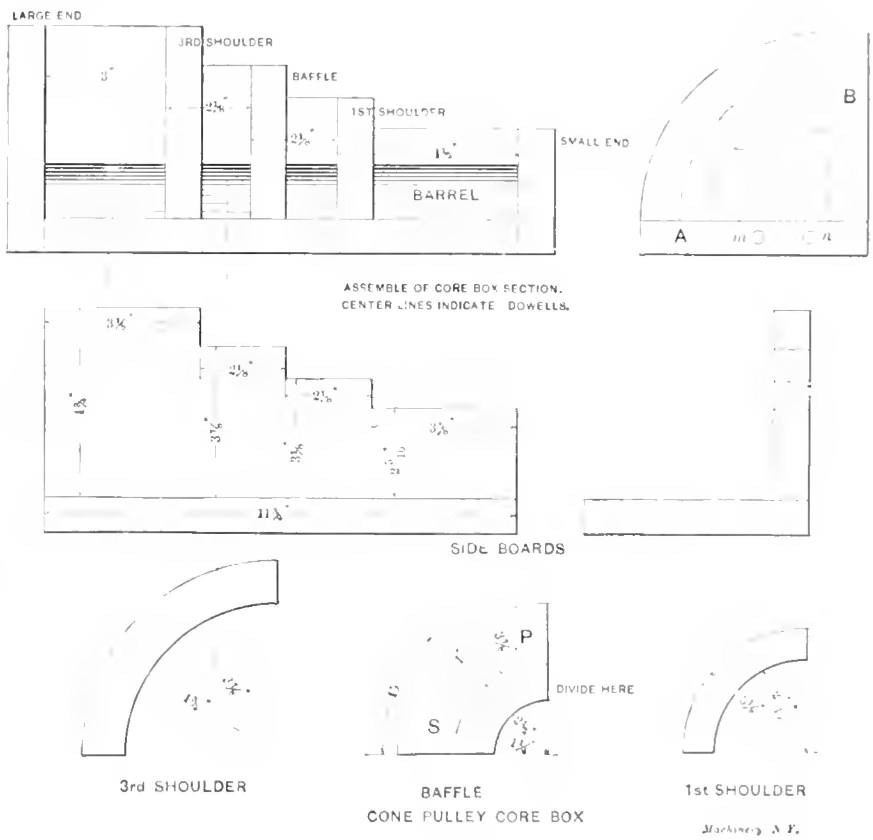

Fig. 3.

Getting out chuck, placing cone, truing up, getting drills at work, changing same, removing chuck and drills, returning tools and getting cone on centers ready for turning, say	55 min
Grinding and setting tools for squaring faces, spotting cone steps, crowning, undercuts on faces, ends of cone, and setting taper attachment	137 min
Allow for indirect time	60 min

A helper will be needed for a short time on this job, and we

Add half an hour workman's time	30 min
Cleaning machine	15 min
Making altogether	711 min

To which we will add

3 per cent. for risk, attention to machines, etc	21 min.
Giving a total of	732 min

Or 12 hours 12 minutes, which we will call 12½ hours.

The actual time on this job in the machine shop was 11 hours 30 minutes.

Combining the items, we have as the total estimated cost:

Patternmaker, 11 hours, at 28 cents	$3.08
52 pounds castings, at 3 cents	1.56
Machinist, 12½ hours, at 28 cents	3.50
	$8.14

Castings of this sort in small lots will sell at about 4 cents per pound, and calculating on this basis our estimate would be as follows:

Patternmaker, 11 hours, at 50 cents	$5.50
51 pounds castings, at 4 cents	2.04
Machinist, 12 hours 30 minutes, at 50 cents	6.25
Total	$13.79

The same items mentioned in previous case must be considered here before profit appears.

It will be noted that the surface speed was calculated for the drilling operation; but this was done simply as an illustration, and is entirely unnecessary in practical work, as tables are published which give surface speed for diameters making certain number of revolutions per minute. One very convenient table which the writer has used was published with the May number of MACHINERY in 1903.

There will be noted a slight difference in the dimensions used in estimating weight and those given in the drawing. This is done to allow for stock and variations in casting.

[While the criticism may perhaps be made that our correspondent has not selected throughout his examples at all times the most economical methods of doing the work, his analysis of the various operations in detail is quite careful and complete, and we think well illustrates such problems as small shops with limited equipment are often called on to handle. A large number of our readers, particularly among the younger men, will find the article suggestive and of much value.—EDITOR.]

* * *

NOTES ON ISOMETRIC PERSPECTIVE.

Mr. Robert S. Brown, secretary of the New Britain Machine Co., New Britain, Conn., sends a sheet of data upon the isometric system of perspective, which is reproduced herewith. He says in explanation: The bulletin print of information on isometric perspective has been issued for the drawing room force of our company. This is presented to the men in lieu of the Farrish treatise on the subject, now somewhat out of date. The Honey method referred to, for determining approximate arcs for constructing any proportion of ellipse, is the closest and quickest the writer knows of. It is in such general use among our draftsmen that nothing more than a reference to it is given on the print.

Isometric Perspective.

Based on placing objects, as the cube (Fig. 1), so that the eye is on a line with the diagonal of the cube. Each of the three visible plane surfaces then appear of same size, bounding lines as A B, B C, C D, of equal length, and extending either vertically or 60 degrees from the vertical to right or left. The angle at which cube is tipped to give this is 35 degrees, 16 minutes from horizontal.

It is customary to measure directly upon co-ordinates A B, B C, or C D, using full-sized scale. This makes each dimension of drawing 22½ per cent. longer than it would appear in a true projection of the object in isometric position.

Exact Construction for the Isometric Ellipse.

Draw both center lines A C, B D, and the circumscribing rhombus (Fig. 2). From point of rhombus at A, erect 45 degree line. A circle with center at center of rhombus and radius tangent to 45 degrees line, will, when continued across center line of rhombus, give major axis of ellipse. The minor axis can be found by 30 degree lines E F, G H. Isometrical diameter lines J K, L M, give four other points on the ellipse, and more if desired may then be located by any of the well-known methods.

Approximate Construction for Isometric Ellipse.

Draw circumscribing rhombus with sides to scale (Fig. 3). With center at B and radius of circle tangent to A D, at its mid-length, draw the long arc tangent to A D, and C D. With same radius and D as center, draw arc tangent to A B, and B C.

Above construction fixes length of minor axis and will vary from the actual about 0.2 inches to full in an ellipse of 10 inches major axis. Sweeping minor axis so found across major axis, gives approximate location of centers, which will finish the ellipse. These centers will be a trifle outside of the circle, but error may be neglected in small work. A close approximation to length of major axis (making same about 0.06 inch too full in 10 inches length) is had by taking ¼ of co-ordinate A B, and sweeping it across major axis with A as center.

This is useful in locating ellipse from the perimeter rather than center (see Fig. 4), for construction of tangent ellipses of same size.

If closer results than the above are required, use method in Fig. 2 for actual major and minor axis, and construct ellipse on the Honey plan. (See Kent, page 47, 5th edition.)

SOME CASES OF DIFFERENTIAL GEARING.

A. B.

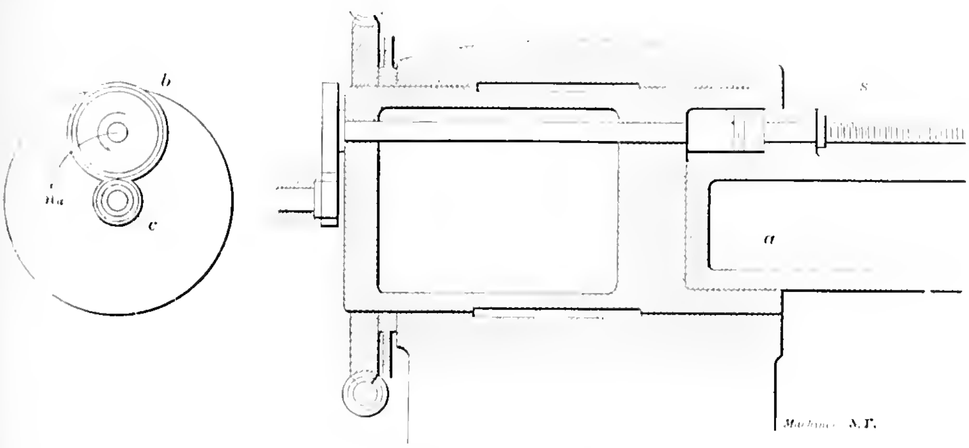
The subject is not a new one but a little study of it, and deriving suitable formulas, will be of interest to those who have not looked into it before.

The principle of differential gearing consists of a gear rotating around another gear, thus creating a ratio. This principle may be used in arrangements which differ in the way the gears are working, giving accordingly different results. Beginning with the simplest one, we take a gear on a crank rotating around another gear, and Fig. 1 (next page) illustrates this case. The bar a of a cylinder boring machine carries the feed screw s for the boring head. On the end of this screw is keyed gear b, which rotates with the bar around gear c. Gear c is a stationary gear, but as b rotates around it,

gear c acts as the driver, whilst gear b is the driven gear. Gear c has t_c and gear b has t_b teeth. Now in order to find the feed of the boring head per turn of the bar, we should know the revolutions of the screw per turn of bar. Instead of the bar making one revolution to the left we may suppose that gear c makes one revolution to the right, whilst the bar stands still. This will have the same effect for the screw. The ratio between gear c and gear b is $\frac{t_c}{t_b}$, so that for one revolution of the bar, the screw makes $\frac{t_c}{t_b}$ revolutions and for n_a revolutions per minute of the bar, the screw makes

$$n_s = n_a \times \frac{t_c}{t_b} \text{ revolutions per minute.} \qquad (1)$$

Gear b and with it screw s turns in the same direction as bar a.



Some Cases of Differential Gearing.

Example: Let the pitch of screw s be 1-3 inch and the feed of the boring head per turn of bar 1-12 inch. This means that the screw makes one-quarter of a turn for one turn of the bar. Then the ratio in the gears is

$$\frac{1}{4} = \frac{t_c}{t_b}$$

Another case is when gear c is connected to the main drive of the machine and therefore revolves too.

Then two considerations are possible: that gear c revolves in the same direction as the bar or against it. See Figs. 2 and 3. When c rotates with bar a, so are the relative rotations per minute of b around c, $n_a - n_c$ and the revolutions per minute of the screw

$$n_s = (n_a - n_c) \times \frac{t_c}{t_b} \qquad (2)$$

Screw s turns in the same direction as bar a if $n_a > n_c$; and in the opposite direction if $n_a < n_c$. In the latter case n_s has a negative value.

Example: As before the pitch of the screw is 1-3 inch and the feed per turn of bar is 1-12 inch but c makes 4 revolutions per minute and bar a makes 2 revolutions per minute. Gear c revolves in the same direction as bar a.

Question: What is the ratio for the gears c and b? For one turn of bar a, the screw has to make one-fourth of a turn, and therefore the number of revolutions per minute of the screw is

$$n_s = \frac{1}{4} n_a$$

From formula (2) we get

$$\frac{t_c}{t_b} = \frac{n_s}{n_a - n_c} = \frac{\frac{1}{4} n_a}{n_a - n_c} = \frac{\frac{1}{4} \times 2}{2 - 4} = -\frac{1}{4}$$

The negative value of this ratio shows us that the screw revolves against the direction in which the bar turns.

The other consideration of this case was that gear c revolves against bar a, and the relative rotation of gear b around gear c is then

$n_a + n_c$. See Fig. 3.

Herewith are the revolutions per minute of screw s

$$n_s = (n_a + n_c) \frac{t_c}{t_b} \qquad (3)$$

and the screw revolves always in the same direction as bar a, because n_s has always a positive value.

Another arrangement is shown in Fig. 4. The driving member in this case is a cone pulley which carries a stud with a couple of gears running loose on the stud. These two gears f and g, however, are keyed together and the stud rotates with them around the gears e and h. Gear e is fixed to some part of the frame and gear h is keyed on shaft i. The cone pulley d runs loose on shaft i.

The question here arises: How many revolutions does shaft i make for one revolution of the cone pulley? The problem is a little more complicated, as we use here four gears. In order to make it well understood we will take first the four gears have an equal number of teeth. Further, instead of revolving the cone pulley once to the left around the fixed gear e, we suppose this gear to turn once to the right whilst the cone pulley remains stationary. Then through e, f and g—h will make one revolution and, like e, to the right. But the gears on the stud were not stationary and they made one revolution around gear h to the left, with the result that gear g rolled off on gear h instead of turning the same. In other words, h makes one revolution less than the ratio between e and g would indicate. Now if the gears are not all equal we reason in the same way. Suppose gear e makes one turn to the right instead of the cone pulley d making one turn to the left, and the latter remains stationary, then gear h makes

$$\frac{t_e}{t_f} \times \frac{t_g}{t_h} \text{ revolutions.}$$

This, however, is not so, as the stud rotates around gear h and as before, gear h makes one revolution less or

$$\frac{t_e}{t_f} \times \frac{t_g}{t_h} - 1 \text{ revolutions.}$$

t_e, t_f, t_g and t_h indicate the number of teeth of the gears, and for n_d revolutions per minute of the cone pulley, shaft i makes

$$n = n_d \left(\frac{t_e}{t_f} \times \frac{t_g}{t_h} - 1 \right) \qquad (4)$$

Fig. 2.

Fig. 3

Shaft i rotates in opposite direction to cone pulley d if

$$\frac{t_e}{t_f} \times \frac{t_g}{t_h} > 1$$

Shaft i rotates in the same direction as the cone pulley if

$$\frac{t_e}{t_f} \times \frac{t_g}{t_h} < 1$$

In the latter case we see that n has a negative value indicating that shaft i and cone pulley d turn in the same direction and in the first case the sign for n is positive, indicating opposite directions.

Thus far, gear c was a fixed gear and the cone pulley with the stud only, the rotating member. Now let us examine the

case when both gear e and cone pulley d rotate. Gear e is then keyed on shaft k, by which it is driven.

We first take gear e revolving in the same direction as the cone pulley and the question is now: What is the ratio between shaft k and shaft i? We split this case in two and observe the results which we get for one revolution of d with e fixed, and for one revolution of e with d fixed, and after this we add the two results.

One revolution of d with e fixed gives us as above

$$\frac{t_e}{t_f} \times \frac{t_g}{t_h} - 1$$

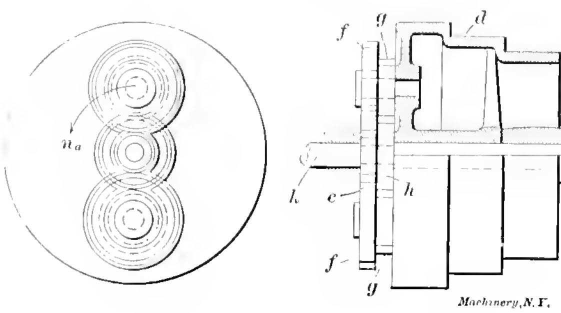


Fig. 4.

and one revolution of e with d fixed gives us

$$-\frac{t_e}{t_f} \times \frac{t_g}{t_h}$$

The value of this must be taken negative because gear e revolving in the same direction as cone pulley d forces shaft i to run in this direction also. The two results added give us

$$\left(\frac{t_e}{t_f} \times \frac{t_g}{t_h} - 1\right) - \frac{t_e}{t_f} \times \frac{t_g}{t_h}$$

and for n_k revolutions per minute of shaft k and n_d revolutions per minute of cone pulley d we get for shafts i

$$n_i = n_d\left(\frac{t_e}{t_f} \times \frac{t_g}{t_h} - 1\right) - n_k\left(\frac{t_e}{t_f} \times \frac{t_g}{t_h}\right) \text{ revs. per min.} \quad (5)$$

If n_i has a negative value shaft i turns with the cone pulley and shaft k in the same direction; and if n_i has a positive value shaft i turns in the opposite direction to the cone pulley and shaft k.

Now let us see what happens if gear e revolves against cone pulley d. In this case everything is as above except the sign for shaft k, which will be positive instead of negative, because shaft i is forced by the rotation of e to run in opposite direction to the cone pulley and the formula for n_i is

$$n_i = n_d\left(\frac{t_e}{t_f} \times \frac{t_g}{t_h} - 1\right) + n_k\left(\frac{t_e}{t_f} \times \frac{t_g}{t_h}\right) \text{ per minute.} \quad (6)$$

If n_i has a negative value shaft i turns with cone pulley d in the same direction but against shaft k. If n_i has a positive value shaft i turns against the cone pulley but with shaft k. Example in figures:

Cone pulley d makes $n_d = 20$ revolutions per minute.

Gear e with shaft k makes $n_k = 40$ revolutions per minute and turns in the same direction as d.

Gears e, f, g and h have respectively 12, 28, 14 and 26 teeth. The number of revolutions per minute of shaft i is then

$$n_i = 20\left(\frac{12}{28} \times \frac{14}{26} - 1\right) - 40\left(\frac{12}{28} \times \frac{14}{26}\right) = -24.6 \text{ revs. per min}$$

The negative sign indicates that shaft i revolves in the same direction as cone pulley d and shaft k.

A HANDY TOOL FOR LOCATING AND ALIGNING SHAFTING AND MACHINERY.

WM. H. BROOKS.

During a recent pilgrimage into archæological methods of doing things I found a new tool for helping along an old job. It was dug up from the bottom of a tool chest and is intended to be used for lining up shafting, machinery, etc. The tool is simple, accurate and inexpensive, and will beat the work of those millwrights addicted to the use of sticks, stones and strings, not to mention nails, wires and full size "chalk prints" on the floor, as well as a great variety of mental gymnastics that would make Euclid blush with shame and mortification.

The body of the tool, Fig. 1, consists of an inverted V marked A in the cut, about 6 inches long and having at the center a spot b about 2 inches in diameter finished perfectly parallel with the horizontal plane of the inverted V and having one line parallel with the V and one at 90 degrees to it, both passing through the center of the spot. Pivoted at the intersection of these two lines rests a dial, c, graduated to 360 degrees and bearing a suitable form of sights or telescope d, similar to that of a surveyor's transit; this latter of course being parallel to the base of the dial and its sight line parallel to the 0 degree and 180 degree lines. A level, e, integral with the sights or

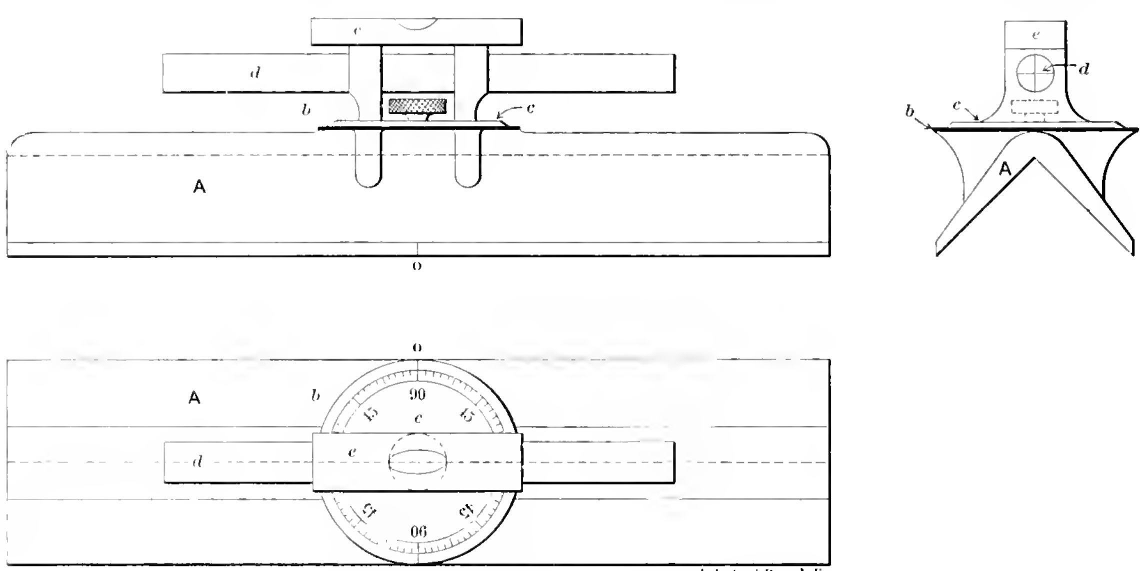

Fig. 1. Leveling Instrument for Aligning Shafting and Machinery.

telescope, and capable of revolution with it about the axis of the dial, completes the tool. A suitable locking device is of necessity added to keep the dial in position. Another detail is the parallel sides of the V, permitting the use of the tool on large as well as small shafts and on which a line o is struck, to correspond with the center of the dial. The form of tool used by the owner was very simple, with poor sights and no glasses, yet a fair degree of accuracy was attained.

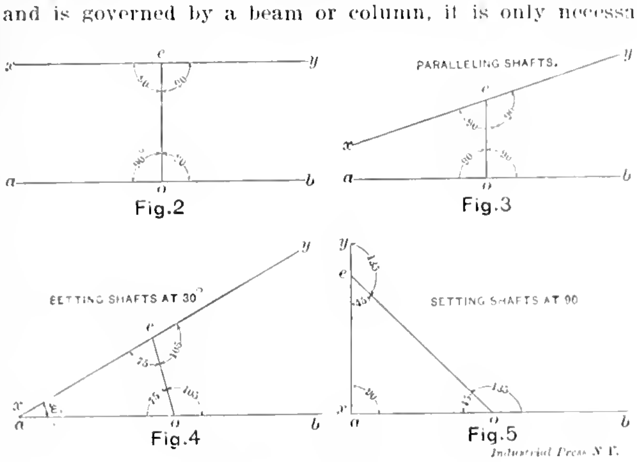
With this simple description of the tool in mind we can consider the principle of its operation, which is simpler than the tool.

In Fig. 2, a b is a straight line, on which at any point o erect a perpendicular, and the angles are equal or 90 degrees each. At any point e in this perpendicular line erect perpendiculars e x and e y, then the lines a b and x y are parallel. If we consider the line a b a shaft of any diameter and take a point o and apply thereto the line o on the tool, with the telescope set at 90 degrees, and sight to a point e on another shaft x y, marking points o and e plainly with a scriber or file, and then transfer the tool to the shaft x y with the o on

tool and point e on shaft coincident and the telescope still set at 90 degrees, any variation of the point o from the line of sight proves the shafts out of parallel, as illustrated in the annexed Fig. 3, much exaggerated. Other forms of the principle are shown in Figs. 4 and 5.

When starting to hang a shaft the same method is pursued as in the case of Fig. 2, the line a b becoming the engine shaft or line shaft, as the case might be, and x y the line of shafting or countershaft to be hung. In the case of short countershafts the hangers can be placed roughly and lined up after the shaft is hung. In the case of long shafts some form of tripod would be of advantage in establishing a long line of hangers or pillow blocks, and the tool again used for a final test. Figs. 2 and 3 are the keys to all these operations. If we wish to extend a short length of shafting already in position we find the location of the nearest or furthest hanger by placing the tool on the end of the shaft and sighting to a plumb line or other target, so the line for all the hangers can be found at once.

Fig. 6 shows an example of a right angle drive, the problem being to determine the position of the mule pulleys, or the driving and driven pulleys. If the position of the mule pulley stand is governed by a beam or column, it is only necessary



Illustrating Principle of Tool.

to sight from the shaft, with the telescopes at 90 degrees, to the rim of the mule pulleys, and the points o and e thus found become the centers of the driving and driven pulleys. If the position of the mule pulleys is governed by the location of the driving and driven pulleys, the location of the mule pulley center is found by adding or subtracting the mule pulley radius. Here another point is projected on the horizon. A squint tells whether a belt will clear a beam, column or other obstruction, before pulleys are ordered or placed. In Fig. 7 I repeat the examples of Fig. 5, where the shafts are at

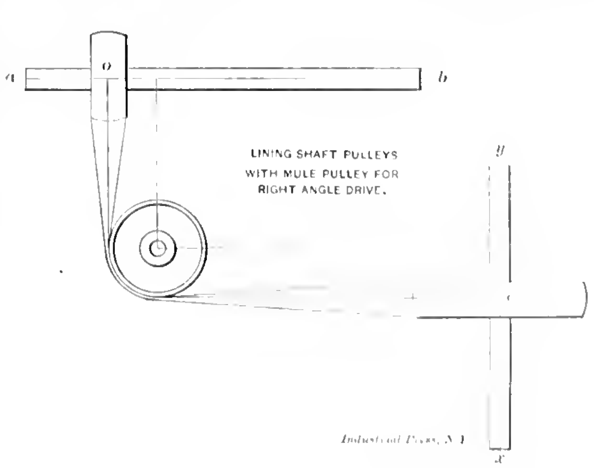


Fig. 6. Lining Shaft Pulleys with Mule Pulleys for Right Angle Drive.

90 degrees but do not intersect. The tool is placed on shaft a, b at any point o, with the telescope at 45 degrees, and the point e is found on shaft x y; the telescope is moved 90 degrees and placed over e; if the point o is in the sight line the shafts are at 90 degrees, if not, the shaft x y must be moved according to the position of o as observed from e.

Fig. 9 shows a horizontal and vertical quarter drive. In this case the height of the "sight line" above the center of the shaft must be known. To find this height place the tool on the shaft and sight to a rule, add the dimension found to the radius of the shaft and the sum gives the height above the center as per Fig. 8. To place pulleys in the case of Fig. 9 place the tool on shaft a b with the telescope at 90 degrees and note that the telescope be level, sight to the center of the shaft x y and mark both shafts; on x y the point sighted, on a b the point o on tool. To point o add the *radius* of pulley

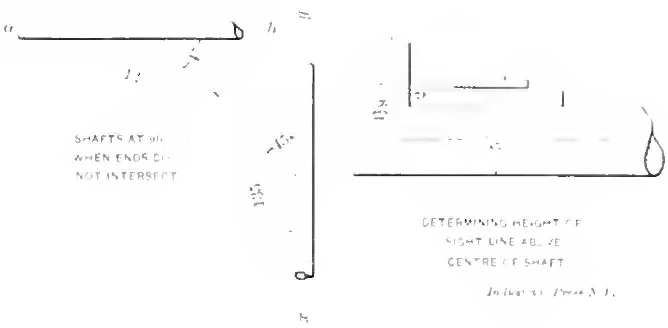

Fig 7. Fig 8.

B and to the point on shaft x y add the *difference* between the height of the "sight line" (per Fig. 8) and the *radius* of pulley A, and the points found are the centers of the driving and driven pulleys. Note that the tool is used but once, with one setting and a small possibility of error, and that the addition or subtraction is governed by the respective directions of rotation, there being four possible positions.

The addition of a cheap tripod and plumb bob dropped through the center of dial permits the use of the tool in place of an expensive engineer's transit, for a great amount of work around the mill, power-house, and in erecting machinery where few tools are available. A string of foundations can be plotted with ease and accuracy and all can be leveled from one position. From one position, such as a certain distance from the walls, the position of engines, dynamos, motors, switch boards, pipes, conduits, main, line and countershafts and machines may be determined, and hangers,

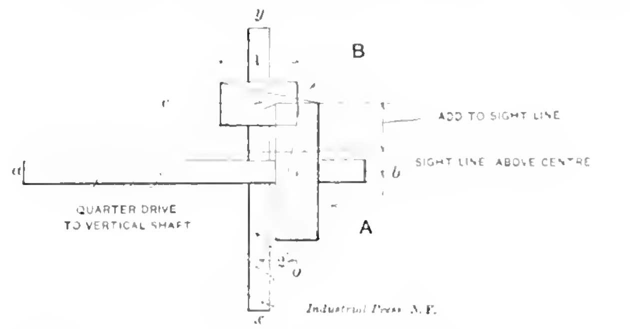

Fig. 9. Aligning Horizontal and Vertical Quarter-turn Drive.

pedestals, brackets, etc. may be placed before the shafting arrives or is finished, and the man in charge can know positively, if reasonable care be exercised, that all will be where wanted, parallel and level. Right angles and odd angles can be laid out with equal facility, and the trouble sometimes encountered by roofs being out of level, can be avoided by sighting a level line and ordering bolts and blocking accordingly. In the same way steam and exhaust pipes can be given the proper pitch for drainage without guessing and making the hangers too long or too short.

He who runs may read and profit thereby. A man may not hold a diploma to squint through a brass tube at any old thing for a target.

* * *

A Boston company, promoting a new form of rotary steam engine, designate it as "fool-proof," a legend to that effect being cast upon the casing. To make any machine foolproof is a big contract—in fact, it is one that is practically impossible. To assert the contrary in cold cast iron type is like tempting fate and is besides something of an insult to the intelligence of the operator whose share of average human nature would indeed be small if he did not some time abuse a machine so labeled.

THE GRINDING OF THREAD GAGES.*

J. R. GORDON.

I believe the best way I can answer the questions of your correspondent regarding the grinding of thread gages, is to describe the different operations I have used in making these tools. I suppose that a large proportion of the toolmakers in this country have at some time or other had the job of making gages to be used as standards of work, and that, too, without any great amount of previous experience in that line of work, and this has been my case. My first job of thread grinding occurred about eighteen years ago when I had occasion to make a tap, which, as near as I can remember, was about 1 inch in diameter, and 20 threads to the inch.

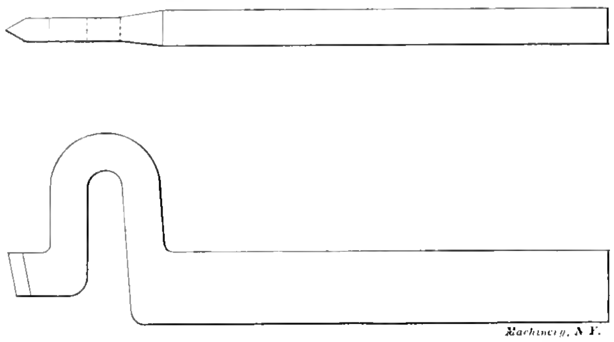

Fig. 1.

It was very important that this tap should be right, particularly regarding the pitch of thread, as it was for sizing a nut in which a measuring screw was to work. I do not remember the steel that was used in this case, but do remember that it was annealed, and was very soft and "draggy," and in order to cut the thread smoothly, it had to be taken out before the full depth of the thread was cut, and given a cold water annealing. After this was done, the thread was finished and the tap milled. It was then heated in a piece of iron pipe in the blacksmith's forge, and then dipped point first into cold water, and immediately after drawn to a light straw color. Upon examination it was found that the tap had shrunk in diameter on the end several thousandths, and the pitch had changed so that it no longer agreed with the pitch of the lathe screw.

It was decided to try grinding it, and the following method was tried. The lathe had a grinding attachment to go in the toolpost, driven by a drum on the countershaft, and in place

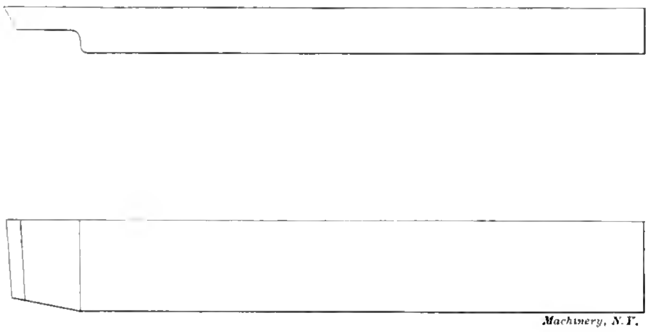

Fig. 2.

of an emery wheel we put on the spindle of the attachment a lap made of unannealed tool steel and charged with diamond dust.

Now diamond dust is by no means a common or cheap article, but it so happened that we had some left over from a job of grinding out spring chucks with very small holes, used in the same lathe in which the thread was cut, and as this was before the days of carborundum we used it for the job. The lap was charged by aid of a hardened steel bushing, acting as a roller, and it being harder than the lap the particles of the diamond were forced into the lap. When all was ready the grinding was done as follows:

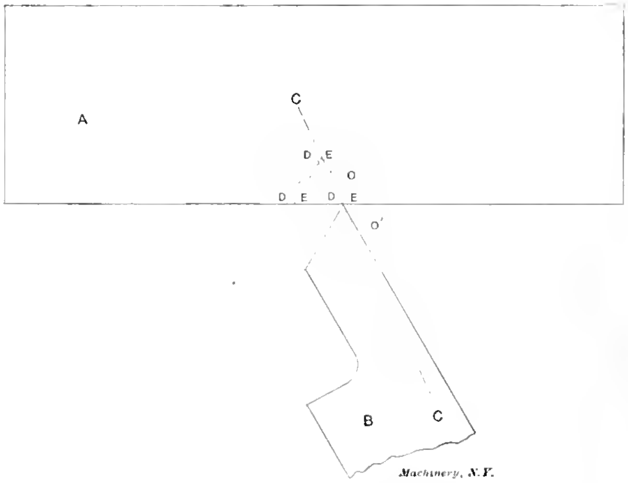
The lap was carefully set to engage in the thread of the tap, so as to have as little stock to remove as possible, and the drum started; the speed was such as to give about 6,400 revolutions per minute to the lap, which was about 1½ inches diameter. The lathe was geared as for screw cutting, the pitch, of course, being the same as the pitch of the tap. The head of the lathe was turned slowly and steadily by hand until the whole length of the thread had been traversed, when the lap was backed out, and the process repeated several times. The job came out first-rate, and the tap made a beautiful thread.

I have on one or two occasions since then used diamond dust, which may be obtained from diamond cutters generally, several of whom have shops in New York City, but I have never had occasion to grind the thread of gages, unless lapping can be called grinding. However, if your correspondent will proceed as follows he will, I think, obtain the results he is looking for. Select for the plug gage, octagon tool steel, Jessop's annealed preferred. If the diameter of the gage will permit it, drill and tap a hole for the handle, and turn and thread the gage on a nut arbor. This will not only save steel, but make it easier to harden the gage. If the lathe is not furnished with a compound rest then the threading tool should be made "goose-neck" style, as per sketch (Fig. 1). The cutting edges of the tool can not be too smooth for this work since the finer the edge the smoother the cut. The goose-neck tool will not remove stock very rapidly, so a more rigid tool should be used for roughing off the greater part of the thread.

When the lathe is furnished with a compound rest I use the following method for cutting the thread, and prefer it to any I have seen: Swivel the compound rest until the slide stands at an angle of 28 degrees from the perpendicular to the axis of the centers of the lathe. Set the tool so that its cutting sides are at the proper angle and its point the right height. Feed the tool in with the screw in the compound rest. The tool then will cut mostly on one face, the other face merely scraping off the metal on one side of the thread. The sketch (Fig. 2) shows the shape of the tool I prefer for this work. To get the proper results the thread must, when finished, be smooth, and this result will oftener be attained with steel that cuts a little brittle than with steel so soft as to drag off under the cut. The thread should next be polished, which may be done in the following manner: In place of

The accompanying diagram will probably make clear the reasons for swiveling the compound rest to 28 degrees instead of 30 degrees when cutting V threads. *A* is the piece to be threaded, *B* is the tool, *C C* is the line in which the tool is fed into the work. In the diagram the angle of this line is 25 degrees as the divergence of a line drawn at 28 degrees would be almost imperceptible in so small a drawing. *D D D* is the thread that would be cut if the compound rest was set at an angle of 30 degrees, and *E E E* is the thread that will result from feeding the tool in at 25 degrees.

It is apparent that the side of the thread marked *O* would show a series of steps, coarse or fine according to the depth of the cuts, when the tool is fed in at 30 degrees angle, whereas by feeding in at 28 degrees the side of the tool *O O* will scrape away a little metal each cut. It is of course understood that the point of the tool is set to 30 degrees to give the proper angles to the thread. Setting the compound rest at a less angle than 28 degrees will give more work for the side of the tool *O′* to perform, and consequently more work for the point of the tool, which is to be avoided as much as possible. The



result as to the shape of the thread would be the same in any case when the compound rest is set at any angle less than 30 degrees. If set at an angle greater than 30 degrees the shape of the thread would not be right.

* This article was written at our request, in reply to a question from a contributor.

the tool in the tool post put in a piece of cast-iron about the size and shape of a lathe tool and using a boring bar in the lathe, bore on the end of the piece, the arc of a circle, equal to the diameter of the gage at the bottom of the thread. Next thread this cast-iron piece the same as a chaser on the end by putting a threading tool in the bar in place of the boring tool, and, keeping the setting as it is, put the gage between the centers and using the cast-iron piece as a lap, polish the thread by chasing it over with the screw-feed. The lap should be very lightly charged with emery or carborundum and moistened with benzine to distribute the abrasive evenly.

To harden the gage procure an iron pot, such as is used to melt solder in and of sufficient size to leave room all around the largest gage to be hardened. This pot should be filled with cyanide of potassium, which should be heated until the proper color is attained. Wire the gage with wrought iron-wire, using care not to injure the thread and leaving ends to which the tongs may be applied. Place the gage in the pot and leavo it there until the proper degree of heat is attained. This will be found to be somewhat deceptive at first, and the color will be lower than it appears in the pot, to those who have never used this method before. When properly heated remove and plunge in cold water; if the gage is of one piece put the handle end first, dipping it in moderately fast, and when cold draw immediately. If the gage is made with the handle separate it should be plunged into the water edgewise. The gage will be found to be bright and clean and to have a very hard shell.

Now return it to the lathe, and using the same lap polish the thread again. Unless the gage has sprung to an unusual degree the lap will quickly polish all parts of the thread. The object of heating in the cyanide is to give a perfectly even heat to prevent springing, and the reason for using octagon steel is the same, it being more evenly rolled in the mill.

When putting the gage in cold water from the pot of cyanide the workman should use care to protect his face and person from the hot cyanide, which flies when it comes in contact with cold water.

For the ring gage the lap should be made of cast-iron, turned the right diameter and threaded, after which it is sawed through the middle, leaving both ends solid. Provision for expanding the lap may be made by a screw whose head comes below the bottom of the thread; or, if the gage is small, by drilling a hole in the end deep enough to reach about half the length of the lap and driving a wedge in to expand it. I have seen threads of ring gages that were made by a hob tap and they were very nicely made, but if the tap "goes" in hardening it is as much work to correct the tap as it is to make the gage originally, so I prefer cutting the thread in the lathe, especially if the gage is split.

Some may prefer to use animal charcoal for heating the work in; in any case, the work should be kept from the flame and air as much as possible.

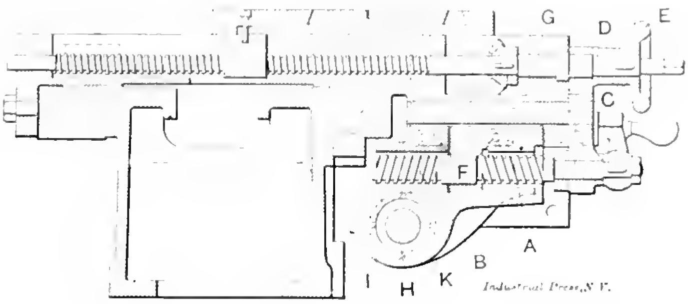
* * *

GERMAN LATHE CARRIAGE FOR SCREW CUTTING.

ROBERT GRIMSHAW.

The mechanical arrangement here shown is intended to simplify the transmission in thread cutting, the opening of the two parts of the nut being employed to withdraw the lathe tool so that only one motion of the hand is necessary. Above the two parts of the split nut, *I K*, which lie under the carriage ways and are opened and closed by a screw with a double right and left hand thread, *A* and *B*, there is an L-shaped slide having the same direction of motion, and this surrounds a shoulder on the upper part of the split nut and slides on the latter. In the front part of this slide, which is directed upward, the carriage spindle has a swivel bearing and is secured by the nut, *D*, and the check nut, *E*. While the spindle *G* follows all of the movements of the slide its own movement is unrestrained. Through the shoulders of the nut are bored the holes, *FF*, in which a steel bolt is accurately fitted. There are in the carriage, slots for this bolt which plays freely therein. Accordingly as the thread to be cut is external or internal, the bolt is placed in the front or the rear half of the nut and this is connected to the slide so that the latter, and with it the upper carriage, must follow, with the cutting tool, the movement of the nut.

In thread cutting the operation is as follows: As soon as the tool is at the end of the thread, the nut opens and the tool is withdrawn from the cut. The carriage is then, by means of the rack, brought back again by hand, the carriage spindle, *G*, is turned far enough for the next cut and the nut is closed. This brings the tool to exactly the depth for the second cut. The lathe runs continually in the forward direction and the tool is almost always in the cut, as the running back of the carriage takes but little time.



Section of German Screw-cutting Lathe Carriage having Automatic Retracting Device for Tool.

This arrangement enables cutting all threads with pitch of an even number. For odd pitches it is necessary to take care that at tho commencement of each new cut the leadscrew, *H*, and the driving arbor have the same relative position, and the carriage be brought to the same place, as before. This is easily managed by starting out, before commencing the thread, with the carriage against the tailstock; or if the threaded portion of the work-piece does not reach far enough, against an interposed piece of metal. The faceplate or the chuck is then turned by hand until the leadscrew nut, *I K*, can be shut without meeting with any resistance or requiring the carriage to be moved lengthwise of the lathe. This position of main arbor and leadscrew is indicated by a chalk mark on the faceplate (or the chuck, as the case may be) and the leadscrew. At each new cut the carriage is brought back to the tailstock or to the distance-piece mentioned, and the nut will close as soon as the two chalk marks appear in the positions in which they were originally made.

This arrangement of the nut saves much time over the usual way of running back the carriage by the belt, and running the tool in and out of the cut; further, the proper strike and depth of the tool are assured. Where the lathe is used for ordinary turning, the connection of the slide with the nut checks is broken by withdrawing the bolt, and the slide is connected with the carriage by putting the bolt in a hole which is bored through carriage and slide, over the slots. The carriage spindle is then connected with the carriage and the nut can be opened and closed independently of the slide, as is the case on ordinary lathes. Lathes fitted with this arrangement are built by H. Wohlenberg, Hanover, Germany.

* * *

Sir William Ramsey, the noted British chemist who recently visited the United States, spoke fully as enthusiastically of radium as a number of other noted physicists who have been quoted. Among other interesting statements, he said that the amount of pure radium existing in the radium compounds isolated by M. Curie and others, is very small indeed—a mere fraction of an ounce, in fact. He stated that radium-bromide dissolved in water, separates it into its component gases, hydrogen and oxygen, and continues to do so indefinitely in spite of all natural laws with which physicists have heretofore been acquainted. This, however, is not the only instance, by any means, in which radium seems to confound the doctrine of conservation of energy. But in this connection it is somewhat puzzling to understand the statement of Sir William that one pound of radium would evolve as much energy as the explosion of 250 tons of dynamite. While this expression is certainly impressive, it falls far short of continuous evolution of energy.

TOOL MAKING.—11.

DRILLS.

E. R. MARKHAM.

Drills used in machine shop work are of several varieties. The more common forms are the flat drill, single-lip drill, straightway drill and twist drill.

Flat Drills.—Flat drills are made with shanks of suitable form to allow them to be held in chucks or collets, as shown in Fig. 1. If intended for use in the engine lathe, for chucking, they are made as in Fig. 2. One end is centered as shown, and this rests on the tail center of the lathe. As this form of drill is seldom used to produce a hole of exact size it is customary to forge it to size and shape, finishing by grinding. If it is necessary to have the drill cut approximately exact to size, it may be forged somewhat wider than desired finish size. Both ends must be centered and the drill turned to size in the engine lathe. If the drill is to be ground to size after hardening, the projection *A*, Fig. 3, must be left on until after grinding. It is seldom considered advisable, however, to drill holes that must be exact with this form of drill, so the operation of grinding is not resorted to in many cases.

As the turning of a piece of stock of this form would have a tendency to cut the portion of the edge nearest the flat surface a trifle deeper than the balance of the edge, it might bind when cutting unless given sufficient relief. This is ordinarily accomplished by draw-filing. When the drill is ground to size the operation of draw-filing is not resorted to. The amount of relief given the edges should be small; .003 or .004 inch will be found sufficient. If given too much the tool will chatter when cutting. The shank should be a trifle smaller than the body of the drill, to prevent its touching the walls of a hole drilled deep enough for it to enter.

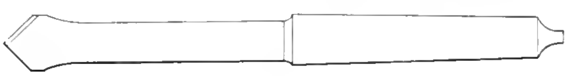


FIG. 1

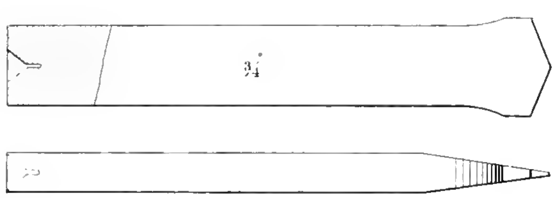

FIG. 2

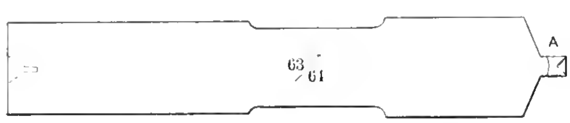

FIG. 3

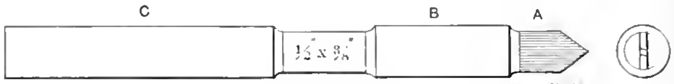
Machinery, N.Y.

When a drill of this form is forged care should be exercised in heating and hammering. It should not be overheated, for this causes brittleness. The blows should be rapid and no heavier than should be given a piece of steel of the size in hand; and as the steel gets cooler the blows should be lighter to prevent a tendency to fracture the grain of the steel.

When hardening, the steel should be given as low a heat as is consistent with the steel used. The heat should extend a trifle further up than we wish the drill hardened. When dipping in the bath it should be worked up and down, to prevent a water line, and around to prevent the steam forming a cushion around the steel, which keeps the water away from the steel and prevents the operation of hardening. The water line referred to is caused by dipping a piece of red hot steel in the bath and holding it in a fixed position. This causes it to contract up to a certain point, which corresponds to the surface of the bath, and as the portion above the surface will, of course, not contract as rapidly as that below, there will result an uneven contraction each side of this given point, and the steel will either crack or break off at the surface of the bath. Working the red hot steel up and down distributes the point of unequal contraction over a greater surface and does away with the tendency to crack. These remarks apply equally well to any piece of steel which is heated for a distance greater than we wish to harden.

For use in drill press work flat drills have been almost entirely superseded by twist drills, yet at times the former are very useful. This is especially the case when an odd-sized drill is wanted, or when it is necessary to drill through the hard scale on the surface of cast iron. When drilling holes in tempered steel flat drills work much better than any other form, partly on account of their shape, and because they can be left very much harder than if a corresponding size of twist drill were used. Flat drills for drilling tempered steel will be found much harder and tougher if dipped in a bath of



Machinery, N.Y.

Fig. 4.

mercury instead of water, or in the absence of mercury a block of lead may be used. Before hardening, the drill may be driven into the lead for a short distance, care being taken not to crook it by carelessness when driving. It may then be removed from the lead, heated red hot, and placed in the hole in the lead. Lead absorbs the heat in the drill rapidly enough to insure extreme hardness, and yet the action is such that extreme brittleness does not follow.

I have seen small drills, gravers, and similar tools hardened very nicely by carefully heating to a red heat and then sticking them into a potato. When drilling tempered steel use turpentine instead of oil as a lubricant.

Transfer drills are used when it is desired to transfer a smaller hole from a larger without changing the location. The portion *B*, Fig. 4, is of the size of the larger hole, while *A* is of the size of the hole to be transferred, and is a short, flat drill. The shank may be of any convenient size. After turning the various portions to size the cutting portion *A* is milled or filed to thickness. The cutting lips are then backed off and the drill hardened. The portion *B*, which runs in the hole already made, should be hard to prevent its roughing from frictional contact with the walls of the hole. The cutting portion is drawn to a straw color, while the portion *B* is left as hard as when taken from the hardening bath.

Single Lip Drill.—For certain classes of work this style of drill is very useful. As it has but one cutting edge its action

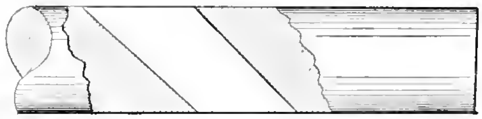


Fig. 5

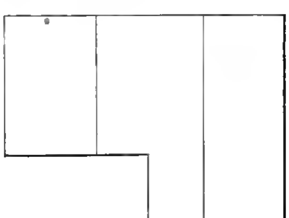

Fig. 6

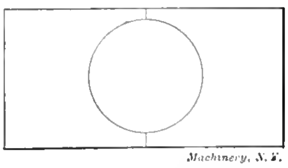

Machinery, N.Y.

is similar to that of a boring tool used in an engine lathe for inside turning. The body of the drill being the size of the hole to be drilled there is little danger of its running, even when drilling stock containing blow-holes or where it is partly cut away. It does not cut as rapidly as other styles, and consequently is not used where a twist drill will answer; but for certain work it answers much better. When it is necessary to drill holes at an angle, through a cylindrical piece of stock, as shown in Fig. 5, this drill works better than the others, provided it is guided by a rest or bushing. It also

works nicely when drilling holes through a piece like that shown in Fig. 6, where part of the stock is cut away. In this case the drill could be guided by a bushing or the hole could be started with a twist drill and finished with the single lip.

In Fig. 7 is shown a form of single lip drill to be used with a bushing. The blank should be roughed to a size somewhat larger than finish size. The portion *C* should be turned to size and the size of the drill stamped on it, after which the shank, *B*, and the cutting end, *A*, should be finished to size, and finally the portion marked *A* may be milled as shown, so that just one-half of it remains.

If the drill must cut a hole true to size it will be necessary to make it a few thousandths of an inch large and grind it to size after it is hardened. To grind the drill it will be found necessary to face the end back, leaving the projection, *A*, containing the center, as shown in Fig. 8. After grinding, the projection may be ground away and the end of drill ground for clearance, so that it may cut. The shape to give the end is shown in Fig. 9. If single-lip drills are to be used on iron and steel and *not* on brass, they will cut more freely by making them as shown in Fig. 10. This cutting rake is given by mill-

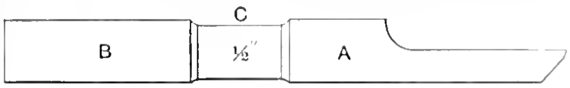

Fig. 7

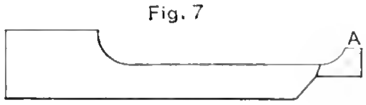

Fig. 8

Machinery, N.Y.

ing the portion *A* to the desired size, which is one-half the diameter of the blank. The end and sides of the blank are heated to a blue, or covered with the blue vitriol solution and the desired shape laid out with a scratch awl. It is then placed in the milling machine chuck on the index head, or in the vise, at the desired angle and the desired amount of rake given by milling with small end mills. The cutting lip must of course run to the center. If it is not cut as deep as the center it cannot cut; if cut deeper than one-half way it will cut, but leave a projection standing in the center of the hole. Use extreme care in heating these drills for hardening, and dip in warm water or brine to prevent springing. Many old hardeners treat drills of this form, and similar pieces of work, by dipping in the bath at an angle, as shown in Fig. 11, so as to counteract the tendency to spring from unequal contraction occasioned by unequal amount of stock at the various portions of the drill.

When single lip drills are used constantly they are made with detachable cutting blades, as shown in Fig. 12. In this case compensation can be made for wear by blocking up under the blade by means of thin sheet metal or paper. It is necessary to have the face of the blade radial. The cutter is held in position by means of two screws, as shown.

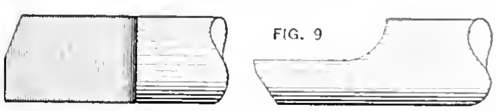

FIG. 9

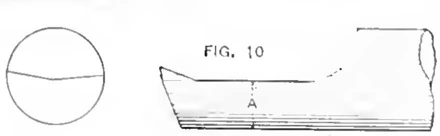

FIG. 10

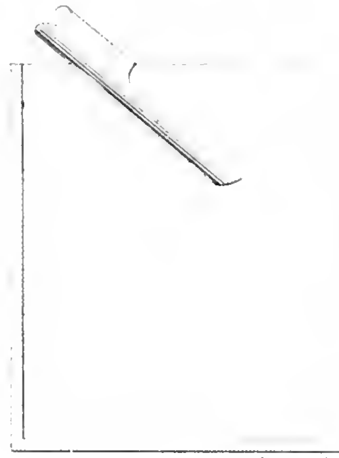
Machinery, N.Y.

***Straightway** or **Straight Fluted Drills**.*—These differ from twist drills in that the flutes are parallel to a plane passing through the axis of the drill, as shown in Fig. 13. They are used in drilling brass and the softer metals as the tendency to draw in, peculiar to twist drills, is eliminated by the form of the flute. They are also used in drilling steel and iron when the holes break into each other, as in Fig. 16, and consequently are used when drilling for the impression in punch press blanking dies and similar work. Drills of this style, and sold in the market, have their flutes milled with a special milling cutter, although a very satisfactory drill may be produced if the flutes are made by use of an ordinary side milling cutter like that shown in Fig. 20, leaving its corner somewhat rounded to produce a round corner; this gives additional strength and reduces the tendency to crack when the drill is hardened.

Twist Drills.—In general it is not good policy to make twist drills in the ordinary machine shop; a superior article can be purchased at a cost much below that at which they are produced by machinery not especially designed for this purpose.



Machinery, N.Y.

Fig 11.

However, at times it is desirable to make a drill for a special purpose, even though the cost is greater. In an emergency the factor of cost cannot always be taken into consideration, and especially when the cost is not great enough to be considered prohibitive. When drawn wire (drill rod) of the proper size and quality can be procured, this can be used; for sizes where it is necessary to turn the stock to size it is well for the operator to use stock enough larger than finish size to enable him to remove the decarbonized portion at the surface.

For most purposes drills which are smaller than ½ inch diameter need not be ground to size after hardening; but if true holes of the size of the drill are desired it is necessary to grind them of a size larger than that above mentioned. To retain the center for use in grinding, the projection on the cutting end, Fig. 14, should be left until after the operation of grinding. After the flutes have been cut and the drill ground to desired size, the projection may be ground off and the cutting lips ground to the proper shape, as shown in Fig. 15. The smaller drills, which are made from drill rod, are cut to length, and the cutting end is given the desired angle

Diameter of Drill.	Thickness of Cutter.	Pitch in Inches.	Gear on Worm.	First Gear on Stud.	Second Gear on Stud.	Gear on Screw	Angle of Spiral.
1/16	.06	.67	24	86	24	100	16 20
1/8	.08	1.12	24	86	40	100	19 20

1	.77	8.95	86	48	28	56	19 20

which is 59 degrees to one side of the blank. When milling the flutes use cutters which will produce grooves of the proper form. These cutters are manufactured by the Brown & Sharpe Mfg. Co., Providence, R. I. The above table and the following explanation are taken from Brown & Sharpe's book entitled "Construction and Use of Milling Machines," being intended for use with their twist drill fluting cutters. These cutters are made both right- and left-handed, and it is somewhat better to use left-handed cutters, especially for small drills, as the cut commences at the shank, thus preventing the blank lifting from the action of the cutter.

The cutter is placed on the milling machine arbor, directly over the center of the drill, and the bed of the milling machine is set at the angle of spiral as given in the table.

To obtain increased strength the depth of groove of a twist drill diminishes as it approaches the shank; otherwise the drill would break from the strain incident to cutting. The variation in depth depends on the desired strength or the use of the drill. To obtain the necessary variation of depth, the spindle of the spiral head is elevated somewhat, depending on

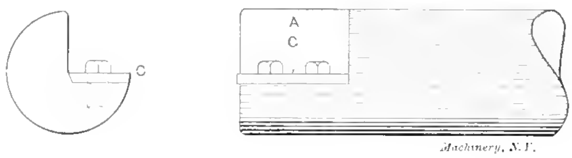

Fig. 12.

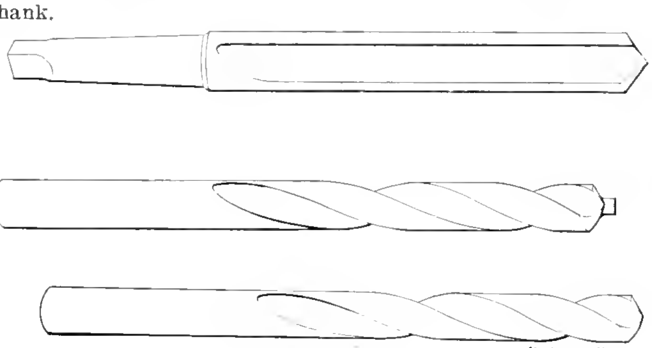
the length of the flute to be made. When less than 2 inches in length the angle should be ½ degree; for 5 inches and over in length, 1 degree. Usually this will be found satisfactory, but for extremely long drills the elevation must exceed these amounts. The outer end of the drill must be supported, as shown in Fig. 17, and when small should be held down firmly until the cutter has passed over the end. If left-handed cutters are used the pressure of the cutter holds the blank down so it is not necessary to use other means. When large drills are held by the centers the spiral head should be depressed in order to decrease the depth of groove as it approaches the shank.



Figs. 13, 14 and 15.

Another very important operation on the twist drill is that of "backing off" the rear of the lip, to give it the necessary clearance. In Fig. 18 the bed is turned to about ½ degree, as for cutting a right-hand spiral; but as the angle depends on several conditions it will be necessary to determine what the effect will be under different circumstances. A study of Fig. 18 will be sufficient for this, by assuming the effect of different angles, mills, and the pitches of spirals. The object of placing the bed at an angle is to cause the mill *E* to cut into the lip at *C* and have it just touch it at *S*. The line *R* being parallel with the face of the mill, the angular deviation of the bed is clearly shown at *A* in comparison with the side of the drill.

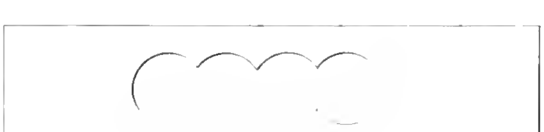


Fig. 16.

While the drill has a positive traversing and relative movement, the edge of the mill at *C* must always touch the lip a given distance from the front edge, this being the vanishing point. The other surface forming the real diameter of the drill is beyond the reach of the cutter, and is left to guide and steady it while in use. The point *C*, Fig. 18, shows where the cutting commences and its increase until it reaches a maximum depth at *C*, where it may be increased or diminished according to the angle employed in the operation. The line of cutter action is represented by *I I*.

Before "backing off," the surface of the smaller drills in particular should be oxidized by heating until it assumes some distinct color to clearly show the action of the mill on the lip of the drill, for, when satisfactory, a uniform streak of oxidized surface, from the front edge of the lip back, is left untouched by the mill, as represented at *E*.

If drills are to be ground and it is not considered advisable to center them, pointed projections of an angle of 60 degrees may be left at either end, as shown also in Fig. 18. The projections may be run in female centers in the grinding machine. After the drill has been ground to the desired size the projection on cutting end may be removed by grinding. If large holes are to be drilled deep the drills must be ground slightly tapering, making them smaller toward the shank. The amount of taper should be about .003 inch in 6 inches of length. This slight taper prevents their binding in a drilled hole, and yet is not great enough to allow the drill to run appreciably.

When hardening any tool it is, of course, necessary to conform to the facilities offered in the individual shop for doing such work; but in order to successfully harden twist drills suitable means must be provided, especially if the drills are comparatively large.

In shops where twist drills are manufactured for the market special methods of heating are provided, which insure uniform heats, and the maximum amount of work turned out. These methods are not generally understood outside the shop where they are in use, and would be of little value if they were, as it would not be feasible to install such equipment for a limited amount of work.

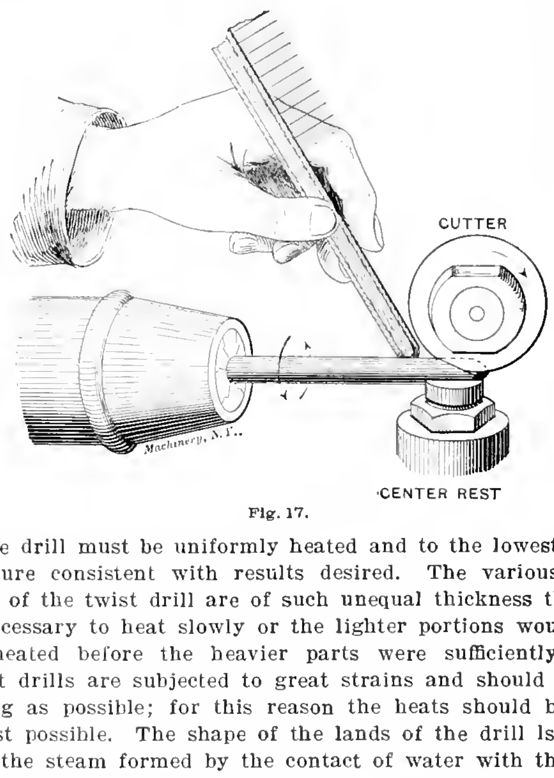

Fig. 17.

The drill must be uniformly heated and to the lowest temperature consistent with results desired. The various portions of the twist drill are of such unequal thickness that it is necessary to heat slowly or the lighter portions would be overheated before the heavier parts were sufficiently hot. Twist drills are subjected to great strains and should be as strong as possible; for this reason the heats should be the lowest possible. The shape of the lands of the drill is such that the steam formed by the contact of water with the red hot steel prevents the water from getting into the flutes and properly hardening the portion at the bottom, and as this portion forms the point of the drill, as it is ground back, it is necessary that it be hard. To overcome the tendency of the steam to force the water from the grooves a bath should be used which will insure the water reaching the bottom of the flutes. Such a bath is shown in Fig. 19. It has a jet of water coming up from the bottom, and also has perforated pipes coming up on the sides by means of which water is projected against all sides of the drill and to the bottoms of the grooves, thus insuring their hardening. This form of bath has been shown in a previous article of this series, but it is of such "all round" value, and especially when hardening articles of peculiar and irregular form, that it seems wise to again call attention to it.

The drill should be heated in a tube to prevent the fire coming in contact with the steel, unless we are using a muffle furnace, or some form where the steel is not exposed to the action of the fire or the air. A crucible of red hot lead furnishes a satisfactory means of heating drills, provided the precaution is used to prevent the lead sticking to the drill.

The following solution not only prevents the lead sticking, but as it is of a carbonaceous nature it increases, in a measure, the surface hardness:

Pulverized charred leather	1	pound
Fine family flour	1½	pounds
Fine table salt	2	pounds

The charred leather should be pulverized very fine; in fact it should be sifted through a No. 45 sieve. The three ingredients

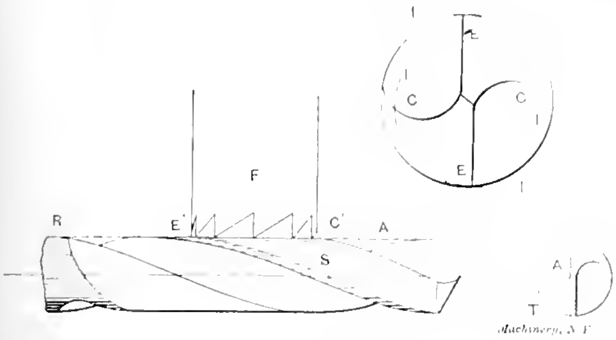

Fig. 18.

should be thoroughly mixed while in the dry state, then water should be added slowly to prevent lumps, enough water being used to bring the mixture to the consistency of varnish.

The drill may be dipped in the mixture and set in a warm place to dry, as it is never safe to immerse anything that is damp in red hot lead, the presence of moisture causing the lead to fly, endangering the eyes of the operator.

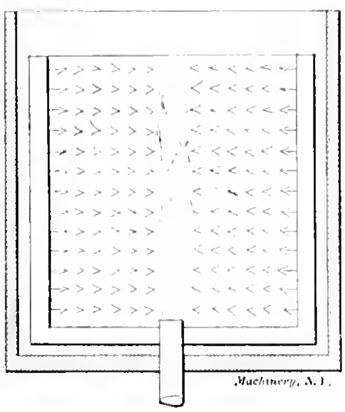

Fig. 19.

When the drill is uniformly heated it is immersed in the hardening bath and after hardening, the temper may be drawn. The amount necessary to draw the temper depends on the heat given the steel when it was hardened and the use to which the drill is to be put, although for most work a full straw color (460 degrees) is about right.

Fig. 20.

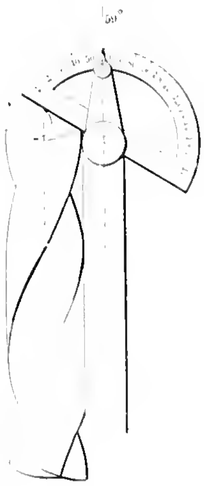

Fig. 21.

Fig. 22

Grinding Twist Drills.—The use of grinding machines designed especially for properly grinding the cutting lips of twist drills, has in a great measure done away with the extreme care necessary when grinding tools of this character by hand. Yet many shops are not provided with such machines and, as it is necessary that twist drills be properly ground, it is advisable for the young mechanic to learn to rightly grind them by hand.

Drills which are properly made have their cutting edges straight when the lips are ground to the proper angle, which, as previously stated, is 59 degrees, see Fig. 21. Grinding to an angle less than 59 degrees leaves the lip hooking, which is likely to produce an undesirable hole. An experienced operator can grind the lips of a drill to the desired angle and length, gaging the shape by the eye. The inexperienced, however, will find a gage of the form shown in Figs. 21 or 22 a great help, as by its use the correct angle and length of lip can readily be determined.

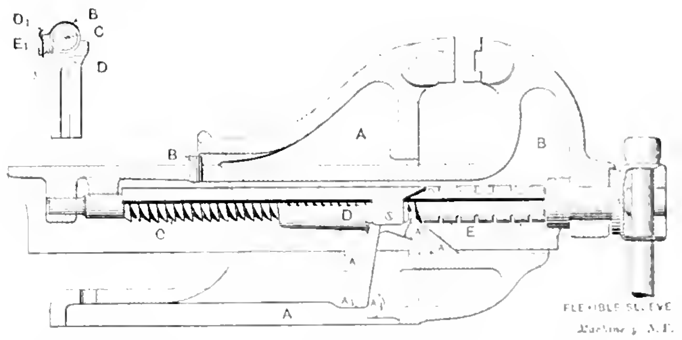
* * *

QUICK-ACTION BENCH VISE.

A large number of quick-action bench vises for machinists' use have been placed on the market, some of which have had very ingenious features. Among this number must be included a new design brought out by Charles Taylor, of Birmingham, England. For the illustration and condensed description, we are indebted to the *Mechanical World*.

A is the fixed jaw and body combined in one casting; *B* the usual sliding jaw; *C* the screw; *D* the half-nut customarily employed in this type of vise; *E* a sleeve which actuates the half-nut, replacing the usual mechanism actuated by means of a trigger, springs, etc. The half-nut *D* is engaged with or disengaged from the screw *C* automatically while rotating the screw in the act of gripping or releasing work, the movement comprising about 1/12 of a turn. Hence the whole work of gripping, releasing, engaging, and disengaging the mechanism is done by one hand in a normal movement of the lever.

In the illustration the half-nut is shown in engagement with the screw. It will be seen that immediately the gripping pressure is relaxed by turning the screw in an anti-clockwise direction, the nut, being free to do so, will fall out of engagement, leaving the jaw *B* free to slide. The work being placed between the jaws, the jaw is pushed up to the work. The lever is then rotated exactly as though the vise was a continuous screw vise. The first portion of the turn (one-twelfth of a turn) raises the nut into full mesh with



Quick-acting Bench Vise

the screw, by means of the sleeve *E*, which has a flexible grip upon the screw and turns with it until held by some positive stop (but not shown), the projection or lip E_1 (see end view) engaging the corresponding lip D_1 of the nut. While lifting, the screw and nut may make contact at the tips of the threads, and the nut be prevented from rising further by reason of the binding strain arising from the forward motion of the screw's thread, and then the tips of the thread are apt to break off. This is a point of failing in similar vises, but it is completely obviated in this vise, thus: A slight clearance is permitted in the upper way A_1 to allow the nut to fall away from the abutment A_2 by reason of its unbalanced position, and by the legs D_2 resting upon the part A_1 of the body. The angular disposition of the ways also tends to the same end, the nut advancing while rising, so minimizing the effect of the advancement of the thread while the screw is turning. This feature with a thread slightly undercut on its acting face also tends to cause a clinging together of the screw and nut, making it impossible for them to separate under blows or vibration. In the ordinary style of screw, the lever hole usually becomes bell-mouthed and reduced in diameter by an accumulation of oily grit, so tending to bind the lever. To mechanics this forms a well-known finger trap. By the removal (by drilling) of the metal at the center of the hole this sticking nuisance is obviated

MACHINERY

DESIGN—CONSTRUCTION—OPERATION.

PUBLISHED MONTHLY BY

THE INDUSTRIAL PRESS,

66-70 WEST BROADWAY, NEW YORK CITY.

LESTER G. FRENCH, Editor.
FRED E. ROGERS, Associate Editor.

The receipt of a subscription is acknowledged by sending the current issue. Remittances should be made to THE INDUSTRIAL PRESS, and not to the Editors. Money enclosed in letters is at the risk of the sender. Changes of address must reach us by the 15th to take effect on the following month; give old address as well as new. Single copies can be obtained through any newsdealer.

We solicit communications from practical men on subjects pertaining to machinery, for which the necessary illustrations will be made at our expense. All copy must reach us by the 5th of the month preceding publication.

OCTOBER, 1904.

NET CIRCULATION FOR SEPT., 1904,—24,156 COPIES.

MACHINERY is published in four editions. The practical work of the shop is thoroughly covered in the Shop Edition—$1.00 a year, comprising more than 430 reading pages. The Engineering Edition—$2.00 a year—contains all the matter in the Shop Edition and about 250 pages a year of additional matter, which includes a complete review of mechanical literature, and forty-eight 6 x 9 data sheets filled with condensed data on machine design, engineering practice and shop work. The Foreign Edition, $3.00 a year, comprises the same matter as the Engineering, but is printed on thin paper for transmission abroad. RAILWAY MACHINERY, $2.00 a year, is a special edition, including a variety of matter for railway shop work—same size as Engineering and same number of data sheets

A movement has been started in New Haven, Conn., to erect a monument to Eli Whitney, the inventor of the cotton gin. A committee has been formed to raise a fund, and when Congress meets, a petition will be presented asking the government to make a substantial appropriation as a basis for the fund. It is proposed to erect the monument in Whitneyville, where Whitney first made his cotton gin and later established his famous factory for the manufacture of firearms.

* * *

Modern machinery applied to many industries has a tendency to shatter poetical ideals. A favorite theme has been the danger, toil and privation of the fisherman's life, and the somber pictures have by no means been overdrawn, but according to a recent report from the U. S. consul at Gothenburg, Sweden, the modern fisherman is likely to escape a great deal of the toil and danger that appeared inseparable from his lot. He says that a good many of the fishermen buy petroleum motors for their boats or cutters, some from Denmark and some from the mechanical works at Lysekil. The motors are expensive, but save so much work and delay at sea that they are still considered advantageous. The first motors used by the fishermen here were made in the United States. Boat motors are now made at several places in Sweden, however, and Denmark seems also to have gained a market there. The Northern Fisheries Exposition held in July, in the city of Marstrand, was expected to make the fishermen more familiar with the advantages of boat motors and to increase the demands for them.

* * *

FIRST AMERICAN ALTERNATING CURRENT RAILWAY.

What is expected to work a great improvement in electric railway operation and to further the transformation of steam roads to electric systems, is a new motor developed by the General Electric Company which works equally as well with either direct or alternating current. Electric railways in general are now operated with direct-current motors with voltages of 550 to 600 volts. For heavy service and extended systems the cost of copper required at this voltage becomes a serious item, and for some time there has been felt the need of a higher trolley voltage. The possible use of alternating current for the trolley would admit of a higher voltage than is possible with direct current, as the voltage could be reduced by a transformer on the car to the potential required by the motors. The development of the large power stations and transmission systems, has been principally with alternating current, requiring rotary converters or other transforming devices for changing the alternating current into direct current suitable for the operation of electric railways. Obviously there would be a great advantage in a railway-motor equipment that could be operated from an alternating-current high-voltage trolley and without the necessity of intermediate-commutating devices. Such an alternating-current equipment would offer a further advantage if it could be operated both on alternating extensions of existing systems and on the direct-current trolley where the latter is already installed.

The development of the single-phase commutator motor and its inherent fitness for traction work have created wide attention among railway interests, and work of a practical nature has been actively pushed on both sides of the Atlantic. Considerable interest therefore attaches to the operation in regular service by the Schenectady Railway Company of single-phase alternating-current motors on its Ballston extension. This is the first instance in this country, it is believed, of an alternating-current road in regular service carrying passengers, and its commercial possibilities are largely due to the fact that the motors operate with alternating-current power outside city limits and with direct-current power within the city limits. The motor as installed on the Ballston line is of the "compensated" type, so named on account of the character of the field winding, which fully neutralizes or compensates for the armature reaction. Both the compensated motors and control are adapted for operation on the 2,000-volt alternating-current trolley between cities and the standard 600-volt direct-current trolley in Schenectady. This ability of the compensated-motor equipments to run over tracks equipped with either alternating-current or direct-current trolley makes their field of application very broad, as the cars can secure all the benefit of running over existing city tracks without in any way sacrificing their running qualities upon suburban sections equipped with alternating-current trolley.

The alternating-current motor with its inherent advantages of high-voltage distribution is particularly adapted to replace the steam locomotive on either high-speed passenger or heavy-freight haulage work; and as the compensated type of motor is perfectly adapted to operate on both alternating-current and direct-current trolley, the alternating-current motor must be considered a large factor in future suburban-railway systems. The compensated motor is essentially a variable-speed motor, differing in this respect from the multiphase-induction motor, whose constant-speed characteristics proved so serious a handicap to its successful adoption in railway work. The speed-torque characteristic of the compensated motor is very similar to that of the direct-current series motor, while its commutating qualities and method of control prove equally satisfactory.

* * *

Successful photography of machine shop interiors is greatly hampered by "halation" around the window, skylight and monitor openings. That is, every opening toward the light is surrounded by a halo in the developed plate which destroys all detail for some distance from the edges. This effect is partially due to the reflection from the interior back surface of the glass plate, thus causing the fog. The so-called non-halation plates are more or less effective in cutting down the destructive effects of halation, but perhaps the best results are obtained by backing the plates with some dark non-reflecting substance. A backing that is recommended by one having experience consists of lampblack and gum-arabic mixed in the proportion of two spoonfuls of lampblack to one of gum-arabic with sufficient water to make a stiff dough. The mixture hardens into a cake and is applied to the back of the plate with a rag, and must be carefully wiped off before developing. Only a thin coating is required and it is easily removed. Backings containing glycerine are said to be bad on account of drawing moisture from the atmosphere.

ENGINEERING REVIEW.

CURRENT EVENTS, TECHNICAL AND MECHANICAL—LEADING ARTICLES OF THE MONTH.

The reliability and durability of the gasoline motor as applied to automobiles would seem to be pretty well demonstrated by the recent non-stop record of a Darracq touring car which made the trip from New York to St. Louis—3,400 miles—without stopping the motor during the entire run. Altogether the motor ran over fifteen days without stopping and during most of this time it was being jolted over roads, some of which are the worst in the country.

A great modern hotel like the Hotel Astor, recently completed in New York City, contains much that is of interest to the engineering profession. This hotel has a large power plant that is one of the show features of the place. It includes four Rice & Sargent tandem compound Corliss engines of 250 kilowatt capacity each, making the total power capacity nearly 1,400 horse power. This immense power capacity is required for the lighting system, operation of elevators, machinery connected with the operation of the kitchen, the ice and refrigerating system, etc.

An ingenious rifle sight called the "hyposcope" is being introduced to the notice of military authorities in Europe, which enables a soldier to sight and fire over a parapet, or other barrier, without exposing any portion of his body. The hyposcope consists of a light metallic tube made L-shape, which is clamped to the side of the barrel with the long part of the "L" vertical and the short part lying across the top of the barrel. A series of mirrors within the L-tube accurately reflect the image of the distant object in conjunction with the rifle sights to the eye, although the soldier's head may be 5 or 6 inches below the normal sighting position.

In his presidential address at the twelfth annual convention of the National Railroad Blacksmiths' Association, Mr. Lindsay referred to the fact that the secret of success is often hidden by a very thin vail, and in that connection mentioned that Professor Langley of the Smithsonian Institute, experimenting on alloy steels twenty years ago had the secret of high-speed steel within reach, but the world lost its use for fifteen years simply because he did not know how to harden it. It would have been deemed the height of foolishness then to have hardened the steel by "burning" it, but that was the secret discovered by Taylor and White, forming the basis of their famous process, which has revolutionized machine shop practice.

It doubtless has often been a matter of curiosity to many how large railway companies keep track of their locomotives. That they do keep track of them is pretty generally conceded, but there is apparently an exception if the statement of a British newspaper is to be relied on; it states that the London & Northwestern Railway has lost a locomotive. Engine sheds are being searched and every mile of the line is being examined from London to Cornwall, but no trace of the missing engine has been found. How it could have vanished the railway officials do not know; but they have two explanations to offer. One is that the engine may have been shunted on to some branch line in Cornwall or Devon, and its existence forgotten, and another that a new number may have been given to it, and the old number still retained on the company's book.

In a communication to the *American Engineer*, Mr. Edward L. Coster gives some figures showing the wonderful efficiency of heating surface of a De Glehn compound Atlantic type express locomotive on the Paris-Orleans Railway. One of these locomotives, which weighs only 80 tons, recently developed 1,900 horse power at a speed of 70 miles per hour. The total heating service of this locomotive is 2,616.8 square feet, hence it developed one indicated horse power for each 1.38 square feet of total heating service, or 0.73 indicated horse power per square foot of heating service. This would indicate that the locomotive boiler is an exceedingly efficient device for boiling water so far as heating area is concerned.

In referring to an accident that occurred in the Robinson Deep mine in South Africa a few months ago, a mining exchange cynically remarks that the hoisting rope broke at a point 350 feet from the top and the cage was precipitated to the bottom of the shaft, 2,050 feet deep, with the result that forty-three Kaffir "boys" were missing from the mine complement. A powerful writer of modern fiction has remarked that there is nothing so cheap as human life, and it would seem that the stony indifference of mine owners goes a long ways towards confirming the statement. Is there any good and valid reason why mining cages cannot be fitted with safety catches to hold them in case of the hoisting rope breaking?

The Technology Club of Syracuse was organized at Syracuse, N. Y., on January 6, 1904, with a membership of 129, including engineers, architects, analytical chemists, metallurgists and geologists. The headquarters of the club are at 707 Dillaye Building. Meetings are held monthly except during June, July, August and September. Annual election of officers is at the October meeting. Visits to manufacturing plants are one of the features of entertainment and instruction and on June last the club took a trip over the Auburn & Syracuse Electric Railway to Auburn, N. Y., and visited several large manufacturing plants and the power house of the above-named railway. Prof. John E. Sweet is president of the new organization.

A collector for the Central District and Printing Telephone Company, states the *Western Electrician*, in opening the money receptacle of the pay stations in four Allegheny, Pa., drug stores discovered a number of coins of the same design as the ordinary penny, but of weight and size of a dime. He reported the matter to the treasurer, who summoned the secret service operatives to his assistance. Examinations were made, and it was discovered that, instead of being counterfeits, the money was nothing more or less than copper cents which had been worked into the size of dimes. Chemical tests showed that the result was attained by immersing the coin in muriatic acid until it was reduced to the desired size, the operation taking about 40 seconds.

A newspaper item states that the *Governor Stanford*, No. 1, the first locomotive to cross the continent from the Pacific coast, is being placed in the Stanford Museum, where it will remain permanently as a relic. This engine was built in the early 60's and was brought from the East around Cape Horn in 1867. After the driving of the golden spike, the last act in the completion of the Central Pacific Railroad, on May 10, 1869, No. 1 was used by Gov. Stanford to draw his private train through Nevada to the scene of the exercises. The Central Pacific Company gave the engine a few years ago to Mrs. Stanford. It has been resting under a shed on the university campus, but is now being removed to the museum, where the rust is being scraped from it, the metal work polished and a new coat of paint added to make it appear as nearly as possible like it did when it was the finest type of locomotive in use.

The bandsaw has worked a considerable change in woodworking machinery, but so far its use in the machine shop is comparatively limited. It is, however, used to some extent with special blades for cutting off bar stock and similar work. A British concern, Clifton & Waddell, near Glasgow, has, however, applied the bandsaw to an interesting metal-working operation. They make a horizontal bandsaw, with a platen similar to that of a planer, which is used for trimming the uneven edges of flanged boiler plates. A flanged

tube sheet, for instance, is bolted to the platen, and the machine started up. The feed of the platen carries the tubesheet against the saw, which trims it off to a uniform height. The wheels, carrying the saw blade, are, of course, vertically adjustable so as to adapt it to all kinds of work within its range. The machine takes work 9 feet long by 6 feet wide, by 2 feet high, and weighs about 25,000 pounds.

There are three methods of sensitive governing under high heads. The first is by means of stand pipes, into which the flow of water is diverted when shut off from the wheel, relief valves being also provided. The second, which is used largely in the U. S., is to deflect the jet or stream away from the buckets, sudden changes of speed in the centrifugal governor bringing a nozzle deflecting mechanism into action. The third is a method introduced by Mr. E. F. Cassel, in which the wheel is divided along the center line of the buckets into two sections, and the centrifugal force developed in the rotation of the wheel body itself is arranged to cause the two sections to separate slightly. A portion of the water jet is thus allowed to pass between the buckets, instead of impinging directly against them, and being part of the wheel itself, the governing action is instantaneous.—*Page's Magazine.*

The use of oil for laying dust on railways and highways has been successful in a certain sense although the cost is perhaps a serious bar to the general mitigation of the dust nuisance on dusty roads. The automobilists also complain that oil is detrimental to their tires because of its well-known destructive effects on rubber. Calcium chloride has been suggested as a cheap and harmless product for laying dust, it being effective for this purpose because of its hygroscopic quality which makes it collect moisture from the atmosphere during even the driest weather. Thus if mixed with the soil of a road bed it soon makes it damp and maintains it in that condition. Although cheaper than oil it doubtless is not nearly so permanent in its effects, and after every heavy rain it would probably have to be renewed. This is one of the valuable features of petroleum, and when used in sufficient quantities it makes a roadway waterproof the same as asphalt

---

The Krupp Works, Germany, according to a consular report by Consul-General Richard Guenther, employed at the time of its last published statement, 45,289 men, of whom 4,190 were officials. The average daily wages in the steel works at Essen for the past fifty years is as follows:

AVERAGE DAILY WAGES IN KRUPP CAST STEEL WORKS, 1853-1903

Year.	Daily Wage.
1853	$0.32
1860	0.49
1870	0.73
1875	0.93
1879	0.72

Year.	Daily Wage.
1890	$.85
1900	1.14
1901	1.00
1902	1.08
1903	1.09

In a paper read by President F. C. McMath at the tenth annual meeting of the Detroit Engineering Society, on the progress of railway bridge building, the author stated that the last two decades had seen great changes and improvements in the manufacture of bridges, in common with the improvements that have taken place in other lines of manufacture. Bridge shops are greatly increased in number and in capacity; where fifteen years ago no single concern had a capacity exceeding 2,000 tons of bridge work per month, there are now a number of bridge shops that far exceed this output. For example, the American Bridge Company, at Ambridge, near Pittsburg Pa., has an estimated monthly capacity of 20,000 tons of bridge work. One of the most important departments in bridge building is the drafting room, and some idea of the scale of the concern just mentioned will be gained when it is known that provision has been made in the office for upward of 500 draftsmen.

In a paper recently read by Mr. John C. Anderson before the Louisiana Engineering Society, on steel-concrete construction, the author made a special point of the firmness with which cement mortar adheres to steel. In his opinion this union is something different from mere adhesion, being more like fusion of the particles of concrete with those of the steel surfaces. The affinity is such that there is a stronger bond between the cement mortar and the steel than there is between the particles composing the mortar itself. This will be noted when concrete is cut away from a steel beam, for the chisel will cut into the beam without causing the concrete to flake off. When it breaks loose it tends to take the metal with it, there being no well defined line of cleavage, so to speak. Another valuable feature of combined steel and concrete construction is that steel and concrete have practically the same coefficient of expansion by heat, which feature is particularly valuable in the insulation of steam pipes, or in any construction where steel or iron are subject to extreme conditions of temperature.

A spirally corrugated boiler tube is a product which is being offered to American railways as a panacea for boiler troubles. The tubes are made plain at the ends for a distance of about 8 inches, and the body is corrugated in spirals of 3¾ inches pitch. These corrugations render the tube elastic, so that expansion and contraction is taken up within the tube itself without throwing severe stresses upon the tube sheets. It is claimed that a 16-foot tube was stretched ⅝ inch without giving it a permanent set. Hence it may be expected that the ordinary expansion and contraction of a tube in service will be compensated in the tube itself without disturbing its connections with the tube sheets which, as is well known, is the prime cause of most tube troubles. A serious objection to these corrugations, however, would appear to be in the corrugations collecting cinders, but it is claimed that there is no trouble experienced from this source whatever. The increased area of the tube due to the corrugations and their angular projections make such flues more efficient in the transmission of heat, it is claimed, so that there is a marked saving in fuel by their use.

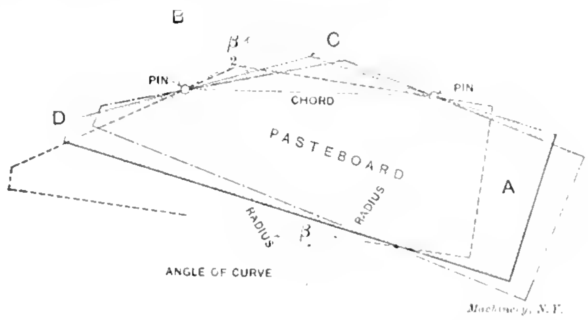
Undoubtedly when all points of advantage and disadvantage are considered the nut-lock *par excellence* for machinery is the double nut with a cotter pin through the bolt back of the second nut. There are, however, some points regarding the size and shape of the second nut that should be recognized and applied to get the best results. It should be made thin, say two-fifths the thickness of a standard nut, and should be chamfered on the bearing side so as to bear heaviest next the thread. Made in this way the lock nut wedges more firmly in the thread and the main nut has less tendency to loosen it under the influence of vibration. A nut-lock has recently been patented in England which is a further extension of these principles. The second nut is made thin and is much smaller across flats than the standard nut. Although it is difficult to understand how a patent was granted for this idea, which has undoubtedly been used time and time again, we must admit that the principle is one that has received little recognition. The smaller nut having less weight than the main nut is less affected by vibration because its frictional hold is greater in proportion to its mass. Hence a vibration which might tend to loosen the main nut only causes it to wedge more tightly against the lock nut, because this remains firmly in place.

Because of the practical impossibility of automatically weighing "run-of-mine" coal when delivered into the tenders of locomotives at coaling wharfs, there has never been a systematic accurate weighing out of fuel to locomotives on American railways, the general plan being the hap-hazard method of estimating the weight from the size of the tender and its condition previous to being filled up. Hence, scarcely any road knows exactly what a class of service is costing for fuel or how any two classes of locomotives compare in the matter of fuel economy. When it is known that coal is one of the biggest items of cost in railway operation it seems lax to

allow this condition to continue. Although run-of-mine coal cannot be accurately weighed on automatic scales such as are used for weighing grain, etc., there is no trouble in weighing in this way coal that is regular in size. This leads a correspondent in the *Railway Review* to call attention to the fact and to the obvious economy that would result in every railway providing coal crushers for reducing all locomotive fuel to an even size. All large power plants regard the coal crusher as a most necessary part of their equipment; crushed coal is easier to handle and is more economical to use since it can be spread more evenly over the grates and combustion is more nearly perfect. Smoke is reduced and the full area of the grates is more nearly utilized.

METHOD OF PLOTTING CURVE FROM AN INACCESSIBLE CENTER.

Correspondents of the *Engineering News* have revived or rather called attention to a useful method of plotting a curve of long radius when the center is inaccessible. Two pins are stuck into the drawing board at the ends of the required curve, and a piece of pasteboard A is cut so that the exterior angle $B\,C\,D$ is one-half that of the required arc. Thus, if the



angle subtended at the center is 40 degrees, angle $B\,C\,D$ would be 20 degrees. To lay off the curve the pasteboard is pressed against the pins, as shown in the sketch, the points of the curve are marked off from the vertex C. The hatched lines show the position of the pasteboard templet and the dotted lines, other positions that it occupies as the points are laid down.

DEVICE FOR PREVENTING EXPLOSIONS OF GASOLINE AND OTHER INFLAMMABLE LIQUIDS.

A consular report from United States Consul Halstead at Birmingham, England, describes an invention called "nonex" which is a device for preventing the explosion of receptacles containing highly inflammable liquids like gasoline, benzine, etc., which give off explosive gases. The consul says that the device is an application of the principle of the Humphrey Davy safety lamp used in gaseous mines, supplemented by a fusible cap or plug. "If a vessel of ordinary type containing an explosive liquid be subjected to sufficient outside heat, or if the contents be lighted at the orifice, the walls of the tank will burst by the force of the expansion. At an exhibition given by the Non-Explosive Device Company, a 20-gallon tank was partly filled with gasoline and placed upon a lighted bonfire. The fusible screw cap, made in two parts which were simply soldered together, soon blew out, the solder having melted, and the ascending vapor caught fire immediately; but no explosion followed, because the orifice of the tank formed the upper end of a tube which projected down inside the vessel to its bottom, where it was closed. To allow the oil or gas to percolate from the interior of the tank each of the metal layers of which this tube was composed had been perforated, and, while the perforations would permit the spirit to be poured out, they prevented the passage of the burning gas to the interior by absorbing its heat as the wire gauze does in the Davy lamp. While the gasoline contained in the tube burned, the flame did not extend to the liquid or accumulated vapor in the half-full tank. The flame was easily extinguished with a bundle of rags and then lighted and put out several times. A motor car tank to which the device was affixed was lighted with a match and extinguished at will. A gasoline can without the device exploded almost instantaneously when lighted."

INDIFFERENCE OF GERMAN WORKMEN TO SPORTS.

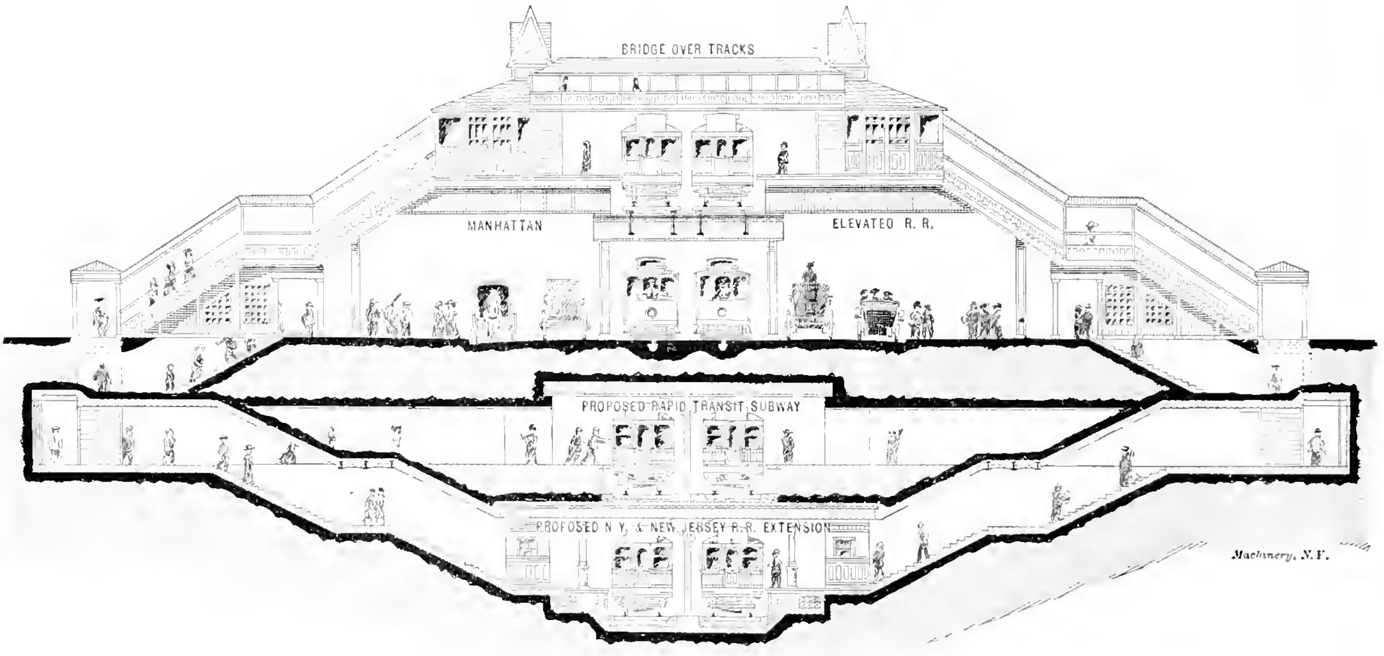
A correspondent of the London *Times*, who has written a series of reports on industrial conditions in Germany, notes a conspicuous difference in the national characteristics of the English and German workingmen as regards amusements. He says: "Amusements play a comparatively small part in the lives of German work people, and such as they have are mostly confined to Sunday. Games have not taken hold of them; they go to no football or cricket matches, although there are matches, and other classes in Germany show a growing taste for games and sports. I went to see a football match between Düsseldorf and a neighboring manufacturing town. It took place on Sunday afternoon. The day was fine and the ground very handy to both towns. A similar match anywhere in manufacturing England would have attracted from 10,000 to 20,000 sons of toil, who would have shouted themselves hoarse from beginning to end. At the German match not one put in an appearance. When I left the field toward the close of the game the spectators, who had slowly increased during the afternoon, numbered exactly 65. They were not workingmen, and they showed no excitement whatever. I noticed a curious difference in the behavior of spectators and players. In England the former keep up an almost continual noise, shouting at nearly every kick, and bursting into a prodigious roar when a good point is made; the players, on the contrary, maintain an almost unbroken silence. It was just the opposite in Germany; the spectators only raised a feeble sound when a goal was kicked, and for the rest were silent, but the players called out incessantly, directing, exhorting, and reproaching each other. They played the association game, not very well. The national game in Germany is kegel, a kind of skittles, and it is played at public houses, but not by workingmen, or seldom by them. They play cards sometimes, but not a great deal. In short, games may be ruled out as an item in industrial life."

REDUCE PRESSURE TO SAVE GAS.

It is a matter of quite general knowledge that there is a certain gas pressure at the burner tip that should not be exceeded if the most light per cubic foot of gas consumption is desired, an excess pressure means that gas is blown away and wasted. The most economical pressure, says Mr. Walter J. May in the *Practical Engineer*, is 0.3 inch water gage, or 0.25 inch if the rooms are not drafty. In the mains the pressure will be anywhere from 0.9 to 4.0 inches, which pressures will be reduced somewhat at the burner tips according to the internal condition of the service pipes. With smooth pipes the reduction is slight, but with rough pipes the loss in pressure is often large. It is a matter of substantial economy to use only pipes of fairly large capacity which are smooth internally and, in fact, cold-drawn pipes are recommended. A "wrinkle" in the economical use of gas is mentioned which is worth knowing. As everyone knows, a stop cock is placed on the supply side of the meter, and no matter whether this is fully or partially turned on, the gas in the meter is the same as on the supply side of the stop cock when the gas is not in use, but if in use the gas expands in the meter if the stop cock is turned on just enough to meet the demand at burner pressure, and this is a big loss to the consumer. To convert this loss to a gain, have a stop cock on the consumer's side of the meter, turn on the one on the supply side to its full capacity into the meter, but regulate the supply to the burners by the stop cock on the consumer's side, and take advantage of the expansion for your own benefit. In many cases this will bring down the gas bill by from 25 per cent. to 50 per cent., but attention must be paid to the regulation. As a matter of actual practice, the gas enters and fills the meter at the main pressure, say 2.0 inches; the amount required is fed into the consumer's pipes at this pressure, reducing the pressure to, say 0.3 inch at the burners, and the reduction thus obtained is obtained by the expansion of the gas in the pipes, the gain being the difference in volume in the gas—*i. e.*, the meter registers the compressed gas—which in the meter is at 2.0 inches—while the consumer uses it at the pressure most economical, and not only saves gas, but what is equally as important, gets more light by reason of the more perfect combustion.

PROPOSED FIVE LEVELS OF TRANSPORTATION IN NEW YORK.

New York, which now grows in a vertical direction because of the natural limitations of Manhattan Island, must also provide transportation facilities on more than one level in order to handle the great volume of traffic during the rush hours. In other words if the skyscraper office building shall eventually monopolize the business section, the city railways must also be built on the same plan, one above the other three and even four "stories" high. For some years the elevated and surface lines have carried the crowds in a fashion more pleasant to contemplate than to experience, and soon the subway will be opened, thus giving elevated, surface and sub-surface transportation lines traversing the city in a general north and south direction. That there will be still another level of transportation is also a possibility if the plans of the New York and New Jersey Railroad Company assume concrete shape. This is an extension or feeder of the Hudson River tunnel north from Hudson St. to the intersection of Broadway and Sixth Ave., which at that part of the route will be a sub-subway or a tunnel underneath a proposed spur of the Rapid Transit Subway. The New York *Herald* recently published an interesting diagram showing in a vertical section the four levels of railway lines at the intersection of Sixth Ave. with Broadway at Thirty-third St., and a fifth level above all in the shape of a foot-bridge over the Thirty-third St. station. This is, of course, an extreme condition, but it gives some idea of the great traffic and future plans for handling it.



Cross-section of Tracks in New York showing five Levels of Transportation.

REMEDY FOR INJURED STEEL.

La Revue Technique, July 10, 1904.

Messrs. Stead and Richards, of England, have developed an exceedingly simple process for the amelioration of steel that has been injured, burned or rendered brittle in the course of manufacture. Large masses of steel that are to be forged or rolled are heated in a reheating furnace before being subjected to these operations. It is essential that they should be raised to a certain temperature, which must not be too high, for otherwise they are apt to be burned, as it is called, and such burned metal is so modified in its characteristics that it will frequently break to pieces when passing between the rolls. It is generally recognized that, to obtain the best results, the temperature of this reheating should not be above 2,200 degrees F. Now Messrs. Stead and Richards have found that steel, which has been rendered useless by having been overheated and crystallized can not only be brought back to its original condition, but can even be improved by a treatment developed by them, which consists in heating the metal after it has cooled, to a temperature of from 1,550 degrees to 1,650 degrees F. It is of the first importance that this latter temperature should not be exceeded. Further than this, the process is perfectly efficacious in healing, if we may use the term, those steels that have become crystallized in service, and after the treatment they are better than when they left the forge in the first place. We know that the object of forging is to do away with this coarse crystalline structure, and when it is found to exist in a metal, we have, up to the present, known of no other way than re-forging to restore the fine texture. Messrs. Stead and Richards maintain that their method possesses the same advantage and, furthermore, that it materially increases the tensile strength, frequently as much as 100 per cent.

It should be noted, however, that the inventors do not make these claims for mild steel, but for the better qualities used in crankpins and similar places. G. L. F.

THE AEROPLANE AND FLYING MACHINE.

Abstract of Paper read by Major B. Baden-Powell, President of the Aeronautical Society, before the British Association.

The day is undoubtedly drawing near when we shall be utilizing the highway of the air for travel, and it is becoming an interesting question as to what form the motor-car of the skies is to take. A great number of abortive attempts to produce a practical apparatus have thrown considerable light on the prospects. During the last few years we have seen a great development in the construction of navigable balloons, and, in my humble opinion, these many attempts have only shown clearly what immense difficulties have to be contended with, and how little hope there is of our obtaining any real success in this direction. I do not wish to imply that the navigable balloon is an utter failure, and though such a machine may prove itself most useful on certain particular occasions, and for special purposes, such as military observation, even that is a long way from being a really practical conveyance, capable of going up in all weathers, and stemming such winds as it may be likely to encounter on any average day. A balloon must of necessity be of huge size, and it must, therefore, offer a great resistance to rapid propulsion. Speed, however, is everything in practical aerial navigation, since the great object is to be able to progress in a given direction without interference from the wind force. If the same propelling power were applied to some smaller form of apparatus, would it be possible for the machine to maintain itself in mid-air, and progress through it? Theory answers very decidedly, Yes, and even practice may point to many promising results. The aeroplane (using the word in its widest sense) may be defined as a plane, or nearly plane, surface propelled through the air in such a manner that the resulting pressure acts so as to support it against the action of gravity. The

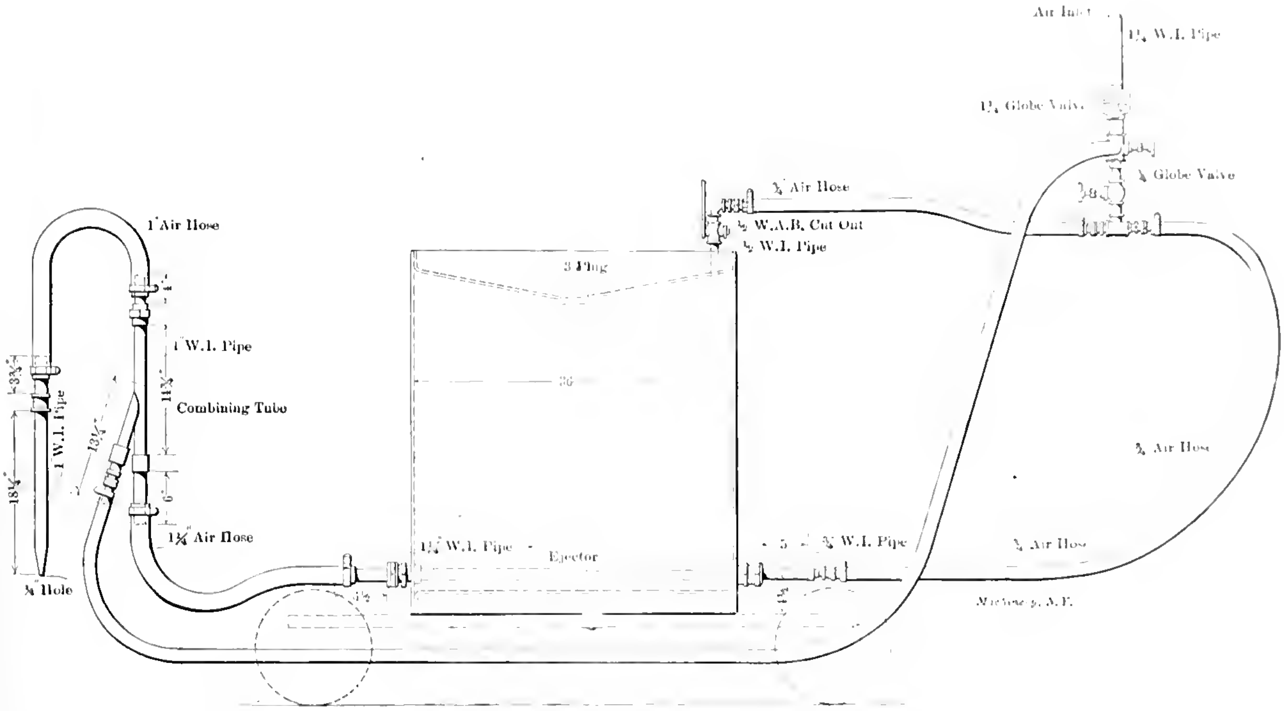
frontal resistance of such a plane, even of very large surface, seems bound to be less than that offered by a large balloon, and it should, therefore, be able to travel quicker.

Devices for attaining artificial flight may usually be classed under one of three headings—(*a*) wing action, similar to a bird's flight; (*b*) vertically-acting screws to lift the weight upwards; (*c*) aeroplanes proper, or plane surfaces propelled horizontally, with a slight upward inclination. All these three, however, are but aeroplanes according to the above definition. The wing is but the aeroplane moved up and down. The vertically-acting screw is but a pair of small aeroplanes moving round a common center. What we have, then, to study, is the action of air on inclined surfaces, and this is a subject not at all well understood. Theory and practice are much at variance. Theorists have worked out their problems, and shown what is, or should be, possible; but practice has been unable to even approximate the attainments suggested. Take the thrust of aerial screw propellers. The following are some of the records I have been able to collect:

Nadar in 1863, as the result of small experiments, computed that a thrust of 33 pounds should be got from 1 horse power. Wenham, with a spring motor calculated on 33½ pounds per

the pressure of the air acting on a plane surface moving in a normal direction—that is to say, so that the air strikes it perpendicularly, has been variously measured. All the older textbooks give the formula thus: Pressure = velocity ² .005. But the more recent experiments of Langley, Renard Dines, Stanton, and others vary from .0027 to .0039, showing a very marked and important difference from the old formula. Commandant Renard made many trials at the French Military Aeronautical Establishments. But the results, which have not been published in full, seem to have been very variable, ranging between 48 pounds and 17 pounds per horse power. He remarks, significantly, that some forms of screw are so much more efficient than others, and that there must be "a screw very much better than others, and its form cannot be much departed from without producing very bad aerial screws."

Another matter of importance on which authorities disagree is that of skin friction. Hitherto it has been supposed that the friction of the air on surfaces moving rapidly through it was negligible. Thus Langley, in his "Aerodynamics," says: "The friction of the air is inappreciable—this fact may be stated as the result both of my own experiments and of well-known experiments of others." Maxim, making his ex-



Sand Blast Apparatus for Cleaning Tenders.

horse power. Dieuiade, with a small steam engine got a pull of 26.4 pounds; and Forlanini made a little engine giving exactly the same results. Vogt, a marine engineer, made some careful comparisons between aerial and submarine screws, finding the former produced 33 pounds thrust per horse power. Later, with large screws rotated by manual power, he calculated that he got 55 pounds per horse power. Yet, when we come to trials on a large scale, we find Maxim, with his great steam engine of 360 horse power and screws of 17 feet 10 inches diameter, only gets a thrust of 2,000 pounds, or at the rate of 5.7 pounds per horse power. Santos Dumont, taking the best of aerial engines tried, obtains a pull of 175 pounds with 16 horse power, or 11 pounds per horse power. Zeppelin, with two engines of like power, only gets 220 pounds thrust, or 7 pounds per horse power. With my own little petrol motor of 1½ horse power I have only been able hitherto to get 5 pounds pull out of the screw. It is true that Walker, in his experiments with large propellers, shows from 11 pounds up to no less than 74 pounds; but these, again, may be classed as laboratory experiments. Then it has been usual for theorists to consider only the pressure of the air on the under surface of the plane. But recently a little more light has been thrown on the subject of what we may call the lack of pressure on the upper side, which undoubtedly has a considerable effect in sucking the plane upward. Even

periments with aerial screws, tested a contrivance like a screw propeller, but with perfectly flat blades, the results of which were that he found "the skin friction between the air and the polished surface is so small that it need not be taken into consideration." It might then have been considered that this point was settled. But no. Within the last few months Mr. Zahm read a paper before the Philosophical Society of Washington, giving an account of a series of careful experiments he has made, which seem to prove that the frictional resistance is at least as great for air as water in proportion to their densities. In other words, it amounts to a decided obstacle in high-speed transportation.

SAND BLAST APPARATUS FOR CLEANING TENDERS.

Railway Age, September 2, 1904, p. 303.

A method of sand blasting locomotive tenders for repainting has been in use at the Scranton shops of the Delaware, Lackawanna & Western for some time with marked success. The illustration shows the connection and form of the sand ejector, combining tube and nozzle. To bring the sand out in better quantities, air pressure is maintained within the tank. The ejector consists of two iron pipes, with open ends opposite, the blast passing from one to the other and carrying sand with it. The combining tube consists of two iron pipes welded at an acute angle, so that an unencumbered air cur-

rent at full pressure enters the sand passage and supplies additional force. The nozzle is a 1-inch iron pipe drawn down to a ¼-inch opening. The nozzle and combining tube wear rapidly but are cheaply made and easily attached.

As to results, one man can clean a 6,000-gallon tank on the trucks, as run in, in from six to ten hours, depending on its condition, quality of sand and constancy of air pressure. The latter is an item not to be overlooked, for in a shop which ordinarily works about to the limit of its air supply such a blast as this is capable of making quite an inroad. Here a good grade of lake sand is used, and it is generally used over, but after the first blasting it loses much of its sharpness and therefore requires a longer time to do the work. However, an average of about 1 square foot cleaned per minute is made. The surface obtained is ideal for painting, as it is just rough enough to hold the primer nicely.

STEAM AND ELECTRIC TRACTION COMPARED.

Railway Age, September 2, 1904, p. 290.

The impressive exhibition of power manifested by the steam locomotive with its heavy blast of smoke and sparks from the stack is quite in contrast with the electric car or locomotive, which starts and moves with so little appearance of effort. The consumption of power for obtaining the same result with trains of equal weight and speed will, of course, be nearly equal with either form of motor. The modern passenger locomotive develops 1,500 to 2,000 horsepower for a considerable period, and, in fact, this amount is often required to move trains of 600 tons at speeds called for by fast schedules. A large amount of power is required to move the locomotive itself at high speeds on account of the head-end atmospheric resistance. For this reason, only a fraction of the total tractive effort developed appears at the drawbar as useful work for hauling cars. The same is true of the electric car or locomotive, so that it may be said that the principal element of resistance at high speed is common to both kinds of traction.

As an indication of the power required to move a single electric car at even moderate speed, the following figures are given:

	Car, Length, Feet.	Weight, Pounds.	Speed, Miles per Hour.	Motor Horse Power.
Aurora, Elgin & Chicago.....	47	75,000	65	500
Columbus, London & Springfield	60	75,000	65	500
Lackawanna & Wyoming Valley	52	70,000	60	300
Rockford, Beloit & Janesville..	46	52,000	45	200

From these figures, which do not represent abnormal cases, it is apparent that from 300 to 500 horsepower is frequently placed under cars having total light weights not exceeding 75,000 pounds, this weight including, of course, the motors. Passenger trains of 600,000 pounds weight are frequently handled by locomotives weighing, engine and tender, over 300,000 pounds, and capable of producing 1,800 horsepower for short periods. This is a ratio of 1 horsepower to every 500 pounds total train and engine weight. With 500 horsepower under an electric interurban car, the ratio is about 1 horsepower to every 150 pounds per car. As all the weight can be used for adhesion and as the rotative force is uniform, the wonderful acceleration and high speed of these cars are therefore easily explained.

We have alluded to loss of power due to great air resistance at high speeds, and it is a fact that, under such conditions, this resistance being almost entirely overcome at the head end of the train, it has been deducted from the power otherwise available at the drawbar. This cannot be charged as a loss against the steam locomotive, for if the engine were absent and the power were supplied by motors the train would create the same resistance.

The operative loss due to dead weight of the locomotive, as compared with electric motor drive, is not as great as many followers of electric traction imagine. With a total engine and train weight of 900,000 pounds, about one-third may be due to the engine and tender. Upon high-power interurban electric cars the weight of the motors and controllers will amount to about one-third of the whole weight, in some cases. Therefore, so far as consumption of power used to move the motive mechanism is concerned, electricity has little advantage over steam, and but for the power consumed in hauling the fuel and water, the difference would be the other way. The great advantage, therefore, lies almost solely in the fact that the total weight of the train and its load is available for adhesion, permitting the use of enormous power. When adhesion is adequate, the steam locomotive operates under conditions far less wasteful than is conceived by many believers in the ultimate supremacy of electric traction.

The electric motor is a less delicate piece of mechanism than the locomotive; it can be worked much harder and more continuously than is possible with its predecessor, and it has, moreover, only about one-third as much internal friction. The electric locomotive is double-ended and requires no turntable. Two electric locomotives can be coupled together and operated by one engineer in the cab of the leading locomotive, each one doing its share in hauling the train. It is not necessary to consider the use of the firemen in electric propulsion, and it is on the fireman's side and not the engineer's that most of the objection to the steam locomotive arises. The disadvantages of the steam locomotive relate largely to the boiler losses and to the smoke and spark nuisance. It is standing idle a good part of the 24 hours of the day, and it is necessary to allow for coal wasted in making up and dampening the fires and the general waste incident to a locomotive when fired up but not running. It is called upon to operate at the varying temperature of the surrounding air, the coal consumption during winter months being often more than 25 per cent. in excess of that during the summer months, hence 12 to 15 per cent. additional is charged to the steam locomotive for this loss in any comparison in fuel economy with the electric power station.

* * *

The International Steam Pump Co. report the excellent performance of a Worthington pumping engine installed at the Park Avenue pumping station, Chicago. The engine is of the duplex, reciprocating, triple-expansion type, having semi-rotary steam valves, but no flywheel. The latter is replaced by compensating cylinders so arranged that their pistons retard the motion of the main piston during the first part of the stroke, but assist it towards the close, giving a uniform resultant thrust. The pistons of these auxiliary cylinders work against air under pressure from a tank. The engines are vertical and the weight of the pistons, plungers and rods is counterbalanced by another auxiliary balancing plunger, also working through the medium of water against air under pressure.

The capacity of the engine is about 22,000,000 gallons per day against a total head of slightly over 121 feet, and 660.9 horse power were indicated in the test. The duty obtained was 174,735,801 foot pounds per 1,000 pounds of steam used, corresponding to an economy of 11.32 pounds of steam per net horse power delivered in water lifted, or 10.01 pounds of steam per indicated horse power. The steam pressure was 144.45 pounds per square inch, with 154 degrees F. superheat at the throttle, the steam cylinders being provided with jackets and reheaters.

CHARTS IN DESIGNING.—2.

THICKNESS OF CYLINDERS.

JOHN S. MYERS.

Suppose it is desired to have a chart which will give the thickness of cylinders for various pressures, sizes and materials.

For thin cylinders not having a seam or joint the formula is, $t = pd/2s$, where t = thickness in inches, p = pressure in pounds per square inch, and s = allowable working stress. For thick cylinders, Burr, in his "Elasticity and Resistances of Materials," page 36, gives $t = r \left\{ \left(\frac{h+p}{h-p}\right)^{\frac{1}{2}} - 1 \right\}$; in which r = interior radius, h = maximum allowable hoop tension at

the interior of the cylinder, t and p having the same values as before. Rankine gives $R = \sqrt{(s + p/s - p)} \times r$, in which R = exterior radius, s, p and r having the same values as before. Lame gives $t = r\,(\sqrt{s + p/s - p} - 1)$. Merriman gives $t = r\,p/s - p$. Changing the notation and solving for s/p, the Burr, Rankine and Lame formulas solve out to the same form, $= s/p \dfrac{(t/r + 1)^2 + 1}{(t/r + 1)^2 - 1}$; Merriman's formula solves out to $s/p = r/t + 1$; for thin cylinders, $s/p = r/t$.

Inserting values of t/r in the Burr, Rankine and Lame formulas, the corresponding values of s/p may be calculated.

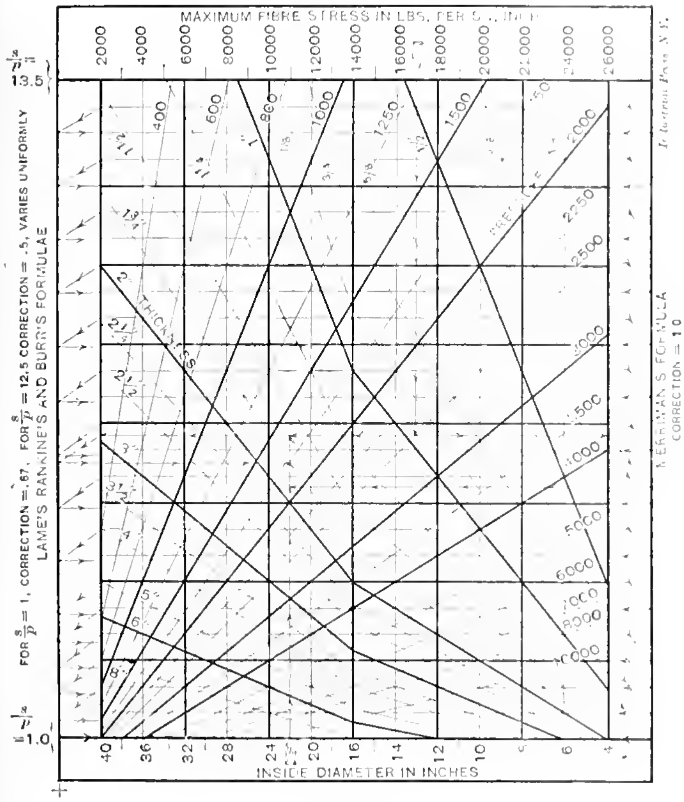

Chart No. 8. Thickness of Cylinders.

NOTATION.

Notation—d = inside diameter, r = inside rad., t = thickness of walls, S = maximum fiber stress, P = pressure per square inch. Inside cylinder, $t = \dfrac{Pr}{S}$, for thin cylinders. For thick cylinders, Rankine, Lame and Burr's formulas solve out to the same form: $t = r\left(\sqrt{\dfrac{S+P}{S-P}} - 1\right)$, or $\dfrac{S}{P} = \dfrac{\left(\dfrac{t}{r}+1\right)^2+1}{\left(\dfrac{t}{r}+1\right)^2-1}$. Merriman gives: $t = \dfrac{rP}{S-P}$, or $\dfrac{S}{P} = \dfrac{1 + t}{1}$. Example: S = 17,000; P = 2,500; d = 22". Following broken line, $t = 1\frac{5}{8}$" for thin cylinder; $t = 1\frac{3}{4}$", Rankine's formula; $t = 1\frac{7}{8}$" by Merriman's formula.

Lay out the chart for thin cylinders, choosing for the first factor at the top of the chart, s, and for the second factor $1/p$; their product, s/p, is represented by a uniform scale on the sides. See chart No. 8. The minimum reading has been chosen as 1, and the maximum reading as 13.5; each space represents 0.5. On the bottom lay off values of r, which have been chosen from 2 inches to 20 inches and doubled to read diameter instead of radius. This radius is considered a first factor commencing at the bottom of the chart, the second factor being $1/t$; their product is r/t, which is equal to s/p and is represented by the same scale at the side.

Since tracing from stress to pressure and thence to the side of chart strikes the same value as tracing from the diameter to thickness and thence to the side, they must intersect at the required thickness. The example illustrated by the broken lines is, stress = 17,000, pressure = 2,500, diameter = 22 inches; the intersection shows the thickness to be $1\frac{5}{8}$ inch, according to formula for thin cylinders. In Merriman's formula $s/p = r/t + 1$, hence a correction of 2 spaces of .5 each is made at the right side, and in the above example the intersection shows the thickness to be $1\frac{7}{8}$ inch. The corrections on the left side for Burr's, Rankine's and Lame's formulas are laid off from calculated values previously referred to. The example indicated shows the thickness according to this formula to be $1\frac{3}{4}$ inch, which is probably the most reliable as being based upon a more nearly perfect theory. It may be noticed that in calculating the corrections for Lame, Rankine and Burr's formulas the values inserted were t/r while the values of the scale on the left of the chart are r/t. This is rectified by the use of a table of reciprocals when plotting these corrections.

Steam Engine Proportions.

Chart No. 9, embodying in 24 subdivisions lettered a to x the proportions for the various parts of steam engines, illustrates how charts may be used to condense data too voluminous for ready reference, at the same time showing relations of parts in such manner that interpolation between values is facilitated. In Kent's Pocket Book will be found a rather exhaustive comparison of the Rankine, Seaton, Unwin, Thurston, Marks, Whitman and many other formulas on the subject of engine proportions, giving average results solved out for six different sizes of engines. These sizes form the basis of this series of charts. The general data of these engines is given in Table 3.

Chart a shows comparative piston speeds; chart b, indicated horsepower; chart c, mean effective pressure, the maximum pressure for all three being taken at 100 pounds per square inch. In b a change of scale has been made in order to save space; d and e show thickness of metal for cylinder and cylinder heads, respectively. It is probably the best practice to make the latter double on large sizes instead of using such thickness as shown. f and g give size and number of cylinder head studs. The curve in f is distorted at the lower end on account of inadvisability of using studs smaller than $\frac{3}{4}$ inch except on very small engines. h gives piston thickness, curve A being for the shorter and curve B for the longer stroke engines, the piston speed of which were equal for equal diameters of cylinder. i gives breadth and thickness of cylinder rings according to an empirical formula. j gives diameter of piston rods, A being for the short and B for the long stroke engines. k gives diameter of center for round connecting rods, and l and m give thickness and depths for rectangular rods, the length of rod in both cases being $2\frac{1}{2}$ times the stroke. n gives area of piston rod guides or crosshead slippers. The scale has been varied in order to save space. o and p give diameter of crankshaft for center crank engines, o being the shaft transmitting the twisting moment as well as withstanding the bending action due to thrust; while p is the shaft carrying this bending action only. q gives proportions for over-hung crank pins. $D.t.$, DB and LA, LB being respectively diameters for short and long stroke and

Chart No. 9. Steam Engine Proportions.

lengths for short and long stroke. *r* gives diameter *D* and length *L* of crosshead pins. *s* shows shaft diameter necessary to transmit the torsion only, which is used in proportioning the crank arm. *t*, *u* and *v* give respectively the thickness, greatest and least breadth of crank arm. It is probably a preferable construction to use a crank disk, counterbalanced. *w* gives the diameter of shaft corrected to take care of the combined twisting and bending moments. *x* gives journal length, the pressures on journal ranging from 102 to 196 pounds per square inch.

A SECTIONAL FIXTURE.

RALPH E. FLANDERS.

The casting shown in Fig. 1 strapped to the table of a milling machine is one of a large variety of housings of widely varying shapes and sizes, which are used in the construction of a certain automatic machine. These housings resemble each other in that they are provided with a V-groove at the bottom, where they are clamped to the bed of the machine, and also in the fact that they are made with various pads and bosses, similar on both sides, which have to be milled off to a uniform thickness of 1½ inches. The cross-hatching in the plan view distinguishes the finished areas.

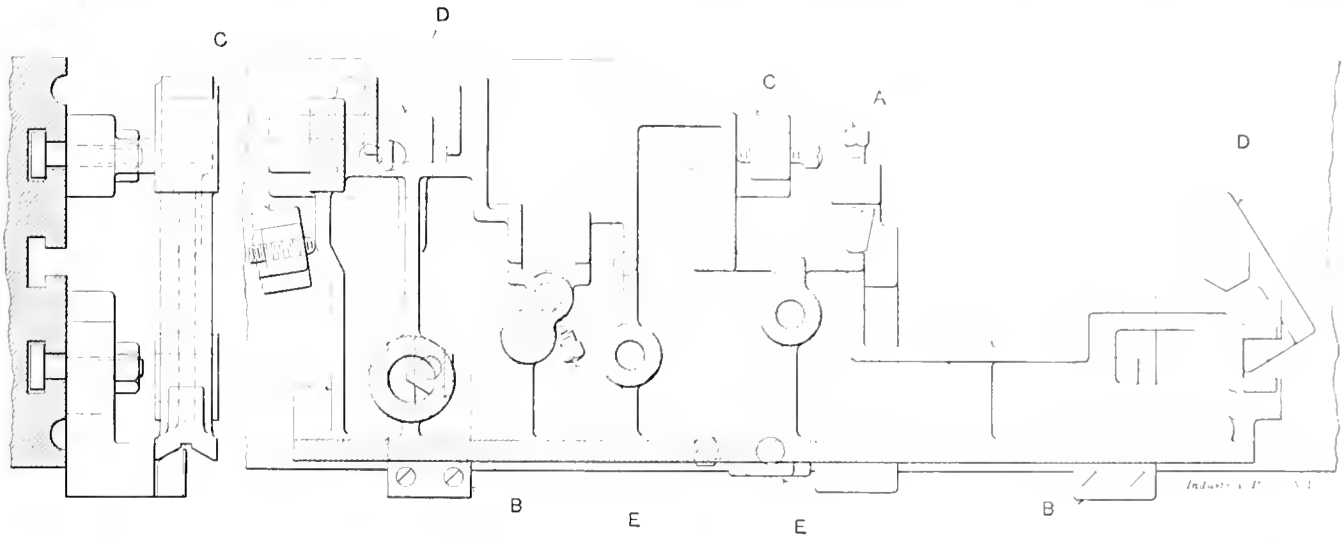

Fig. 1. A Sectional Fixture or Jig Holding a Machine Housing on a Milling Machine Platen.

The large number of patterns used would have made the job of providing a separate fixture for each style of casting a very costly proceeding. After a little thought, we made the hereinafter described sectional fixture, and it has worked well on all the different pieces on which it has been tried.

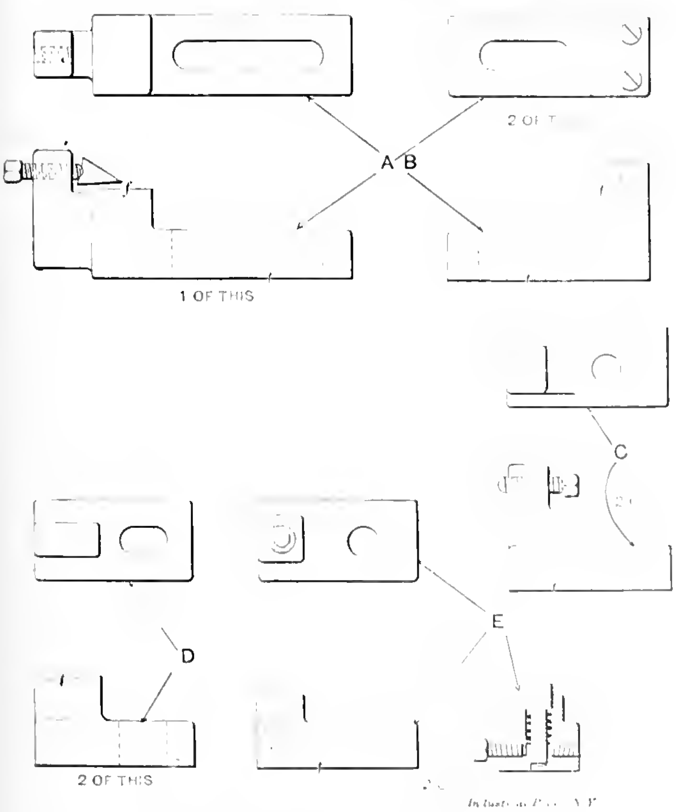

Fig. 2. Parts of the Sectional Fixture.

Fig. 2 shows the different parts of the fixture in detail: *A* is a block with a setscrew and spur, similar to that used on a planer; *B* is an abutment provided with a steel block to enter and hold down the V-groove edge of the casting; *C* is a simple stop to take the thrust of the cut; *D* is a wedge used under springy places in the casting; and *E* is a spring-jack used where convenient for a similar purpose.

In Fig. 1 a typical casting is shown on the milling machine platen with the various holding pieces arranged about it. The two blocks *B* are laid at the outside edge of the table, and the work is supported on these and the spur block *A*, thus giving a three-point bearing for a foundation. The spur holds it down on one side, and the steel blocks in the V-groove hold it down on the other. Blocks *C* with their setscrews are arranged as shown to take up the end thrust in each direction, and wedges *D* are slipped lightly into contact with outlying corners of the work where support is needed. Spring-jacks *E* are also located where the work is most liable to spring under the influence of the mill. These jacks are fastened permanently in place, the setscrews loosened, then the work is pressed down into place and fastened with the spur block *A*. The setscrew, which bears against the teat of the spring plug, is then clamped, and the casting is thus supported without the possibility of the casting being sprung as it would be if fastened down onto a solid bearing which might or might not be of the right height. The setscrew may be placed in either side, as is convenient. See detail of spring jack in Fig. 2.

A 6-inch end-mill is used in the vertical milling attachment to make the surfacing cut. This does its work more rapidly and with less pressure than a cylindrical cutter would. Care is taken to feed in such a direction that the thrust of the cut will be toward the V-blocks *B* or the stops *C*, although when by mistake the cutter was run toward the spur *A*, this seemingly insecure fastening held the work well. These housings are allowed a limit of 0.002 inch over or under the standard thickness of 1½ inch.

* * *

SOLUTION OF THE BEVEL CURVE.

CHARLES CLOUKEY.

A comprehension of the title as given above would require some knowledge of cutter heads upon which the knives or tools are bolted. These are familiar to and used mostly by woodworkers, but are the same as a milling cutter would be if the cutters were bolted to a rectangular head, with the proper extension to make the cut required. In the working of wood moldings it is often necessary to make bevel cuts of some considerable depth, and the operator is surprised to find that his knife which he has carefully ground to the proper bevel, with its cutting edge perfectly straight, does not cut the bevel with a flat surface, but with so great a convexity as to spoil the detail. By experiment he is able to grind sufficient curve on the edge of the knife to correct the error, but by a solution of the puzzle he will be able to lay out his knife properly at the start.

In the illustration is shown the plan of a cutter-head *a*, from the center of which a perpendicular, *a x*, is dropped to the bed of the machine, represented by the line *b c*. The line drawn along the side of the head in its first position intersects the vertical line at the surfacing cut, *e*, or, in other words, it is where the molding pattern begins, and all calculations are made from this intersection downward.

A careful study of the matter will show that in order to make a knife cut 1 inch deep, when bolted to a 4-inch head, it

must be projected 1 7-32 inches beyond the surfacing line, and to cut 2 inches deep the extension will be 2 5-16 inches, a gain of only 3-32 inch in the second inch of depth, and for the third inch there is little more than 1-16 inch gain, while for the fourth inch the gain is but 3-64 inch.

The trigonometrical reason for the above may be illustrated by the figure, and is contained in the statement that the line *d e* is longer in proportion to the line *o e* than the line *f i* is to the line *o i*. By using the protractor we find that the angle *d e o* is 38 deg., the tangent of which is .7813. This decimal is the ratio between the side adjacent, or *o e*, and the side opposite represented by *o d*. We find the sine of 38 deg. to be .61566, and .7813 ÷ .61566 = 1.27, which represents the hypotenuse, *d e*. Solving the triangle *f o i*, in the same manner, using the angle *f i o* of 16 deg., we find the hypotenuse or the line *f i* to be 1.04, and 1.27 — 1.04 = .23, which shows that the line *d i* is nearly ¼ inch shorter for every inch of its length, in proportion to the line *o i*, than the hypotenuse *d e* is to the line *o e*.

Now as the line *o e i* represents distance from the center of the head straight down to the bed, and the hypotenuse is the

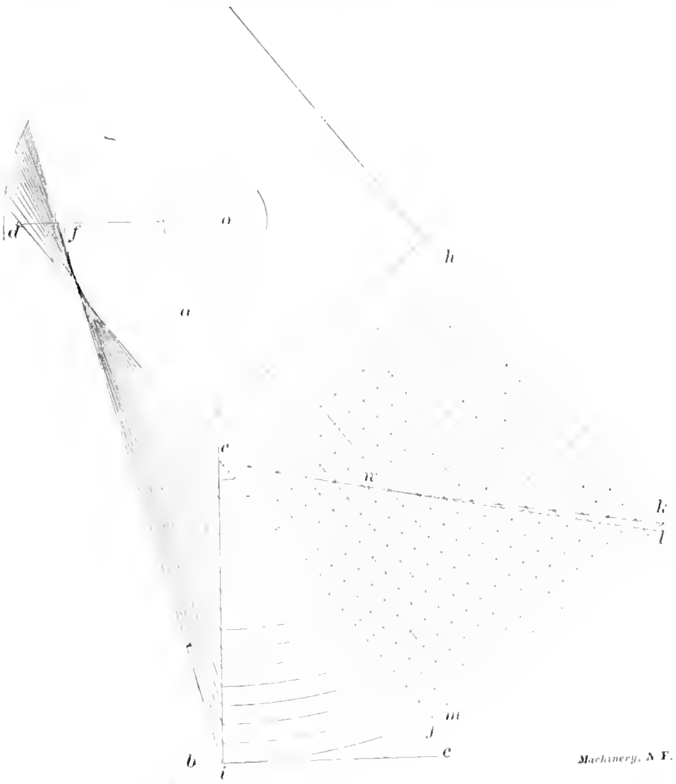

Fig. 2. Graphic Solution of the Bevel Curve.

inner line of the knife, it will be seen that to shorten the latter in relation to the former is to shorten the projection of the knife in relation to the depth of the cut. By using a full-sized drawing and a pair of accurate dividers, and measuring down the line *e j*, the first inch is found to be 11-64 inch longer than the fourth inch, so that if a knife is to be made to cut a bevel 4 inches deep the first inch will require 11-64 inch more allowance than the last, and as the variation is a gradual one it appears at once that the cutting edge of the knife cannot be straight.

Another reference to the figure will show that the knife makes its finishing cut at the vertical line *e i*, no matter what the depth, as this is the point directly under the cylinder, and that when the knife is finishing at *e* the outer end has reached *j*. This discloses the fact that the only straight line a straight knife could make across a bevel would be developed where the knife was actually cutting, and would always be ahead of the finishing line, as each cut practically begins at this line. However, the above knowledge would be of little value to the mechanic except to give him an understanding of his trouble—a diagnosis, if you please—unless a practical method is given for plotting the curve required for the edge of the knife. A still further study of the figure will show that this plot is so simple that anyone can develop it correctly, even though he is ignorant of every trigonometrical function and knows only such arithmetic as is found on his two-foot rule.

Let the point *e* represent the edge of the knife that does the surfacing, and from which point the bevel would start, and from *e* to *i*, which represents 4 inches, lay off in eighths of an inch exactly to the standard scale as found on a rule or square. The line *d e* extend indefinitely, and with *o* as a center describe the arcs from the divisions on *e i* to their intersections with the line *e j*, which gives a new and proportional scale along the line of knife extension. To develop this scale draw the lines perpendicular to *e j*, from the ends of the intersecting arcs, and extend them to the right 4 inches, or indefinitely. Along the line *e h* lay off another standard scale, the same as the one from *e* to *i*, and extend the divisions to the line *j k*. This gives a combination of the standard with the proportional scale, and by drawing the line *e k* 4 inches out and 4 inches down, through the intersections of the lines on the diagram, it will show the required curve.

If it is required to cut a sharper bevel with the same knife the practical limit is shown by the dotted lines, *n l*, on the projection. An attempt to make a vertical cut would necessitate drawing the knife back and using the 4 inches of the outer end, bringing the point *n* in coincidence with *e*. A straight line tangent to the curve at *n* and extended 4 inches diverges ⅛ inch from *k* at *l*, and transferred to *m* shows the limit beyond which the curved edge of the knife would produce a concave surface. The upper part of such a steep cut would be slightly convex for reasons already given.

The illustration and explanation so far have contemplated the use of a head 4 inches in diameter across flats, or between the faces to which the knives are bolted, and the curves for all other sizes of heads would be different, though geometrically similar. This is shown by the fact that the original of the illustration was drawn to a scale of 2 inches to 1 inch, or the same as an 8-inch head, and the printed reduction has the proper curve for the sized head that appears in the figure.

The depth of 4 inches for the cut was chosen for purposes of illustration, as in practice the cuts seldom exceed a depth of 2½ inches.

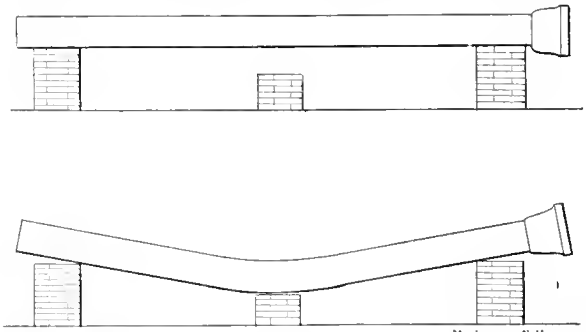
BENDING CAST IRON PIPE.

A feature of the twelfth annual meeting of the Pacific Coast Gas Association, held at San Francisco, July 19-20, 1904, was the presentation of a paper consisting of a collection of "wrinkles" contributed by practical men. Mr. T. R. Parker, Napa, Cal., sent a sketch of a method successfully followed in bending cast iron pipe. His first attempt at bending cast iron was at a lumber camp, which he relates as follows:

"Our cook could not bake bread in the stove oven on account of the cross-piece between the lids having become bent or warped so that it allowed too much cold air to pass over his



Bending Cast Iron Pipe.

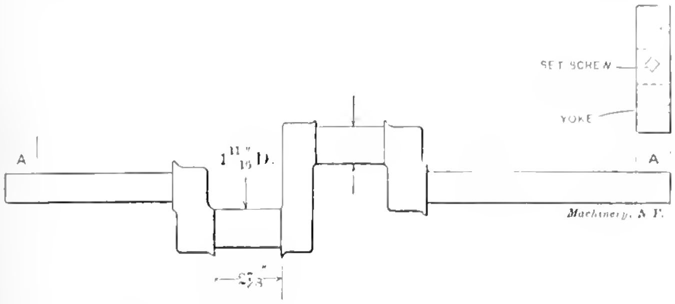
oven. He asked me if I could straighten it. I thought the same medium that bent it could unbend it, so I put it in the forge and got it to a bright cherry red, then placed it on the anvil upside down, and with a gentle pressure from the sledgehammer, brought it down straight again. So when occasion required to swing around a curve with nothing but straight lengths of cast iron pipe to do it with, I have done this, building a fire around two or more pipes, as the case might be, and letting them warp down until the center pier wall touches, then knocking out the fire and using no water to extinguish it. I have made some very pretty bends this way for the water company, withstanding 150 pounds pressure. The wood is piled after the manner that a blacksmith heats his tires."

LETTERS UPON PRACTICAL SUBJECTS.

WHAT IS THE CAUSE OF THIS TROUBLE?

Editor MACHINERY:

In the course of my work I have to turn cast steel crankshafts of the form shown in the sketch. My trouble is that I cannot get them to come round; even after taking a very light cut they will vary from 0.002 to 0.005 inch. They come small-



Why do the Cranks come "out of round" in the Center?

est in the centers of the crank-pin bearings, as indicated by the arrows. The crankshafts are held in yokes at *A A* by setscrews.

I would like to know if anyone else has such trouble, and how it can be helped. W. K.

"STANDARD" NOSE THREADS FOR LATHE SPINDLES.

Editor MACHINERY:

Over thirty years ago, as foreman of a machine shop, I was worried almost to death by the confusion in spindle threads, as chucks could not be exchanged even on lathes of the same size in many instances; so I determined that when I got to my own works that difficulty would be avoided. This was done by selecting a nose thread from each class of lathe—10 inch to 12 inch, 16 inch to 20 inch, 24 inch to 30 inch, etc.—and making gages. For example: From my first purchase of lathes, arbitrary class 16 inch to 20 inch was looked over and the best average nose thread selected for the gage. Now, some of the lathes would be larger and were, therefore, recut to it, but in those which were smaller it was necessary to put in new spindles. Each of these classes was treated in this way. Lately we have been sending these gages to the lathe builders when we order lathes. The advantages of this are too patent to need explanation, as all chucks, faceplates, etc., can be exchanged. Even in the matter of fitting new chucks the item of saving is noticeable as regards fit as well as time, since we cut the chucks to the gage and not to any lathe. Did you ever watch a good "practical machinist" fitting a new chuck back to his lathe by the old method?

Further, each lathe (excepting the smallest) has hubs or "masters" fitted with the smaller sizes of nose threads, all made to the gages. This makes the system universal, for each lathe will take all chucks of its own class, and also all chucks of smaller lathes. The sizes of these threads are not given because they are not all the sizes we would recommend. But they are practically perfect for our own work, since the advantage is primarily in the system and not in the exact diameters and pitches. We have not been so successful in changing between lathes and milling machines, as we must still make bushes and hubs to effect this class of transferring. My opinion after over forty years' experience is that all lathes and milling machines should be standard bolt threads, the length of thread to be one diameter in all cases. This would give a coarser pitch than is usual, but would be all the better for that, as chucks are less likely to seize with a coarse pitch. By this method work could be transferred, chuck and all in one piece, between lathes and milling machines. Some sizes we can now take through three machines—lathe, milling machine and gear cutter, without letting go hold. Another advantage in bolt threads is that taps can be bought in the market for sizing chuck backs. Similar remarks apply to diameter and taper of center tails. It might be well to point out that we hold all drills, reamers and facing tools in a similar manner—any lathe taking in both live and dead heads, all tools of its size and all smaller ones. The general method is that the greater includes the less.

Speaking of the existing confusion in spindle noses—lead screws and change gears are just as bad. Some time ago I asked a lathe builder in the presence of two listeners why he made a lathe for *general* use with a six-thread leading screw and the change gears in steps of four teeth, and offered a dinner for the four persons present if he would tell me. He looked a little bewildered for a short time and answered openly: "I'll be d—d if I know." This answer might be given in many instances, quite correctly, by tool builders.

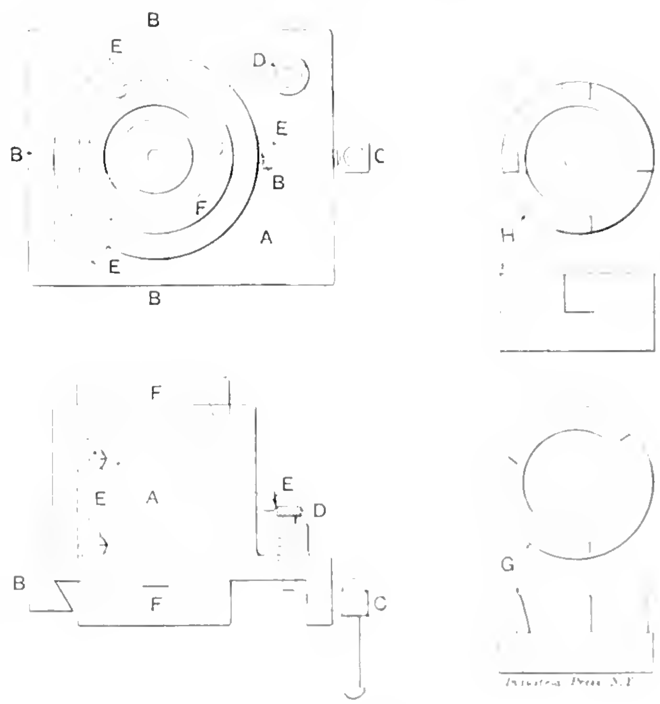
JAMES ARTHUR,
New York. President Arthur Co.

SOMETHING MORE REGARDING IDLE MACHINES—A TAPER ROUGHING REAMER—TIME-SAVING CHUCKS.

Editor MACHINERY:

In the March number of MACHINERY, I find some remarks referring to the time a machine is idle while the man is working, and I should like very much to say a few words on that subject myself.

The average workman knows a lot of ways to find something to do that requires stopping his machine, and he is inventing new ones all the time. For instance, there is a man turning down a shaft to fit a hole. He knows the shaft is one quarter inch large, but instead of starting a roughing cut he must first



Jig and Tools for Boring Pinions.

get the exact size of the hole—which he probably loses before he gets to the finishing cut—and then has to stop his lathe while he goes after it the second time. Probably the shaft in another part fits into another sized hole. If it does, this chap, unless he has an inspiration, will never think of taking a second pair of calipers and getting both measurements at once.

There are several other members in his family. There is the chap who never grinds a tool until he wants to use it, the one whose oil can is oftener empty than not, and who borrows his neighbor's because he can't stop just now; the fellow whose machine is littered up with a lot of junk, including a choice assortment of old bolts that require two wrenches to operate,

A. MERTES was born in Allegheny, Pa., February 22, 1863. He served an apprenticeship with the Pittsburg Locomotive Works, and shortly after completing his apprenticeship he started the A. Mertes Mfg. Co. (now the Union Foundry & Machine Co.) for the manufacture of gears. For the last four years he has been with the National Gear & Foundry Co. Among other positions Mr. Mertes has held that of superintendent of shops; his specialty is designing special machinery and tools.

and last, but not least, the individual who doesn't bother about how he is going to do the new job the foreman has left at his machine. Time enough to think about that when his present job is done. Besides he is not paid for thinking. He *works* for his wages.

There is a great deal of work in which the time consumed in chucking is a large item, not infrequently requiring more time than the machining, and it is in such cases that the ingenuity of the man counts. If the job becomes frequent, special facilities for handling will be provided and one of the fellows we have been talking about can do it then.

I have lately noticed an advertisement of a small plain plate provided with T slots by means of which a piece of work may be bolted to the plate and the plate secured in the machine. During the time of machining the workman can secure another blank to a second plate, and it is ready to go on the machine as soon as the first is finished, and this method of working can sometimes be used to great advantage on multiple machines.

Some years ago the writer built a machine for boring bronze spur pinions. It had six vertical spindles, three on either side, and below each set of spindles a table with an independent vertical movement. Upon these tables were placed the chucks for holding the work to be operated on. The chucks were all of the same pattern and were secured to the table in one direction by clamping against a slide and located in the other direction by a spring dowel. Being interchangeable any one of them could be used on either side of the machine and under any spindle.

Referring to the cut, *A* is the body casting which after being planed and fitted with the locking screw and spring dowel was bored on the machine by one of the spindles. The chuck was then placed central under the remaining five spindles and the holes for the dowel pin *D* located. The five holes for setscrews *E* were drilled and tapped and the four pieces of machine steel *B* fitted and fastened in place. The rings *F* shown in position were used only to center the blank and, after the setscrews were tightened, were removed. They were first made plain but as trouble was experienced on account of the blanks not being round, they were afterward cut away to give three bearing points as shown at *G*. At first they were made as shown at *H* and cut out on the thin edge to allow them to pass the four pieces *B* and the two upper setscrews.

In handling the work the first operation was roughing with the No. 1 spindles. Two castings were operated on, one on either side. While this rough boring was being done the operator chucked two other castings, using two more chucks. The first two chucks were then moved under No. 2 spindles and those just chucked went under No. 1, for roughing. The No. 3 spindles were for the finishing cut. After the finishing operation the chuck was removed from the machine and taken to a small bench where the chucking was done, the finished piece taken out and another blank chuck ready to go to No. 1. In this way the machine was running nearly all the time, yet the man had ample time to chuck the blanks and change the chucks from one position to another.

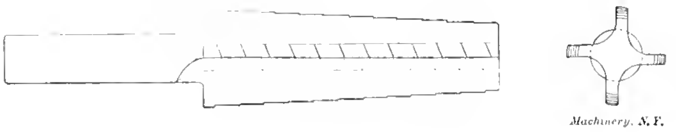


Fig. 2. Taper Reamer with Stepped Teeth.

Eventually the bronze pinions were discarded and steel forged ones used instead. This required drilling the hole from the solid. In one case, the hole, about 1 3/8 inch diameter at the smaller end had a taper of 1 1/4 inch per foot. Here was something not provided for, but by doubling the speed of No. 1 spindle, and using a one-inch drill for the initial hole, enlarging it to 1 13-16 inch on No. 2 spindle, rough reaming the taper on No. 3, and doing the finishing reaming on a drill press, it went through very nicely.

Not having had any previous experience with such a problem, I considered quite a while, and finally decided to make the roughing reamer with stepped teeth. I chased a triple thread of 1 1/2-inch lead, setting the tool so that the tops of the thread were parallel to the axis of the reamer as shown in Fig. 2, whereby the cutting was all done at the corners of the teeth. This reamer was a surprise to all who saw it in operation, it required so little power to drive it. After the roughing reaming was done the chuck was taken to a drill press which held a finishing reamer with a depth gage. The chuck was here set on a spherical seat which was mounted on a compound slide. This was done to allow the work to align itself easily, which it readily did.

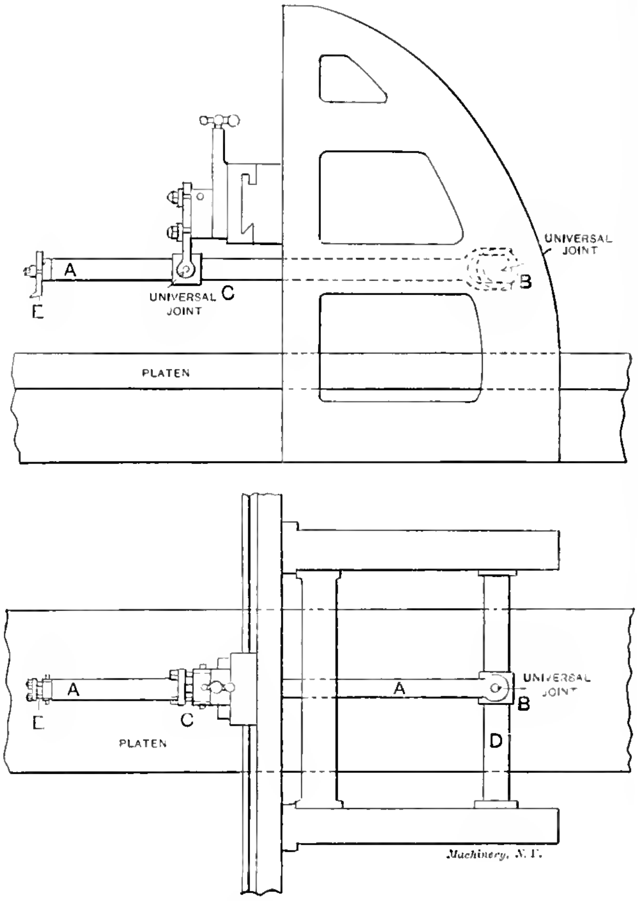
The time required to chuck a piece was about one minute and the drill passed through the blanks in from five to six minutes. The reaming required about two minutes.

Emsworth, Pa. A. MERTES.

PLANER BAR WITH STIFF SUPPORT.

Editor MACHINERY:

A troublesome job on the planer is that in which it is necessary to use an advance tool, as when planing into a cavity, taking short cuts on work wider than the housings, or cutting a keyway in a hub. The latter, of course, is a job that should not be done on the planer, but it often is done, especially on heavy work such as the hubs of large propellers, etc. When we consider the trouble and vexation caused by such jobs—nursing them to prevent the tool digging in and spoiling the work or breaking the machine—it seems strange that something better than the conventional tool with no other support than the cross-rail of the planer is not more generally used.



Planer Bar with Stiff Support.

The accompanying cut shows a side elevation and plan of a planer equipped with a planer bar or advance tool that is of old design, it having been introduced to the public some thirty or forty years ago. For some reason it seems never to have become generally known, perhaps because it was originally covered with a patent. The patent has now expired so that the public is free to use it without paying royalty. The planer bar, *A*, is forked at its rear end where it pivots on a sleeve, *B*, which is free to turn on the cross support, *D*. This latter is made of heavy section and is firmly secured to the sides of the uprights. The bar is also supported from the cross-rail by a universal joint, *C*, but this need not be of the form indicated in the cut; a ring formed from round bar stock to closely fit the planer bar and provided with a shank to clamp in the toolholder, will usually allow for the necessary vertical and transverse movements. The ring must, of course, fit the bar closely,

but if forged from a round bar it will permit considerable movement while fitting closely enough. If the bar is large enough a clapper-box can be fitted on the end for the tool, *E*. The regular feed movement is used with no change save that it is necessary to use a somewhat finer feed than usual because the movement of the tool *E* is multiplied, the factor depending upon the relative lengths of *EC* and *CB*. It will be observed that the thrust on the tool due to the cut is transmitted directly through the bar to the uprights, and that there is no twisting or canting effect upon the cross-rail whatever.

Newark, N. J. F. Emerson.

QUICK-RETURN SHAPER MOTION.

Editor Machinery:

The drawings accompanying this article represent an attempt to evolve a shaper motion in which a uniformly rotating crank gives a rectilinear motion of variable length to a shaper ram and in which it is possible to vary the length of stroke by moving an otherwise stationary point of the mechanism. The result attained seems satisfactory and has an added advantage not expected at first, that the ratio of cutting to return stroke is the same for all fractions of full stroke. As is well known the Whitworth and sliding link motion lose much of the benefit of their quick return as the stroke becomes shorter.

Figs. 1 and 2 appended illustrate the mechanism and its movements. In the two figures like elements are lettered alike. Crank *A* swings through the full circle shown by the dot-and-dash line in the direction of the arrow. Rocker *B* swings through arc *x y* on a fixed center, *k*. It is connected to crank *A* by link *C*. The relative position of the crank and rocker and their lengths are so taken that rocker *B* completes its swing from right to left in one-half the time required for its swing in the opposite direction. Bellcrank *E* rocks on pivot *G*. This point is movable and can be clamped anywhere along line *h k*. This line *h k* in the actual machine takes the form of a slot in the side of the column.

In Fig. 1 bellcrank *E* is set at half stroke. It is given motion from the end, *D*, of rocker *B*, connected to its end, *P*, by link, *F*. It will be seen that if pivot *G*, of rocker, *E*, is set at *h*, that end, *P*, will lie over *k*, and the link, *F*, will simply vibrate back and forth coincident with rocker, *B*, and the bellcrank will have no motion or will be in the position of zero stroke. If *G* is set at *k* then point *M* of the rocker will vibrate back and forth the same as the point *D* of rocker *B*, making a full stroke.

In Fig. 2 the area between the shaded arcs shows that covered by point *P* of the rocker at all positions between zero and full stroke. Arcs *r*, *s* and *t* represent the movement of point *P* for ¼, ½ and ¾ stroke respectively. At the top of the figure arcs *u*, *v* and *w* represent respectively the movement of the point *M* of the rocker for the same fractions of stroke, and on the horizontal line, Fig. 3, is shown the resulting movement of the ram. Its positions at each end of full stroke are shown by the figures 1—1, at ¾ stroke, by figures ¾, ¾, etc. It will be seen that the stroke shortens mostly at one end which, being at the back end of the stroke, we considered rather an advantage than otherwise.

The motion of rocker *B* remains the same at all times and its relative backward and forward motion is transmitted without material change through the succeeding links and cranks, so that the motion of the ram remains in the same ratio no matter how short the stroke. A ratio of 2:1 is as great as can be obtained by the mechanism shown without making the angularity of the connections too great for durability. We did not require a higher ratio but if we had we could have improved on it somewhat by substituting a Whitworth quick-return motion for the simple crank, *A*. In the actual mechanism as planned the connecting-rod *N* was turned in the opposite direction, making the mechanism more compact.

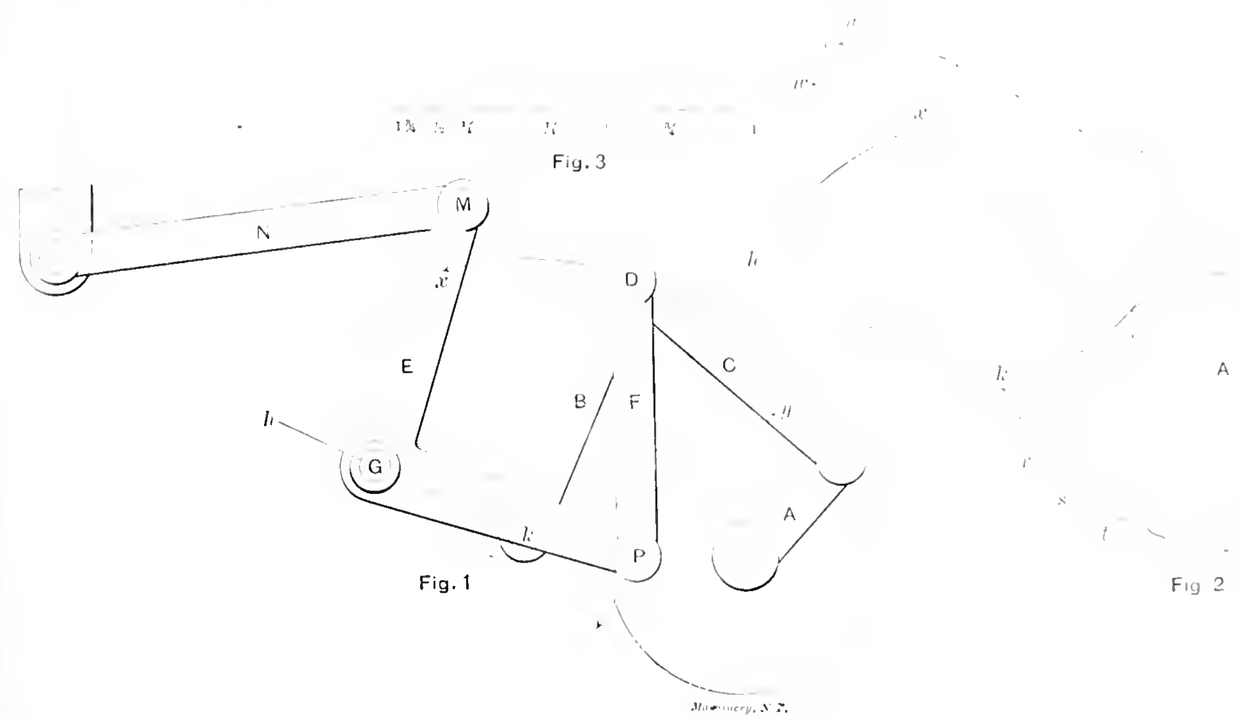
Paxton, Mass.



Quick-return Shaper Motion, giving Uniform Ratio between Cutting and Return Strokes.

THE IMPORTANCE OF LEVELING MACHINE TOOLS.

Editor Machinery:

When a man is selling lathes, and knows that they are good lathes, and then time and again has some of them roundly "cussed" because they "will not turn true," when the fact is that there is a "wind" in the bed, he soon arrives at a comprehension of the extent to which the need for correct initial setting of machines and for the preservation of this level condition is unknown or ignored. Incidentally, he studies the subject and learns considerable that before he had not even suspected to be true, and realizes the real importance of the matter.

Such is the situation with the writer, and it seems to him that the good of the trade generally and fair play for the builders of good machines, demands that the subject be given careful attention by every machine operator and owner. I speak of lathes because it is with them that I have had the most to do in this respect, and they are also probably the tools most susceptible of distortion.

At the works the parts of machines are made to fit when everything is perfectly square. If a lathe is twisted in the bed it cannot do true work. The ways, then, will not be straight and flat and the carriage in accommodating itself to their "crowns" or "dips" will give the tool point an erratic movement, and the turning will be correspondingly erratic.

Then, the tail center will be out of line, and altogether there is no telling what shape the work will take. So much for accuracy.

Possibly in these days of rapid work the question of accuracy will average up of secondary importance when compared with durability. Now, consider the increased *wear* that must result, when the ways are not straight. Then the carriage instead of bearing practically its entire length, really does so only in a few spots, and metal is rubbed off at an immensely accelerated rate. This condition will be present in a less degree at every bearing, for the strain in the bed will be communicated throughout the entire machine. The headstock will get some of it and the spindle will tend to bind in its boxes; some of the gears will not line up as nicely as they otherwise would, etc. As a consequence the tool must become worn out and decrepit long before it legitimately should.

A lathe after being run for a time while twisted will become incapable of doing accurate work, even if straightened. When under strain any metal will spring. The question is not whether it will spring but *how much* it will spring, and no matter how heavy a lathe bed may be and how well proportioned, it will "give" enough to make trouble on particular work if it does not stand just as it did when on the testing plate at the works; and because a lathe is of comparatively small size it does not follow that it will work well on three legs, so to speak.

None but a high grade level should be used. A fraction of a thousandth of an inch is the standard in fitting first-class lathes and very little "wind" in the bed will be required to cause an error of a thousandth. A "wind" of 1-16 inch in a short lathe will completely incapacitate it for fine work and yet none but a pretty good level will indicate such an error with any certainty. Surely a wooden carpenter's level will not and a short machinist's level is about as useless. A sixteen- or eighteen-inch one on the order of Starrett's No. 95 will answer very well and as the cost is only two or three dollars it would seem that the tool room of every shop should contain one. The line should split the bubble *exactly*.

The ideal location for tools is on the ground floor, of course. Vibration is bound to be present on upper floors and this and the settling of the building increases the difficulty of keeping the machines in proper shape; and in fact there are many shops whose floors are so unstable that it would be impossible to maintain a machine level in them. Yet the writer has been read the "riot act" because a lathe turned out a few thousandths under just such circumstances.

Now, give the machines and the man who sells them a "fair show." If a lathe built by a responsible concern will not do good work it is pretty safe to assume that there is or has been something wrong with the conditions, so don't insist on a new one without first investigating minutely. Have a good foundation, if possible, and if you cannot have such, do not expect too much of any lathe.

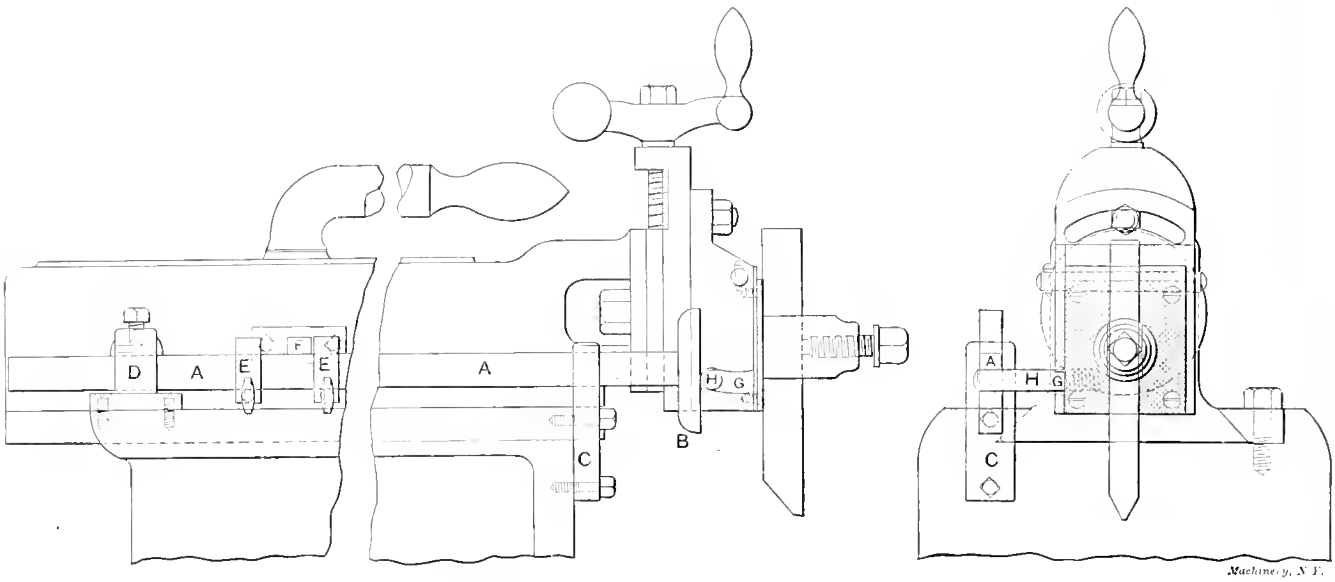
It is certainly exasperating to be forced to pocket the loss for sending a representative to look into a complaint, when nothing is wrong but this eternal leveling, and I hope that this expression may serve in a modest way to promote a better understanding between the two parties in tool deals.

"SELLEM."

DEVICE FOR PREVENTING WEAR OF SHAPER TOOLS.

Editor MACHINERY:

As our whole trade of late years is paying a great deal of attention to the small devices which save time, produce more or better work, or even make the machine operator's task easier or lighter, I will briefly describe an attachment which



Figs. 1 and 2. Side and End Views of Automatic Lifter for Shaper Tools.

we made for a Gould & Eberhardt shaper about two years ago to lift the tool during the return stroke, which I consider to be superior to anything I have seen or heard of.

Fig. 1 shows the side elevation of the shaper with the attachment connected; Fig. 2 the front end elevation, and Fig. 3 the view from the front at the section of break shown at Fig. 1. This attachment is quite simple, is easily made and is effective. *A* is a 1-inch by $1\frac{1}{2}$-inch cold-rolled steel bar with a piece welded on one end as shown at *B*. A machine steel bearing piece, shown at *C*, is attached to the front end of the shaper body and has a hole in it to allow the

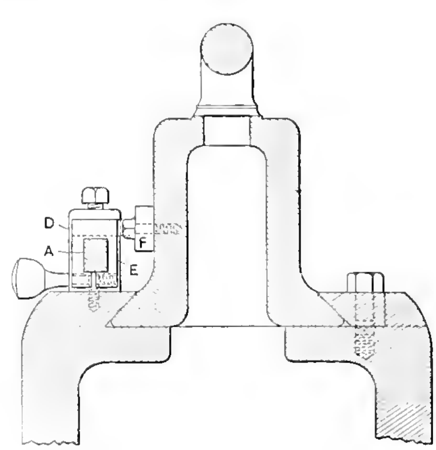


Fig. 3. Cross Section through Lifter.

bar *A* to pass through freely. The rear bearing *D* is cast gray iron and has a gib faced with leather and held down by a setscrew to produce a slight, even friction on *A*. *EE* are two machine steel blocks fitted to *A* and slotted on the under side as shown in Fig. 3. They are firmly clamped to *A* by the thumb screws. *F* is a machine steel forging bolted to the side of the shaper ram and has an arm or finger which extends over the top of *A* to engage with the blocks *EE*. For cases where it is desired to use this attachment on com-

paratively short stroke with the shaper head well forward, or back, inside the shaper body, we drilled and tapped two more sets of holes in the ram for *F*, as in such extreme cases we had to move *F* either forward or backward to accommodate the job. A slot was milled in the shaper head at *G* to allow a stud *H* which was screwed into the swinging tool block to oscillate.

The drawing Fig. 1 shows the shaper about to start on the forward stroke; during the forward stroke *F* engages with *E* and shoves the bar *A* forward, *B* being just behind *H*. As soon as the ram starts on the back stroke *F* comes back with the ram, leaving *A* and *B* until it engages with the other block *E*, when *A* is carried back with the ram. Of course, when *F* disengages with the forward block *E* at the start on the back stroke *B* comes into contact with *H* and thus raises the tool clear from work. When the back stroke is completed the bar *A* is left by *F* until the shaper ram and swinging tool block are again in the position shown. It will be noticed that the amount that the tool is raised is determined by the distance which *F* must travel between *E* and *E*, and is very easily adjusted to suit the case in hand.

We have used this attachment on a large variety of work, such as dovetailing, facing down with the vertical slide, etc., and find it gives good satisfaction, although it was originally intended only to save the tool from wear on nice finishing cuts on straight work.

A. R. Chern.

IMPROVED PLUG GAGE CONSTRUCTION.

Editor Machinery:

Having been in several large machine shops during the past two or three years, my attention was particularly attracted to the different kind of gages that were being used. First, I wish to call your attention to the fact that I am referring especially to the shops and large manufacturing plants whose articles of manufacture require exact measurements and where gages are used extensively.

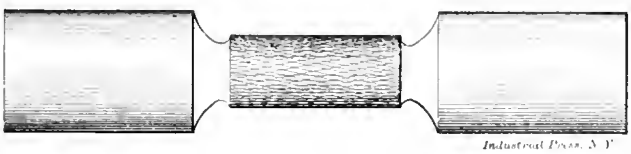

Fig. 1.

Referring to the plug and male thread gage, which I am about to discuss, the majority of these shops use the solid gage or in other words, a gage with the gage disk and handle turned from solid stock as shown in Fig. 1. This form of gage gives good satisfaction when a small gage is needed, but where one is required 1½ inch, or over, in diameter, this style becomes very heavy and awkward to handle. It has not only these drawbacks, but also others, such as requiring more high-grade material in its construction; and if the gage disk wears too much, an expensive operation has to be gone through to put it in the right shape.

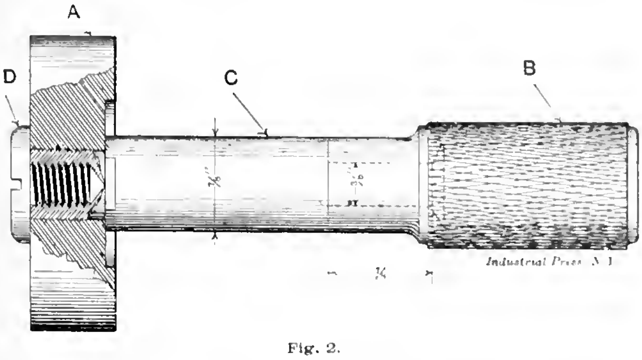

Fig. 2.

The sectional gage shown in the assembled drawing, Fig. 2, is becoming more popular each day, not only on account of its lightness, but also because of its gage disk being transferable when it becomes worn, requiring but a few seconds to make the change provided the disks are kept in stock. The handle is bored out to lighten it, and is knurled, as shown at *B*; it is turned to one or more sizes, according to the requirements of the shop, a quantity being kept in the tool room for future use. I recollect one shop in particular, which keeps four sizes of handles in stock constantly. The fastening screw, *D*, is also made in one or more standard sizes, of which a quantity is also kept in the tool room. The shank *C* is turned to size, according to length, as required.

More or less trouble has been experienced in the past in the use of the sectional gage, especially the male thread gage, on account of the fastening screw becoming loose when the gage gets stuck in the work. I remember one instance, not long ago, where a sectional gage, which depended upon the fastening screw to keep the handle from turning, was being used in

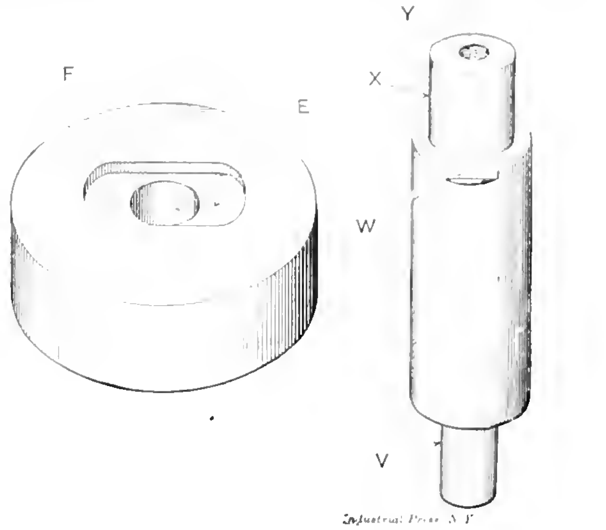

Fig. 3. Fig. 4

a cylinder, which was threaded on the inside at one end, the other end being blind. This particular gage was being used to test the thread, and when it was run part way through it became fast. As soon as the inspector tried to turn it back, the handle became loose, and then the trouble began. The inspector worked for a half an hour trying to extract it, but without success, after which it was turned over to the toolmaker, who finally extracted it after two-and-one-half hours' work. So you see a gage of this kind would not only be a tantalizer but a very expensive tool in the long run.

The improvement on this class of gage shown in Figs. 3 and 4 avoids all such trouble as I have just described. Referring to Fig. 3, which is the plug or male thread gage disk, as the case may be, the disk may be any diameter, generally 1½ inch or over, and any suitable thickness. It is made of tool steel and hardened, with one side end milled about 1-16 inch deep, *E*, with a diameter ⅛ inch less than the diameter of the shank. The shank, Fig. 4, is flattened on both sides 1-16 inch, which allows it to enter the milled slot in the disk, thereby securing the disk so that it is unable to turn on the shank.

One end of the shank is turned for a drive fit in the handle, while the other end is turned to size to fit the hole *F* in the disk. This end is tapped to receive the fastening screw which holds the shank and disk firmly together. The shoulder at this end is flattened to enter the slot in the disk, as just described.

This construction for gages of this class has been in constant use in one of the largest manufacturing plants in the United States for about two years, and has given satisfaction.

W. E. G.

A SUCCESSFUL APPRENTICE.

Editor Machinery:

In the last few months I have noticed several articles about apprentices in various papers and nearly all of them seem to have poor regard for his natural inclinations and habits. Several years ago I had the privilege of working in a shop where an embryo mechanic of the opposite kind came to learn the machinist trade, and with the indulgence of your readers I will try to tell what success he met with.

When Will first came he was placed in the tool room waiting on the men, operating the saw, and sharpening drills. To me, the first thing that distinguished him from his predecessor was that he was very quiet and had little to say to the men; not shy, but reserved—some of the boys said he was

"stuck up;" next, that he always had the room neat and clean and took much less time to serve the men, consequently was of value to the shop, a thing not likely to be overlooked. He remained in the tool-room about two months, during which time a 14-inch lathe was being remodeled. We had decided to put one of the young apprentices on it turning collars and roughing out stock. When it came to deciding which one the foreman said he believed Will was the best, although pretty new; so he got the chance and his steadiness and ability to learn were very gratifying.

He had this job for about a month when several of the men quit and he was advanced to much more particular lathe work, which he did for about a year with much credit to himself.

Then he asked for and was given erecting work, and naturally the same quality of work was turned out, and after he had been at this for about eight months he got an idea he was worth considerably more money, but he and the superintendent could not come to terms, so he found another job in a small shop as a planer hand, his previous experience on this machine being obtained through observation alone.

When he started learning the trade he had only a grammar school education, but he soon realized that it was not sufficient, so he enrolled in a mechanical course with a correspondence school.

The job he took was evidently not satisfactory for I learned shortly afterward that he was working in a drafting room. In the course of a year I secured a job with the same people and I was very much pleased to find that he was successful and was becoming a very good draftsman. We became intimate friends during the next year and decided to go West together. I got as far as the Rockies and Will went to California.

He worked around in different shops and traveled pretty nearly all over the state, in other words, became a tramp machinist. He finally got a good job as engineer for a mining company and advanced from that to assistant superintendent. He held this job for about a year and then took a job with another company and now, a year later, at about the age of 23 years, he is holding a position at $1,400 per year, while I—well I am making good wages, but I guess Will has more "go-ahead" and ability than most of us. B. A.

THE MAN WHO IS THE "WHOLE THING."

Editor MACHINERY:

While visiting one of the large manufacturing establishments of New England, a few days ago, and talking with one of their prominent men, a fact dawned upon me which I had known before, but which I had never before so fully appreciated. That is, that in the majority of concerns each one has its man who is "the whole thing."

We were speaking of a factory which I had visited the day before, for the first time, and referring to my impressions in regard to the place, I said: "Mr. Jones seems to be quite a prominent man over there." "Oh, yes!" was the reply, "Mr. Jones is the 'whole thing' in that shop."

That is just the phrase I have been looking for through all my mechanical experience and if that man had not said it this would probably never have been written. I have known for a long time that in the majority of shops there is one man who has more to say than all the others put together; this is not as it ought to be. I don't mean that there ought not to be one head to every establishment, because I believe there should be, and that from him all general orders ought to go. But they ought to go through their legitimate channels until the detail is properly carried out, and if orders do not go through their proper channels the detail will *not* be properly attended to.

This "great evil," if I might so call it, exists to a very great degree in our manufacturing establishments to-day. I do not know whether or not it is of recent birth, or whether it is growing or dying (the latter, I hope.)

The man of whom we are speaking is usually very busy. Sometimes he is a man who works very hard, is of humble mind, and honestly wonders how the work would go on without him. He does not know how to divide the responsibility of the shop so that he would be the real head, and yet have others decide the more unimportant matters for him. A man once told me about a machine he had designed, and built for drilling a large number of holes in a piece of wood at the same time. He said it had been in operation in the shop for more than a year, and that a boy could run it, but that he (the designer) had to grind all the drills himself, and as he was foreman of the shop, he had to hustle to look after his work, grind the drills for the machine, and attend to the other duties which only he could do. I suggested that he teach the boy who ran the machine to grind the drills; he replied that he did not believe the boy could do it right. A few months later he told me that the boy was grinding the drills and was doing it just as well as *he* could.

Then there is the man who is the "whole thing" and who delights in it. He likes to handle every matter so that at any moment he can come forth, and give an order to do it this or that way, regardless of all previous orders. This is the most dangerous man of all the list. Most dangerous to the welfare of the business, and most dangerous to the dignity and efficiency of those in charge under him. He gets his subordinates after a while, so that they are afraid to express an opinion in regard to the work, unless they can say: "This is the way *he* wants it." That word "*he*" is the most despicable (to my mind) of all those used by men who are looking after work. It does not make any difference to the man who works for me how the man above me wants it done. The only thing that concerns him is as to how I want it done. And if he does it according to my instructions his responsibility is ended.

I was shown through a factory not long ago by a man who was called the assistant superintendent, but that was not his real position. His real position (if you will permit the genuine truth) was errand boy, or since he was a full grown man "errand man." I do not wish to reflect discredit upon the man in question; the trouble was with the man who hired him, and for whom he worked. I do not know what his motive was, if indeed there was a motive in having his so-called assistant so helpless. Perhaps he might say he was not qualified to take any responsibility. Well, if he was not, why did he keep him? When speaking of the various fixtures, and methods in use in the factory this superintendent would say: "This is how 'he' likes to have them made," or, "I don't just know what his idea was in making it this way, but I guess it is all right." And on another occasion: "Mr. Jones is a great believer in this method of doing a certain thing, and I don't know but I am almost convinced myself that it is the best way, ha, ha, ha."

Now, I like to have my employer tell me what he wants and then give me a clear field to think the matter out. Then I can go at it with a will, take an interest, and bring the work out much more satisfactorily than if he should limit my horizon with detailed instructions which are unnecessary. I like to give a man a piece of work and tell him to do it right, and quick, and that he will not hear from me until the job is done, unless he asks for help or instructions.

A common expression among employees of a man who is the "whole thing" around his plant, is: "Come and look at it for yourself." I have known his foreman a number of times to send a man up to him after completing a piece of work and ask him to come down and look it over. The foreman knew very well that his judgment on the matter was likely to be overruled. So far as I can see, in all cases the man who is the "whole thing" is to blame.

To show the general helplessness of the errand man, caused by the man who is the "whole thing" I will cite a case which came under my observation while a very small boy. A contractor and builder sent a man in charge of a number of carpenters to remodel an old building, with instructions to put in new whatever parts of the building ought to be made new. Now the rub came in in the clause "ought to be made new." The man knew right well that his judgment was more liable not to be accepted than otherwise, and that when the man who was the "whole thing" came, there would most likely be a change of plans. So he was careful not to do much real work until he came around and, in his endeavor to get his employer's mind on all points, as they approached the build-

ing he looked up and said. "Is that post sound?" "What post?" asked his employer. "That rotten one(!)" was the earnest reply.
C. M. C.

SOME LATHE FEATURES.

Editor MACHINERY:

The heavy cuts that have been attempted recently have developed a number of weak points of the lathe. In the first place many lathes chatter excessively on large diameters; this is invariably caused by the fact that the carriage overhangs the bed. The thrust *P*, Fig. 1, of the tool, tends to bend the carriage down on the outside. This can readily be seen on many lathes while the machine is taking a heavy cut on a large diameter and especially when the cut runs over slots. The movement of the carriage up and down is quite perceptible. Fig. 1 represents a construction commonly seen on lathes. The apron *A* is held to the carriage by small bolts

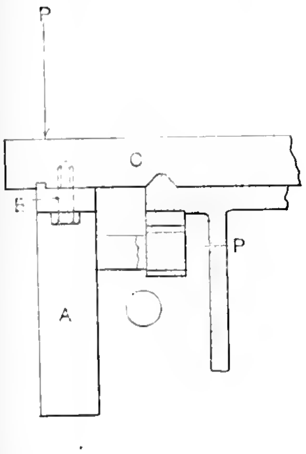

Fig. 1.

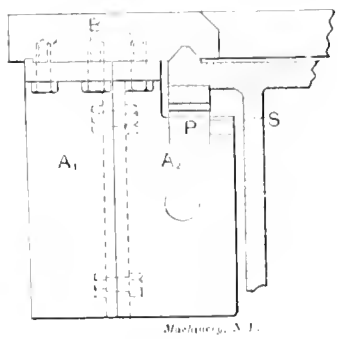

Fig. 2.

B, which upon investigation will be found to be too light. There is a very severe thrust brought upon this carriage when the pinion is pushing the carriage along the rack, against the heavy cut, and the thrust of the pinion *P* against the rack tends to twist the apron out of place. It will also be seen on these lathes that the pinion *P* overhangs the support. In a number of cases, the pinion shafts have become bent and the aprons have been broken. This is not likely to occur on small toolroom lathes, but on 36-inch lathes and above, these things have happened.

Fig. 2 represents a construction of the apron which embodies a number of good points. In the first place the apron is supported by a sufficient number of bolts *B*, and the apron itself is arranged in two parts, A_1 and A_2. The latter extends around the leadscrew and forms a support *S* for the pinion *P*

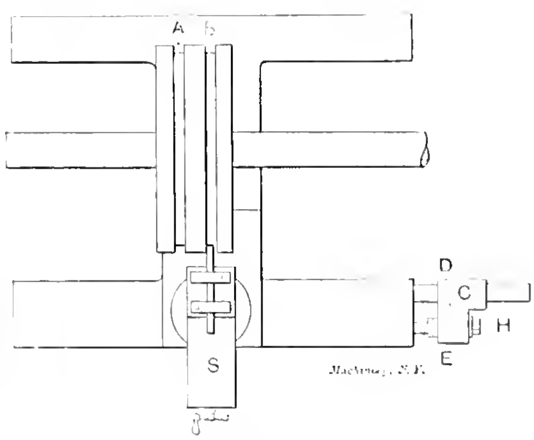

Fig. 3.

This prevents the pinion from bending over on the end. At the same time there are a number of other shafts extending through the apron which are thus supported on each end.

On large lathes the weight of the carriage and the accessories belonging to it are considerable. To move this carriage along the ways by hand requires considerable energy even though the gear ratio from the handwheel to the rack is high. One prominent lathe builder employs a ratchet lever in connection with the handwheel; we thus employ a much longer lever arm and consequently get a more even movement of the carriage with, of course, a proportionately less amount of exertion.

It frequently happens that the lathe hand is obliged to move the carriage along the ways in order to get the proper width for grooves, etc. Fig. 3 represents a piece of work of this

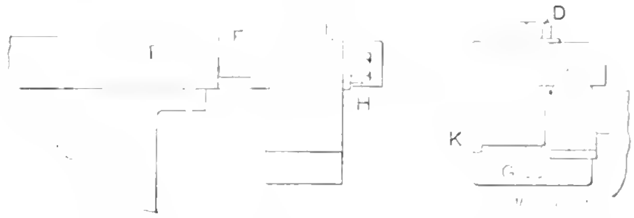

Fig. 4. Fine Adjustment Device for Lathe Carriages.

character. The grooves *A* and *B* must be of a definite width and must be located to suit given dimensions from each other and from the edge of the piston. It is not an easy matter to move the heavy carriage along the ways in order to obtain these exact dimensions; we will either get too little or too much as the carriage moves along the ways by jerks. Since the swivel head *S* must be used as shown, the only method is to move the whole carriage. The lathe hand having experienced difficulty in getting the tool located properly, will invariably get it approximately right and then pound the carriage back and forth, as the case may require, with a soft hammer; and if a soft hammer is not at hand, it will be bumped with a bar or hand hammer, which cannot help but mar the carriage.

The arrangement illustrated at *C* Fig. 3 can be put on all new lathes and on a great many old ones. *C* is arranged in the form of a clamp and by means of a bolt *D* it can be fixed in any position. *E* is an adjusting screw which has a hexa-

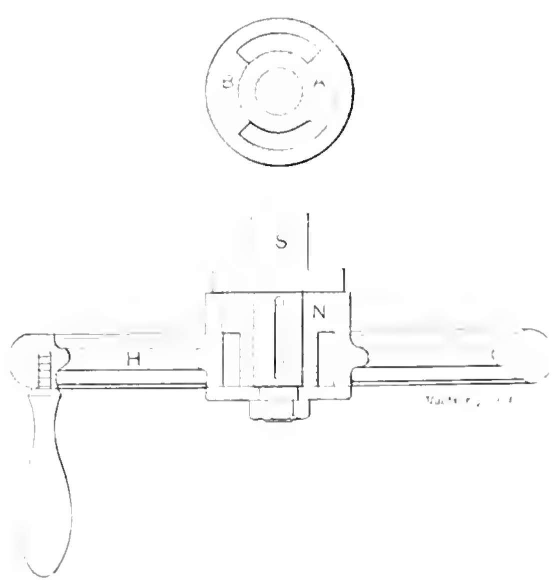

Fig. 5. Handwheel Construction for Easily Loosening Friction Clutch

gonal head *H* as indicated, and it can be made to fit the standard tool clamp wrench. By means of this screw the carriage can be adjusted to almost any degree of fineness. The head of the bolt *D* can be made to fit the same wrench; a quarter turn one way or the other will either lock or loose the clamp. When the clamp is loose it slides back and forth on the ways with the carriage. A detail of this clamp is shown in Fig. 4. The adjusting screw *E* has a long tap *F* into the carriage. The clamp bolt *D* extends through the clamp proper and is threaded into the gib *G*, which in turn clamps against the under side of the rack. The clamp should be cut away except the small portion *K* in order to give a better clamping effect.

In locking and unlocking the friction from the cross-feed and traverse, in the apron, difficulty is sometimes experienced. In taking cuts the friction must be clamped so tight, in order to keep it from slipping, that it is necessary to hammer the friction in. Of course, when the tool is rapidly digging into

some portion of the work, it cannot readily be knocked out, and a spoiled job is apt to be the result.

In Fig. 5 is shown an arrangement for knocking in and knocking out the friction. *S* is the friction shaft, *N* is a nut, while *H* is the handwheel. The nut *N* has a lug *A* extending outward on one side as shown. The hub of the handwheel *H* has a hub *B* extending inward on one side as shown. It is possible to turn the handwheel through half a turn before the two lugs *A* and *B* come in contact. Once the handwheel is turned so that the hub *B* bumps against *A* any further movement of the handwheel in the same direction will turn the friction shaft *S*. When the friction cannot be drawn tight enough, it can be hammered into place by moving the handwheel back and forth and thus knocking the shaft around until the friction ceases to slip. If the friction is thrown in and the tool accidentally digs into the work, we do not need to hunt for a hammer, but just simply throw the handwheel around and as there is some weight in the handwheel, one knock will disengage the friction.

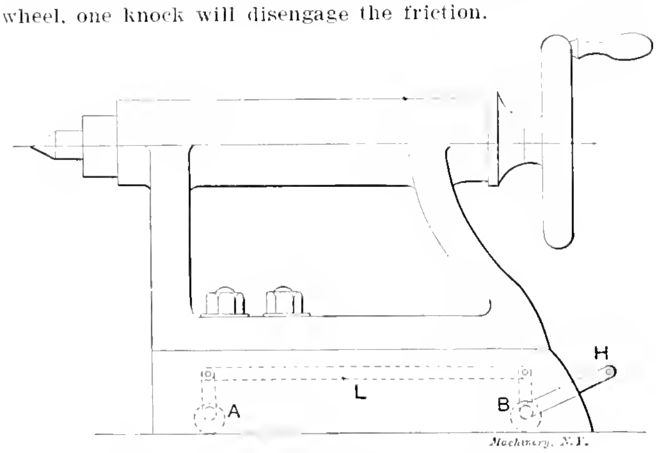

Fig. 6. Anti-friction Attachment for Tailstocks.

As it is difficult to move the carriage along the ways for a considerable distance, it is frequently pulled back and forth by the leadscrew; the tailstock, however, must be pulled along by hand, either by a crank directly connected to a pinion or else by a crank connected to the pinion through intermediate gearing. We can readily obtain any amount of gear ratio and can readily bring the pull at the crank within any desired limit in order to move the tailstock. In gearing this up, however, we lose too much time in moving the tailstock along. A good arrangement is to place a crank directly on the pinion shaft and then place two pairs of eccentric rollers as shown at *A* and *B* in Fig. 6. *H* is the handle which revolves the eccentric and raises the tailstock slightly off the ways. The link *L* connects the eccentric shafts. The lift need not be more than 1-32-inch—just enough to take the weight off the ways. The friction will thus be reduced so that the high gear ratio will not be necessary. The operator can thus readily move the tailstock from a short to a long piece of work and *vice versa* without much fatigue.

FRANK B. KLEINHANS.

CARBORUNDUM WHEELS.

Editor MACHINERY:

Carborundum wheels are cutting material, and not grinding, as usually applied. They are composed of thousands of miniature carborundum chisels, or cutting tools, hard as diamonds (even cutting diamonds), with keen, sharp, cutting edges, placed promiscuously and in every conceivable position throughout the wheel. Many of these cutting edges are just in the proper position to do excellent work on any kind of metal, or material, usually finished up in this way. Experiments have proven that the coarser the grit the more satisfactorily the work is done, but it is necessary to have the wheel balanced, clean, true and firm on a steady running arbor.

I recently was asked to make some tests on soft steel and cast-iron with a No. 16 grit wheel for a party from Cleveland, O. After making a satisfactorily smooth finish on the soft steel, and before starting on the cast-iron, I touched off the face of the wheel with the diamond. I was asked, "Why do you do that?" I replied, "To insure a true and clean face of my wheel," and was told, "That won't do; the wheel must work on either stock without having to first true it up." While this remark was made by a gentleman who admitted on a previous occasion that he knew little about the use of wheels, it is often only too true that the manufacturers, who should know better, expect too much for nothing. One might, with the same propriety, say there is no use in properly fitting the tools for the various kinds of work, and finish, on the materials worked on the lathe, planer, shaper, drill-press or miller. No good mechanic will even attempt to use a tool on any machine without first preparing the tool for the particular job he intends doing.

Now, it does not follow that a carborundum wheel with its thousands of small cutters (which, when in order, do more and better work than the tools just referred to) should be deprived of the very trivial attention of simply keeping its face clean and true. Rather, were it necessary, give it more attention, since its cutters do so much more and better work. Tools of any kind, however good, must be kept in proper order to do good work.

A 12 or 16-grit carborundum wheel is well adapted for almost any class of work when requirements, as above stated, are complied with, for either roughing down or finishing. Of course, for a fine finish it requires to be run without any feed till the sparks cease to show, and with sufficient water, to prevent the work from heating. All wheels will heat more or less when used without water, and the work will expand and continue to cut away the stock, as it heats more and more, and is liable to be spoiled, especially where accuracy is required.

A wheel that will glaze heats, of course, much quicker than one that will not; much care and attention to the keeping

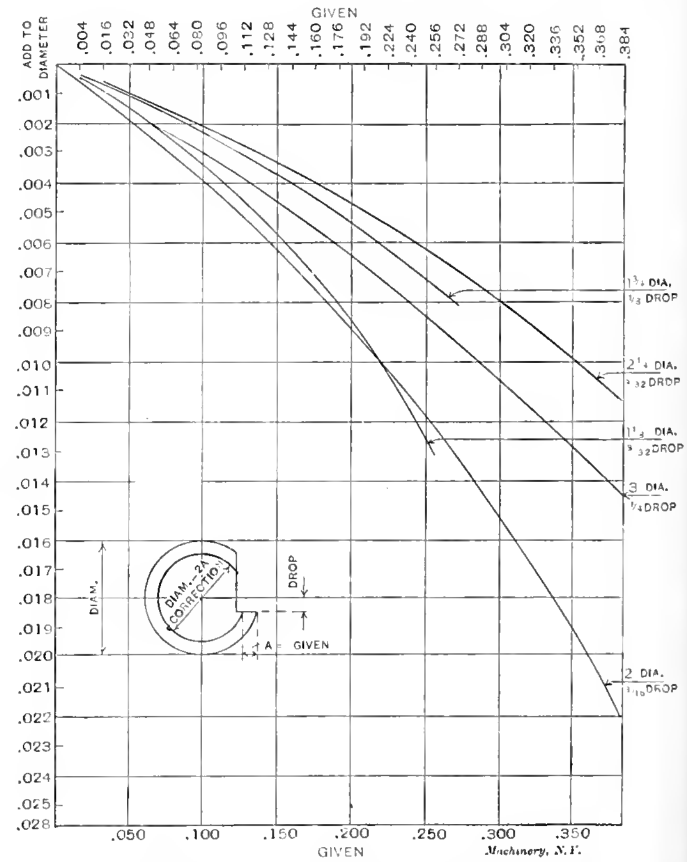

Fig. 1. Chart for Circular Forming Tools.

in order of both wheels and machine must be given. As before stated, arbor and wheel must run true and steady. When you are depending on the small cutters or chisels to make a neat finish they must necessarily run steady, so that the periphery of the wheel does not vary in its travel, otherwise a good finish with a coarse wheel cannot be expected.

Again it must be remembered that there is a difference in finishing work—holding it on the wheel by hand or rigidly holding it between centers, or in a vise or chuck. It would be a hard matter to get a fine finish with a coarse wheel simply by holding it on by hand, as the pressure would be irregular against the cutters. A good finish by hand, how-

ever, is easily obtained by the use of a carborundum buffing wheel of 36 or 40 grit.

I would be glad to hear of the experience of others who are using carborundum as cutting tools. EZRA F. LANDIS.

La Salle, N. Y.

CHARTS FOR FORMING TOOLS.

Editor MACHINERY:

I have read with much interest the article "Straight and Circular Forming Tools," by Mr. J. M. Stabel, as found in the June, 1904, issue. As it falls to my lot to design tools of this character, I have a suggestion or two to make on the tables that he has had appended.

Table No. 3 is gotten up very well; we have a wide range in diameters to select from, with various depths of cutting faces below the center, etc., but unfortunately the value of this table is limited. First, let us glance at Table No. 1. Here we can find the correction for any distance for *a c*, up to ½-inch varying by 0.001 inch. For an odd figure the method of arriving at the correction by means of adding the constants, is not really first-class, as there is that element of danger of an error in the adding operation. Let us now refer to Table No. 3. It is just as necessary to have the correction known, for distance *B C*, varying by 0.001 inch as in Table No. 1, but this table is calculated for *B C*, being either 1-16, ⅛ or ¼ inch, and you may make dozens of forming tools and not have use for the table.

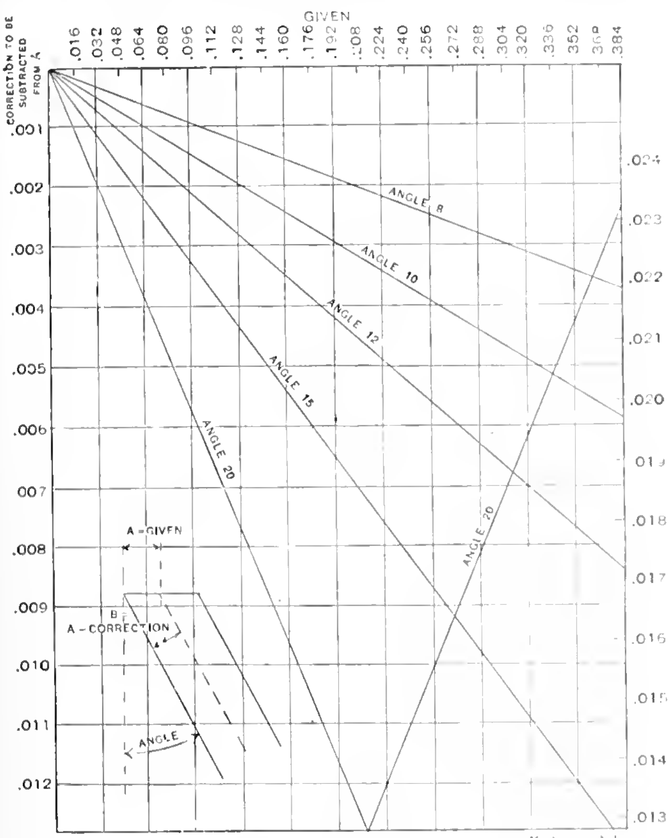

Fig. 2. Chart for Straight Forming Tools.

Accompanying are two charts that I have designed; the various curves and lines thereon are made from what I know to be generally used. I will give an illustration of their use as the best way to explain them. Referring to Chart No. 1, the distance *A* (see sketch) thereon is calculated from whatever the piece is, we have to make. Under the word "Given," at the top and bottom of the chart, locate *A*, and follow down (or up) the vertical line until it intersects the proper curve. This point carried to the right by the horizontal line, will indicate the correction to be added to the diameter, after subtraction 2*A*, of course. The horizontal divisions for the verticals vary by 0.004 inch, and the corrections read to 0.0005 inch, which for practical use is as near as required.

The same illustration will answer for Chart No. 2; in this the correction is carried around to the right of chart.

The Chart No. 1 shows only five curves and there is no question but what there are many other standards, so it is quite impossible to make a complete chart or table. This one covers the range of my experience in automatic and hand screw machines. For instance I use a circular tool 2¼ inches diameter and 5-32-inch drop as much as any other; on straight tools I generally use angles of 8 and 12 degrees, seldom 10 or 15 and never 20 degrees. Unless we know all standards I think it best to avoid useless calculations.

GEO. D. HAYDEN.

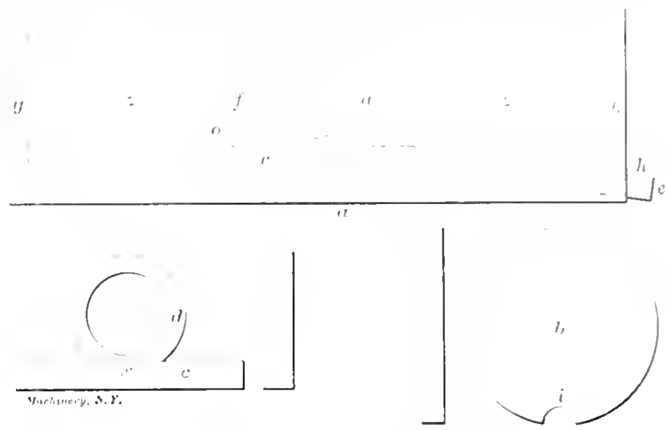
New Bedford, Mass.

MUFFLE BRAZING.

Editor MACHINERY:

Oftentimes in model and experimental work it is cheaper, and better in most cases, to braze two pieces like *c* and *d* together at *x*, than to make the shape out of solid stock.

I made a pot *a* of suitable length out of iron pipe, and had the bottom *g* welded in, to make it air-tight, as all air must be excluded to make the job a success. Then I took a piece of ½-inch gas pipe, *h*, cut it off to the right length, and closed the end at *o* with an iron plug. The top of the pipe *h* was



Apparatus used in Muffle Brazing.

filled for a distance of ½ inch with brass filings, *f*. *c* and *d* were firmly secured together with iron wire, and brass filings were placed around the joint at *x*. The job was wound up with cotton cloth and string to keep the charcoal off the work, and was placed in the pot *a* so that *c d* and *h* would come central in *a*. *h* was placed on a slight incline, as shown. The remaining space in *a* was filled with clean charcoal. The cover, *b*, which is milled out at *i* to allow *h* to pass by it, was put in place and luted with fireclay. The muffle was then placed in a furnace. When the work has attained the proper heat the brass filings *f* will melt and run down the incline in the gas-pipe, *h*, and out at *e*, and in coming in contact with the air will emit the characteristic blue-green flame which indicates that the brazing material has reached the liquid state.

The operator should then wait a short time after the brass has flowed to make the job sure, then take the pot out of the furnace and lay it aside to cool. After taking the job from the pot, it will be found to have a perfectly brazed joint, and as clean and bright as a new silver dollar.

New Haven, Conn. A. L. MONRAD.

[The old-time German locksmiths practiced muffle brazing to a considerable extent, but the muffles they used were made of common clay. Suppose a key of complicated shape was to be made. It appears, from what the editor has been told by one of these old-time locksmiths, that the common practice was to build up such a key from bits of iron arranged to form the projections to fit the wards of the lock. These, of course, were filed to shape afterwards, but by the building-up process it appears that considerable labor was saved on account of the simplicity and sureness of the clay muffle brazing process. When the parts of the key were built up, they were firmly bound together with wire, and brass filings were placed around the joints. The whole was then luted with clay, forming a mass considerably larger than the work. This was put into the forge and heated until the brass flowed, which was known by the color of the flame; then the whole mass intact was removed and allowed to cool before breaking apart. The process is said to have been absolutely sure every time, and one easily learned.—EDITOR.]

SHOP KINKS.

A DEPARTMENT OF PRACTICAL IDEAS FOR THE SHOP.
Contributions of kinks, devices and methods of doing work are solicited for this column. Write on one side of the paper only and send sketches when necessary.

A DRAFTING KINK.

Here is an expedient in making scale drawings, which, while very simple, seems new to almost every one I meet. If drawing circles of scales half size or smaller I take the radii off directly from the scale of half the size I am working from. For instance, suppose that a drawing is being made half size and that a circle of 18$\frac{5}{8}$ inches diameter is to be drawn, I set the compasses to 18$\frac{5}{8}$ inches on the 3-inches-to-the-foot scale and they are set right without any calculation or chance of mistake. If working with a scale of 1-inch-to-the-foot then I lay off radii on the $\frac{1}{2}$-inch-to-the-foot scale and so on. Compare this with dividing 18$\frac{5}{8}$ inches by 2, and the saving in time and gray matter will be evident. E. H. Fish.

Paxton, Mass.

SIMPLE BALL REAMER.

To make a fluted ball reamer of the ordinary style requires considerable time with the facilities at hand in most tool rooms and to make it so that it will be accurate a great deal of care must be exercised, but here is one which is inexpensive, easily made, and it will bore an almost perfect ball socket. This style of ball reamer has been used by one of the local firms for years and has always given good satisfaction. A piece of steel is turned to the desired size and a cut-off tool partly forms the disks. The disks are then finished, as in Fig. 1, on the outside, making a slight shoulder on either side and cutting a shallow angular groove around the center. They are then further separated by cutting in with a parting tool again as far as possible without bending the steel, after which

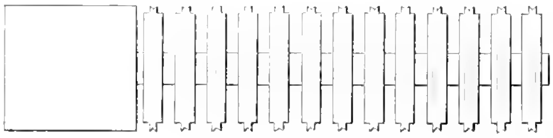


Fig. 1

Fig. 2

Fig. 3

the disks are faced off to a uniform thickness and cut apart with a hacksaw. The roughness left by the hacksaw is smoothed off on an emery wheel. Each disk is filed away on one side of the angular groove for nearly one-fourth the circumference, then the alternate side for nearly one-fourth, and so on entirely round the disk, allowing cutting edges to lap a trifle, as in Fig. 2. They are then ready to temper. The cutters are held simply by being driven into the holder, Fig. 3, and are used until dull, when they are given a half turn and fresh cutting edges are presented to the work. With careful usage one cutter will last a long time.

Salem, Ohio. Roy W. Harris.

SCREW CUTTING WITH THE FEED GEAR.

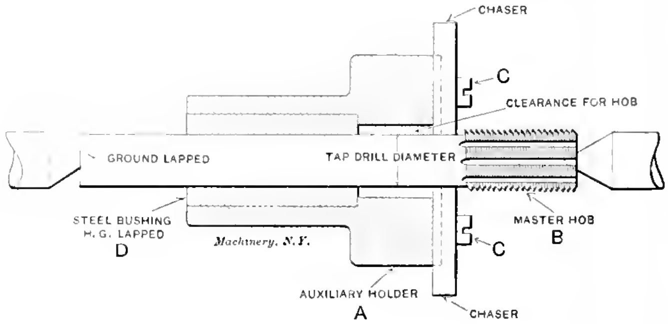
Many articles have been written about screw-cutting, but the following may be new to some of your readers: I was employed at one time in a little mining camp repair shop, the only lathe being 26-inch swing; the finest pitch that it would cut was twelve threads per inch and no provision was made for compounding the gears. One of the first jobs I had was to make a new needle valve for a lubricator, the threaded part being about $\frac{1}{4}$ inch diameter and 24 threads per inch. I placed two gears of the same size upon the stud and screw and started the feed, the friction being driven through leadscrew. Counting the number of revolutions to 4 inches of travel of carriage I found 80 revolution to 4 inches, or a feed of 20 per inch. Taking that as a base the same as if I had a 20-thread leadscrew, gave the proportion 20:24 = 40:48.

A 40-tooth gear was put upon the stud and a 48-tooth gear on the screw, which gave the desired pitch.

At another time I had to repair a drill grinder chuck; the thread on the spiral or scroll plate had been broken out. The old spiral was faced off and a steel plate was fastened on in which a new spiral thread was to be cut, the pitch being $\frac{1}{2}$ inch double thread. The lathe to be used was a Putnam—one of those in which the driven gear on the stud slid upon a feather that it might be driven either by a gear on the cone or by a gear of the same size on the lathe spindle. The cross-feed was driven through the screw. Two gears of the same size were mounted on the screw and stud and starting feed the revolutions were counted. I found the cross-feed tool block moved 5 inches for 35 revolutions of the lathe spindle, or equal to 7 threads per inch. Using this for a base the same as if I had been using a 7-thread leadscrew gave the proportion 7:2 = 70:20. Having those gears I used a 700-tooth gear on the stud and a 20-tooth gear on the screw, and thus gained the desired result. J. T.

RECUTTING THREAD CHASERS.

For those who are interested the accompanying sketch will show more thoroughly the manner in which thread chasers can be accurately re-cut than would be possible in a briefly worded description. *A* is an auxiliary holder, of machine steel, having slots cut in same to fit chasers, and it also contains a steel bushing, *D*, that is hardened, ground and lapped. The master hob, *B*, is made having a long shank which is ground and lapped to fit the bushing. The diameter of shank



is same as that of tap drill for chaser to be cut. To re-cut chasers remove same from slot in die head proper, and after annealing, the chasers are placed in slot in auxiliary holder and the master hob also is placed in holder, as per sketch. The chasers are now brought to bear against shank of hob and securely tightened by means of screws, *C*. The hob can now be made to cut chasers in same manner as an ordinary tap and the long bearing in bushing *D* insures accurate results. Two hobs should be used, one to remove stock, and one to cut finished sides. It is almost impossible to obtain accurate results if the chasers are cut independently, on account of the difficulty experienced in getting the threads of the different chasers to match up when in place in the die head. The above fixture was designed by the writer for cutting chasers used in self-opening dies and the method is perfectly reliable. Frank E. Shailor.

Great Barrington, Mass.

ANOTHER "HARDENING WORK IN PART."

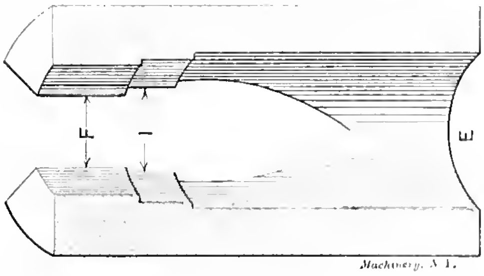
As Irm J. says of the letter from O. M. B. in regard to hardening work in part, "There is perhaps one shop in fifty that is equipped to turn out work in that way;" and Irm J.'s method would work only on steel that had sufficient carbon in it to cause it to harden. What is the use of going to all that trouble, even if you were fitted to do it?

Suppose you have a piece of shafting that you wish to harden where the bearing comes, and do not care for the rest to be hard. Locate the bearing and put that part in the fire and heat it to a cherry red, and put on it some cyanide of potassium and let it run around over the part you wish hardened. Then take the piece from the fire and cool it quickly with water, as you would if it were tool-steel and you wished

to harden it, only in this case you do not need to draw the temper. This way is much easier and any shop that has a forge can do it as well as the best equipped shops. C. H. A.
New London, Conn.

TO PREVENT SPRING DIES CLOSING IN.

I have read Mr. Markham's articles with much pleasure and have received a great deal of benefit from them, and I wish to call his attention to this method of overcoming a troublesome feature of spring dies. Having a great deal to do with this class of dies I find that when hardening them they have a tendency to close in at the top, which makes the die under size; and to overcome this, I use the methods here shown in the sketch, which shows a sectional view before threading.



After having them all finished and ready to temper, I heat the dies to a low heat and drive a piece of punch rod into the portion *I* which is left enough smaller than *E* to make a driving fit. This forces the die outward and just enough to counteract the closing in, so after the die is tempered it comes back to its normal state. We had a great deal of trouble with our dies until this method was used and now we have no trouble at all with them. I have seen a great many dies thrown away on account of their closing in, and where one makes the dies and never gets a chance at tempering them, he hardly ever knows whether they are good or bad, for when a die does not work just right, the men usually throw it away and get a new one. W. Van Orman.
Lorain, Ohio.

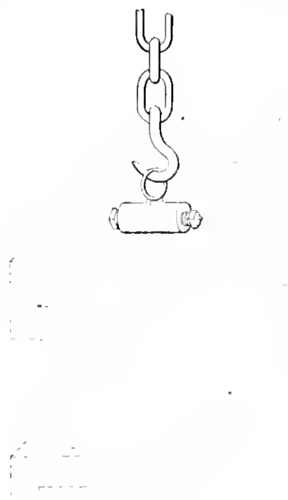


Fig. 2

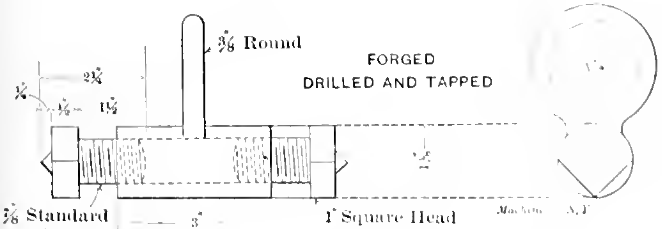

Fig. 1

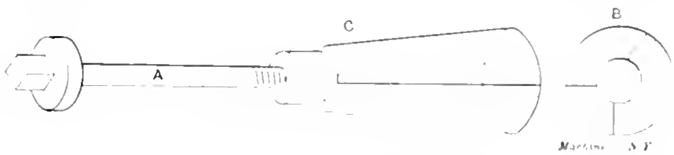
DEVICE FOR LIFTING DRIVING BOXES.

The sketch herewith shows device for lifting driving boxes, and although it is a small device, still it is one of the best shop kinks that I have ever seen in a railroad shop for this purpose. It is something of my own design and has been in use for the past three years, proving very handy for lifting driving boxes on and off machines, and also in fitting driving boxes to driving journals on the erecting side of the shop. By the introduction of a small traveling crane over pit, which is used for fitting the above mentioned boxes, and a small air hoist, an apprentice boy, without the assistance of a helper, can apply a driving box on one of the modern engines without any effort.

Fig. 1 shows the construction of the lifting device, which can be made of wrought iron or steel forging, or a brass casting. By simply drilling a hole through the body, tapping out and inserting two setscrews, the device is completed, and after the setscrews are imbedded into the flanges, it is impossible to pull away. The cost of making this device is very little. Fig. 2 shows the device in operation, and the manner in which it is applied in the driving box. Prior to using this I was compelled to use chains and clamps of different styles and rude construction. L. C. Hicks.
San Bernardino, Cal.

CHUCK FOR HOLDING END MILLS.

I saw in July issue of Machinery a description by Mr. Ridderhof of a chuck for holding end mills, which is without doubt a very good tool for the purpose; but I have made and used one for the same purpose, and often wondered at people being satisfied with the old taper shank mills which Mr. Ridderhof justly criticizes. I herewith submit a rough sketch of the one which I prefer to all others I have seen and which, if made accurately from good machinery steel, will remain practically accurate for an indefinite time, if reasonably used. The mills to fit it are cheaply made, being straight shanks that may be ground true after tempering, and they may be allowed to project more or less to suit the work in hand. The chuck body, *B*, may be made any size to suit the hole in the main spindle or the vertical attachment; if for the large hole, chamber out at *C* to allow it to spring and clamp the shank firmly the whole length. Bolt *A* is of any length to suit. L. E. Muncy.
Syracuse, N. Y.



TURNING SHAFT LONGER THAN CENTER DISTANCE OF LATHE.

Not long ago we had a shaft 4 inches square by 15 feet long that had to be turned to 3 15-16 inches diameter, about 1 foot at one end and 3 feet at the other. The largest lathe in the shop then, would take but 12 feet between centers. I finally planned a way to turn it as follows:

We had a cathead similar to that described by J. J. Dawson in the July number, only that it had four setscrews in each end. By the way, I wish to make a suggestion in regard to such catheads. The ends where the screws go through should be made quite heavy; otherwise in tightening them on the work, the pressure from the screws is liable to spring the cathead out of true, making it slightly oval; and that would likely cause trouble with the steady-rest.

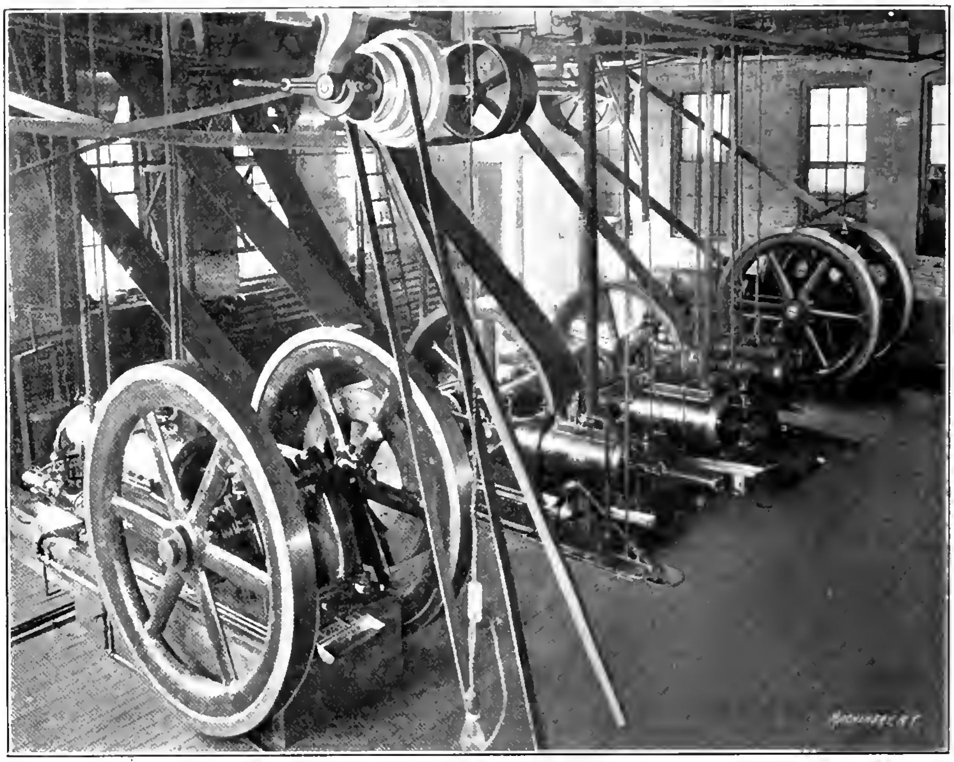
I first took a short piece of shafting that was centered, and slipped the cathead on it, and then put the piece in the lathe on centers. After adjusting the cathead till it ran true I adjusted the steady-rest to it—which centered the steady rest. I then removed the cathead, short piece of shaft, and the tailstock from the lathe, and slid the steady-rest down to the other end of the lathe and clamped it there. Slipping the cathead onto the shaft, I hoisted the shaft into the lathe and chucked one end and let the end with the cathead run in the steady rest. It was then easily trued by the chuck at one end and the cathead screws at the other, and then the end nearest the headstock was turned, after which it was an easy matter to change ends and turn the other end. The shaft had a couple inches in length to spare, and that gave enough to chuck. The ends, of course, were not turned, but were sawed off later, leaving the two ends turned to size, and in line and true. C. H. A.

GAS ENGINE POWER PLANT.

The works of the Star Drilling Machine Company, at Akron, Ohio, are of interest, as it is one of the few large plants operated entirely by gas engines. The power plant consists of four 60 and one 35-horse-power Columbus engines, making a total of 275 horse power. These engines are so distributed throughout the various departments as to reduce the amount of shafting to a minimum. Altogether they constitute a unique installation for so large a manufacturing plant.

One 60-horse-power engine operates the wood-working machinery, another of the same size operates the metal-working department, and the 35-horse-power engine operates the lighting plant. The other two 60-horse-power engines shown in the illustration drive air compressors to operate drop hammers, formerly operated by steam, and all the other pneumatic tools, such as drills, chipping hammers and hoists.

Mr. Miller, superintendent of the Star Drilling Machine Co., states that they find this division of their power very convenient, as they can run any part ot the plant without operating the balance, and having no long lines of shafting, the loss by friction is small and the cost of attendance, fuel and supplies much less than with the steam plant which has been abandoned. The gas engines in this plant were installed by the Columbus Machine Company, of Columbus, Ohio.



Gas Engine Power Plant of the Star Drilling Machine Company.

STURTEVANT ECONOMIZER.

As a natural consequence of their mechanical draft apparatus the B. F. Sturtevant Co., Hyde Park, Mass., are to manufacture an economizer. While the economizer is adapted to installations with or without mechanical draft, special attention is given to equipping power plants with the combined apparatus. In order to adapt the economizer to every possible condition it is built up of sections, with pipes staggered to intercept the gases to as great an extent as possible. There is also built what is termed a Pony economizer, designed to give the smaller power plants from 50 to 300 H. P. capacity an apparatus adapted to their needs. The headers supporting the different pipe sections are carried by so-called wall boxes, which are placed in the side wall of the setting, forming a part of the wall. The whole weight of the economizer is carried by these wall boxes and is thus distributed throughout the length of the setting. Practically all the joints are metal to metal, with taper fits, which facilitates making the repairs.

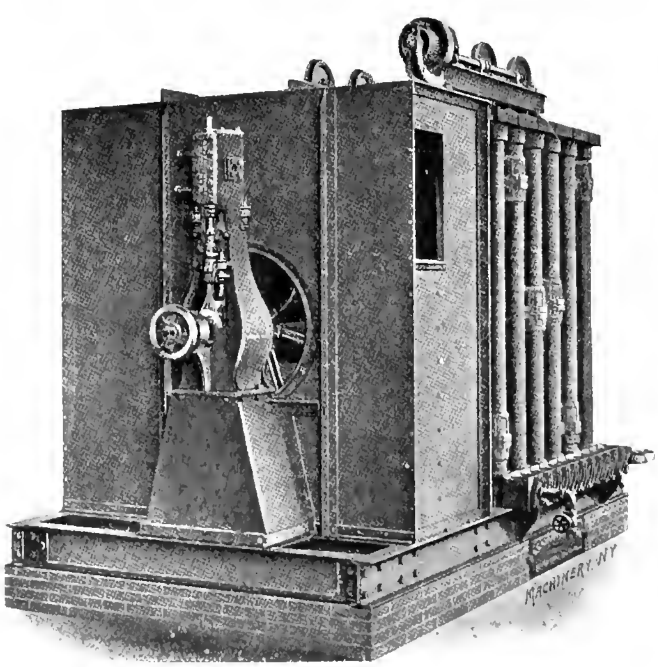


Fig. 1. Sturtevant Economizer.

In Fig. 2 is a diagram showing the process of removing an old tube and inserting a new one. Pipe No. 1 is shown in position, with the inside cap in place at the top. No. 2 is a cross-section of the pipe in position. No. 3 shows the draw-out rods in place to start the pipe from its friction joints. The left-hand rod has a hook which fits under the lower edge

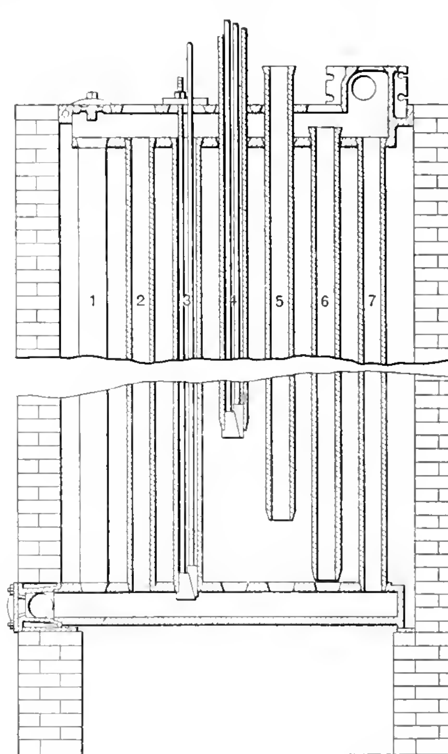

Fig. 2. Diagram showing Method of Replacing Tubes in Sturtevant Economizer.

of the pipe and is wedged in place by the taper end of the right-hand rod. By merely turning the nut at the top the pipe is started from its position. No. 4 shows the pipe removed. Nos. 5 and 6 illustrate the new pipe entering and No. 7 the new pipe in place. By hammering the pipe in slightly the joints become tight. The economizer is fitted with scrapers which automatically travel up and down the pipes. They are operated by an improved form of reversing apparatus.

* * *

HOW AND WHY.

A DEPARTMENT INTENDED TO CONTAIN CORRECT ANSWERS TO PRACTICAL QUESTIONS OF GENERAL INTEREST.

Give all details and name and address. The latter are for our own convenience and will not be published.

8. H. S. has sent us a sketch showing two methods of connecting two shafts, and wishes to know which will prove the more efficient and about what the losses will be in each case. In the first example a gear wheel with 31 teeth drives one with 13 teeth, and on the same shaft with the latter is a sprocket wheel 12 inches in diameter which is connected by a sprocket chain with a wheel 6 inches in diameter on another shaft. In the second example the two shafts are connected by a chain drive without any intermediate gearing. We think it probable from the sketch that the gear wheels have cast instead of cut teeth and that the sprocket chain is of an ordinary type. Under such conditions we should expect the loss to be about the same for a sprocket drive as for a gear drive. Assuming the loss for the gears to be 15 per cent., and for the sprocket drive 15 per cent. also, the total efficiency in the first example would be $.85 \times .85 = .72$. The efficiency of the direct drive in the second example would be about 85 per cent.

---

9. S. C. Co.—Will you kindly advise us what is understood by the amount of power conveyed by a "run of stone?" A good many property rights in water power have in the past been conveyed under the description of "so many run of French buhr mill stone and the necessary machinery," and we would like to get the best statement of the amount of power which engineers agree on as being covered by such a term.

A.—We have submitted this question to Mr. Samuel Webber, who, for so many years was identified with mill work and power transmission, so that he is unusually well qualified to supply the information requested. He replies as follows:

I have devoted a great deal of time to this question, and looked up every available authority, from old Nicholson's "Operative Mechanic" down, coming to the conclusion from the older authorities that "one horse power per bushel of grain, ground per hour" was an average rule. This was verified by the results of the test of an automatic engine at the mill of Gibson & Co., at Indianapolis, published in Van Nostrand's magazine for December, 1877. In this article the mill was stated as containing "12 runs of 48" French buhr stones, and the consumption was $7\frac{1}{2}$ to 8 bushels wheat per hour. The power used by indicator cards was: Condensing, 105.4 horse power; non-condensing, 115.4 horse power. This included cleaners, bolts, etc., but in the non-condensing trial the elevators were worked more steadily than in the condensing one. This gives in the non-condensing trials a little less than 10 horse power per run; in the condensing trial a little less than 9 horse power, and deducting engine friction, about 9 and 8 horse power respectively. So that I have called the water power required from 8 to 10 horse power per run, according to the character of the wheel, whether modern turbine or old breast. For the old deeds, when breast wheels or overshots were in use, I usually call it 10 horse power per run.

---

10. O. W.—Will you kindly tell me the fusing point of aluminum, and if it can be molded. Also the sand to use for a green sand mold. Will chilling have any effect upon the mold?

A. We submitted this question to the Pittsburg Reduction Co., who reply as follows:

The fusing point of pure aluminum is 1,250 degrees F. Aluminum can be cast in both sand and metal molds as readily as brass, and in general castings can be satisfactorily made by the use of an ordinary sand mold, such as would be used for brass casting. The only additional precaution which is necessary to be taken is that the mold should be thoroughly well ventilated, and also that it should have a large gate and high riser. These points cannot be too strenuously insisted upon. The object of the large gate and high riser is to allow the metal to flow in and supply the shrinkage, as the aluminum in the body of the mold shrinks, and it is very much more necessary to have large risers in the use of sand molds than it is in the use of hot iron molds, where only small gates are necessary. As in other castings, of course the finer the sand that is used in making the molds the more perfect the surface of the casting. The metal should be poured as cold as possible in order to insure sound castings, free from blow-holes (caused by the very great absorption of gas by overheated molten aluminum), or cracks and depressions due to shrinkage. A good method of producing sound castings in iron molds is to heat the molds to about 1,200 degrees F., or about the temperature of the molten aluminum, and cause the metal to cool from the bottom of the molds upward by a blast of cold air or other suitable means. Thus the metal in the comparatively large sinking head or riser remains molten until the casting is solidified. In this way the impurities segregate in the sinking head and the shrinkage is replaced with fresh additions of molten metal.

---

11. C. G. B.—Can you give me information as to the carrying capacity of ball and roller bearings? As far as I can find, this information is not accessible, except such as is given in catalogues of manufacturers where I think the capacity of such bearings is overrated.

A.—In the November (1898) number of MACHINERY Prof. C. H. Benjamin contributed an article upon ball bearings in which he gave results of tests and directions for the design of such bearings. He also has given similar information in his excellent treatise upon machine design, which is published by Charles H. Holmes, Cleveland, O. The carrying capacity of ball bearings is generally calculated as some factor of the strength of the balls. This is not a satisfactory method, but may be as good as we have, with our present knowledge of the subject. The strength of steel balls varies greatly with different grades of steel. Values for breaking strength have been selected from the tables referred to, however, as follows:

For $1\frac{1}{4}$-inch hardened steel balls, 6,000 pounds per ball; $\frac{3}{8}$-inch, 18,000 pounds; $\frac{1}{2}$-inch, 30,000 pounds; $\frac{5}{8}$-inch, 42,000 pounds; $\frac{3}{4}$-inch, 54,000 pounds; 1-inch, 77,000 pounds.

In the Journal of Worcester Polytechnic Institute, Vol. 1899, Alton L. Smith says: The rule of loading balls to 1-5 of their breaking capacity is far from being approximate. If held between two parallel surfaces less than 1-10 of their breaking load would be a nearer approximation for safety. If, however, the ball rolled in V-grooves so as to have four points of contact, a higher load could be carried. The surface resistance of a small ball of $\frac{1}{4}$ or $\frac{1}{2}$-inch diameter is probably as great as that of a 1-inch ball, in which case it might safely carry the same load as the large one if this were within the elastic limit. The safe load should not be based on the breaking strength but on that load within the elastic limit which will mark its surface, when in contact with a hardened flat plate. In his book on machine design Prof. Benjamin states that ball bearings should not be called upon to sustain nearly as great a load as 1-10 of the breaking strength of the ball, as stated above. He says that experiments he has made show that a $\frac{1}{4}$-inch ball loses all value as a transmission element, on account of distortion, at any load of more than 100 pounds. He also quotes Prof. Gray, who places this figure at 40 pounds only, for $\frac{3}{8}$-inch balls; also see Machine Design, Vol. II., by Prof. F. R. Jones.

We know of no information upon roller bearings, excepting such as was obtained by tests upon the Hyatt roller bearings by a committee from the Franklin Institute. This information can doubtless be secured from the manufacturers of this style of bearings, the Hyatt Roller Bearing Co., Harrison, N. J.

* * *

Pure gold has the unique property of welding at ordinary temperatures. It must, however, be absolutely pure and clean, and must be annealed just previous to using. When in the thin leaf state mere hand pressure is sufficient to get an intimate cohesion, although dentists generally use light percussive tools when using gold for filling teeth

NEW TOOLS OF THE MONTH.

A RECORD OF NEW TOOLS AND APPLIANCES FOR MACHINE SHOP USE.

SIXTY-INCH ROLL TURNING LATHE.

A 60-inch motor-driven roll turning lathe has been built by the American Tool Works Company, Cincinnati. In view of the severe duty for which the lathe is intended, it is built exceptionally heavy. The lathe is driven by a 25 horse-power variable speed motor, which is mounted on a substantial plates. The range of speeds thus obtained through both the headstock and the motor is very wide, varying by minute gradations.

Below the headstock, on the head end of the bed, is located the geared feed changing device. Through the three levers shown at the front of the box, seven positive feeds are

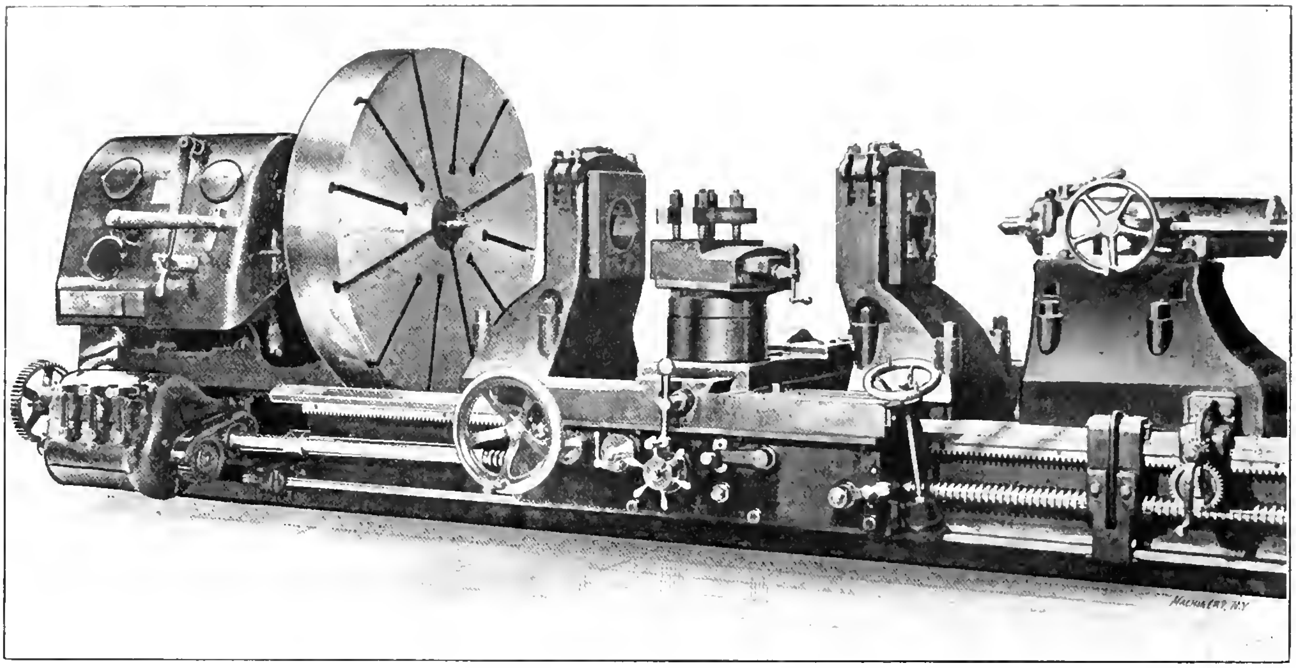

Fig. 1 American Tool Works Company's Sixty-inch Roll Turning Lathe.

stand at the rear of the headstock and is connected to the driving shaft in the headstock by silent chain, as shown in Fig. 2. Primary speed variation is obtained electrically, through manipulation of the hand wheel at the right-hand end of carriage, which starts, stops and reverses the machine, and also varies the speed by minute increments. These electrical changes are supplemented by mechanical changes obtained through the all-gear headstock, by means of the two levers

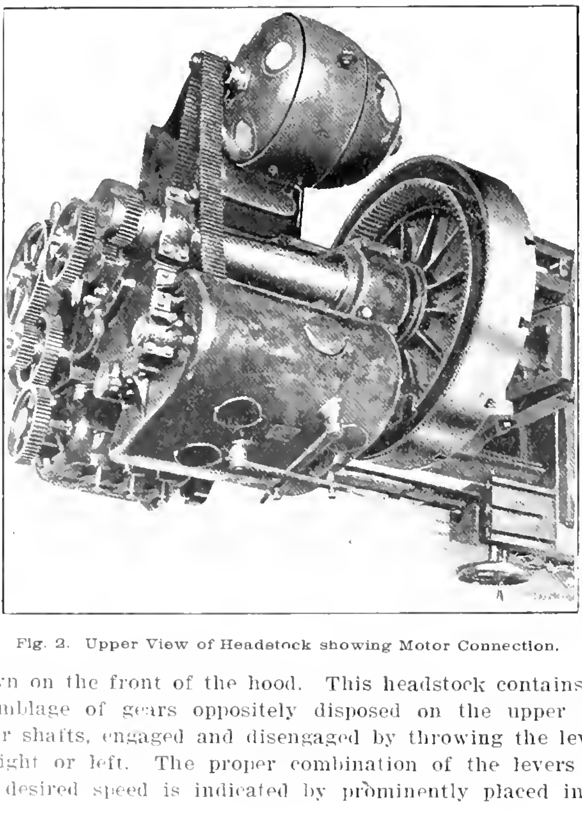

Fig. 2. Upper View of Headstock showing Motor Connection.

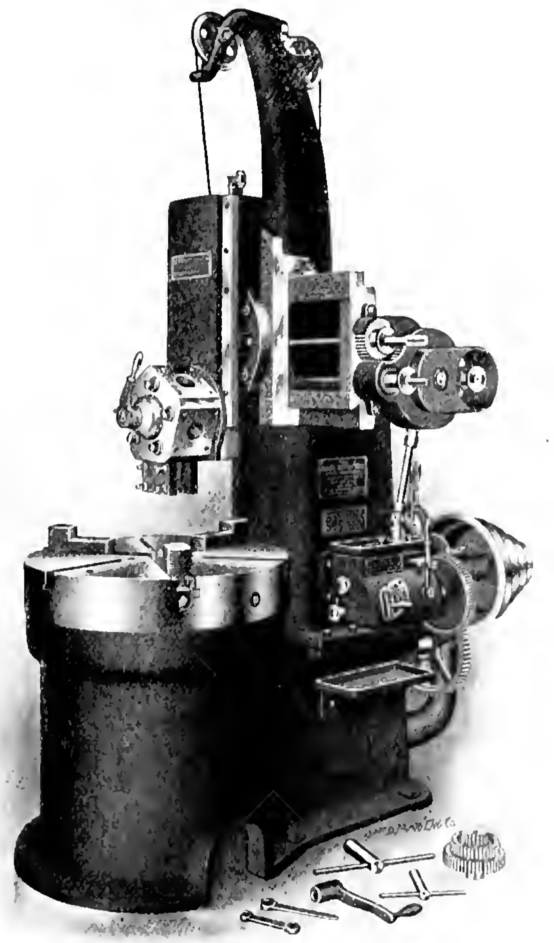
shown on the front of the hood. This headstock contains an assemblage of gears oppositely disposed on the upper and lower shafts, engaged and disengaged by throwing the levers to right or left. The proper combination of the levers for any desired speed is indicated by prominently placed index obtainable, without removing a single gear. The gears are mounted on two shafts and are completely housed in. Simple index plates show clearly the various combinations for obtaining any desired thread, pitch or feed.

Aside from the motor drive, the features of especial interest on this particular lathe are the roll turning attachments. The heavy housings are for the purpose of holding pipe roll castings. At the rear of the machine, mounted on the rear of the bed is a roll forming attachment, the purpose of which is to impart curved surfaces to long pipe straightening rolls. It operates on the principle of a taper attachment. A shoe, provided with anti-friction rollers, slides in a trough following master bars, thus generating the same curve on the rolls being turned. Straight work can be turned by simply disengaging the nut which holds the shoe, and by tightening the cross-feed nut. A concaving rest for semi-circular grooves is interchangeable with the compound rest, and is used for grooving out pipe welding rolls, with a capacity for rolls for pipe from 2 to 20 inches diameter, a limiting gage being provided for setting the tool to any desired diameter. This rest operates with rotary motion, through a worm and worm wheel, with either hand or power feed, the latter being derived through the feed rod and carriage with all the advantages of the regular feeds.

THIRTY-INCH BORING AND TURNING MILL.

The boring and turning mill illustrated herewith has just been placed on the market by the Baush Machine Tool Co., Springfield, Mass. It is built with a swivel turret head and swings 32 inches in diameter and 15 inches under the cross rail. The chuck or faceplate has eight changes of speed. It is bolted to a large driving gear which has an outer bearing with automatic oiling device arranged in the bed so as to keep the bearings well lubricated. The center spindle is 7 inches in diameter and 18 inches in length, and is made with angular bearing to receive side strains, with check nuts on the under side of the spindle to prevent any lifting tendency. The turret has five sides—10 inches across the flats—and five 2 3-16-inch

holes. The turret slide has a traverse of 16 inches and in the swivel head can be set over at any angle up to 30 degrees, and will face 30 inches diameter. The vertical feeds have 20 changes, and the horizontal feeds also 20 changes. A cone of large diameter, having a 3-inch belt, drives this mill, but it can be equipped with motor drive at any time. Back gears can be changed by means of a lever without the use of a lock-nut.



Baush Boring and Turning Mill.

The machine is self-contained and does not require an expensive foundation. On the upright of this mill is a Hendey-Norton change gear device for feeding and thread cutting. Threads from 5 to 20 to the inch can be cut. The mill weighs 5,900 pounds.

LUTZ ADJUSTABLE SCRAPER HOLDER.

The cut shows a convenient scraper holder made by the Lutz Tool Company, Springfield, Ohio. It is adjustable, which feature makes it convenient for finishing flat, grooved, curved or angular surfaces, and for getting down to the faces of small valve seats, for instance, which, in some designs of engines and pumps, are inaccessible to ordinary scrapers save when they are bent to an angle. The Lutz scraper can be instantly

Adjustable Scraper Holder.

adjusted and securely locked at any required angle. It holds any size blade up to 2½ inches, and the blades can be quickly changed for others when special shapes are required, etc. The holder is a steel drop forging, well finished, making a handsome and durable tool that should be highly prized by mechanics who have much close and accurate fitting to do.

SHAPER FOR HEAVY WORK.

The cuts herewith show the "Queen City" 16-inch crank shaper especially designed for heavy duty and durability. The column is large and very heavy, and is reinforced where necessary to resist working strain. The design of the ram is original. The arch construction brings the maximum section of metal into service at the point where leverage is greatest, that is, when the cutting tool is at its extreme forward position. The bearing for the ram is 30¼ x 10 inches, and the slides for same overhang, thus giving the tool increased stiffness. The position of ram and the length of stroke can be changed without leaving the work and while the tool is in motion or at rest.

The rail, too, is very heavy; the cross traverse is 21 inches and the screw has a graduated collar. A vertical adjustment can be obtained by the use of bevel gears provided with ball bearings.

The rocker arm is connected to the ram by means of a link which gives a straight pull, an even cutting speed, with quick return and no lost motion. Fig. 2, on the next page, shows this construction, and also the excellent adjustment to compensate for wear of the crank shoe. The table has a V for holding shafts and similar work vertically, and can be readily detached from the saddle. An extension provides for a broad clamping surface, and the manufacturers, the Queen City Mch. Tool Co., Cincinnati, O., will furnish an outer support if desired.

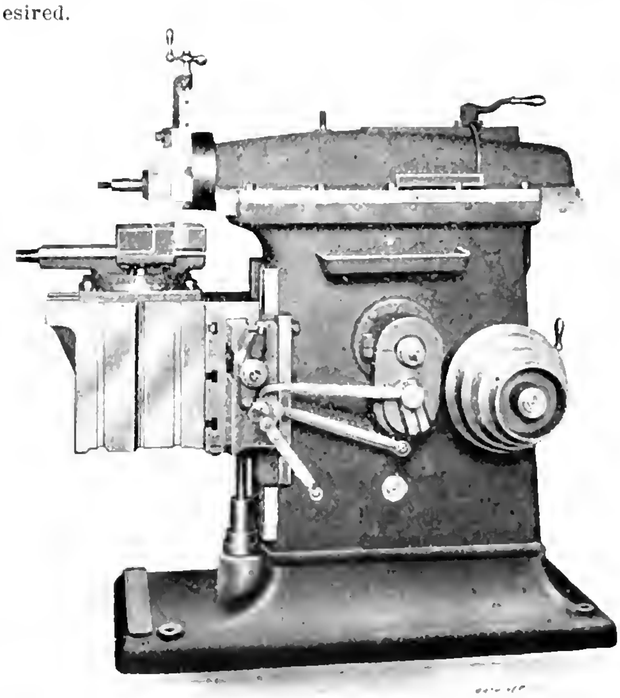


Fig. 1. Shaper for Heavy Work.

The vise is of the planer type and is stiff enough to hold the work solid even on angle cuts. The flat wearing surfaces are scraped to a standard surface plate and are very wide. All extra attachments, such as power down feed, concave attachments, tilting and removing table, etc., are furnished when required.

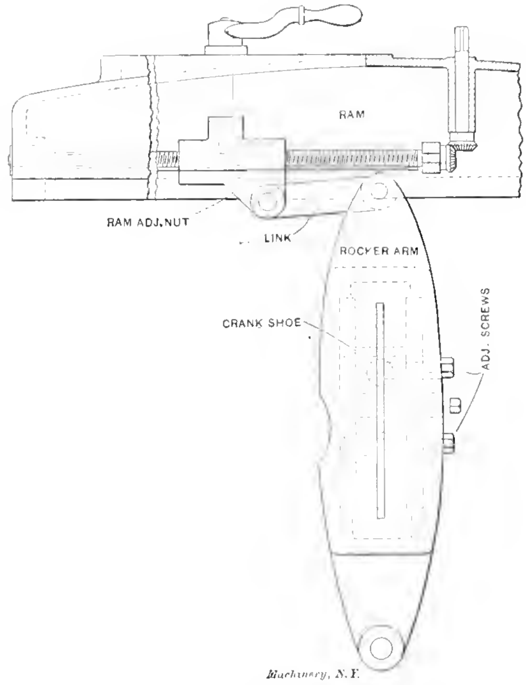
THE GORHAM HEATING FURNACE.

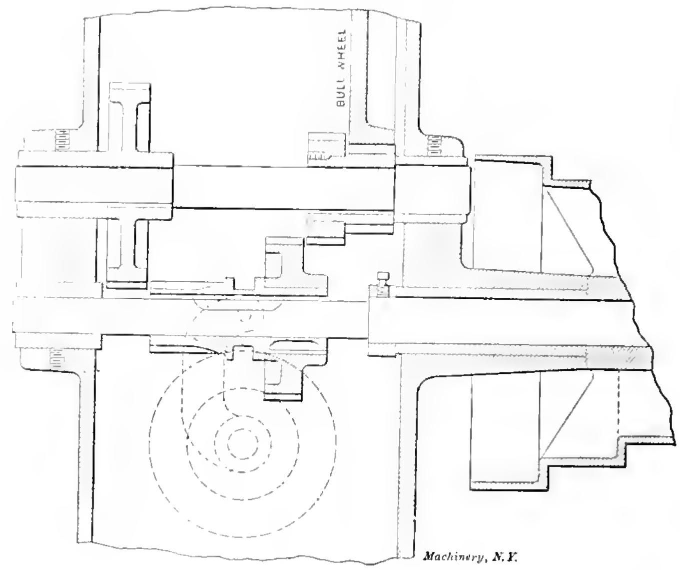
The cut herewith is of the "Gorham" revolving forge furnace now being built and sold by the National Machinery Co., Tiffin, O. This is an oil or gas-burning furnace, and is especially suitable for use in connection with bolt headers, or forging machines, for heating bolt blanks, wheel spokes and similar forgings.

The design of this furnace is such that its four sides are used as heating surfaces. The furnace proper turns on a ball bearing base, and is revolved by the attendant with extreme ease. This arrangement requires but little floor space, and as only one side of the furnace faces the operator the heat radiated upon him is slight. There is a large economy of fuel in comparison with a horizontal furnace of equal capacity, as the irons to be heated are in the most advantageous place, i. e., where the hot gases concentrate, and where the heat is most intense. Furthermore, the heating effect is uniform, as

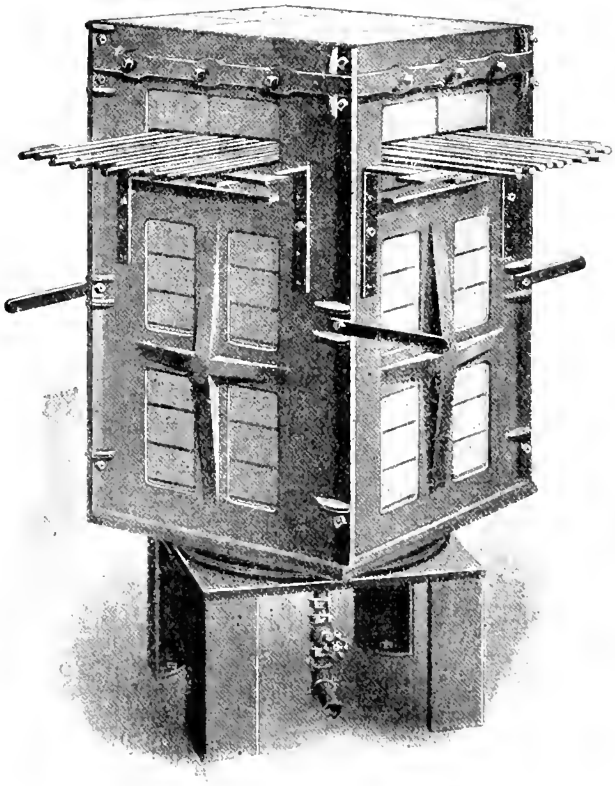
the irons are practically equidistant from the burner, and will heat at the same rate of speed. The lining and also the top of the furnace are made of commercial size 9-inch fire brick, and no especially molded tile is required. Either low or high-pressure burners are used; one requiring an air blast of about eight ounces per square inch, and the other a blast of fifteen pounds or more per square inch. The latter is recommended as being the most convenient and economical. The burner is attached to the base of the furnace, and is vertical and stationary, and requires no swivel joints. The spray of air and oil passes from the burner through a flue at the bottom of the chamber, strikes against a baffle brick and ignites after passing it. As stated above, the heating chamber is vertical and revolving, and although a few vent holes are provided upon the top, a chimney is unnecessary, as the combustion is practically perfect, and the escape of gas is slight. The openings in the top of the sides of the heating chamber are to be partially bricked in, leaving suitable slo s to receive the irons to be heated. Suitable lighting and slag holes are provided, and the internal arrangements prevent slag from flowing into and clogging the burner flue.

The approximate output per hour is four hundred 1-inch, seven hundred ¾-inch or one thousand ½-inch blanks heated three diameters in length. The net weight of this machine complete with lining is 1,400 pounds. The floor space occupied is 21 x 21 inches, and the height is 4 feet.





Figs. 2 and 3. Details of Ram, Rocker Arm and Back Gears of the Queen City Sixteen-inch Crank Shaper.



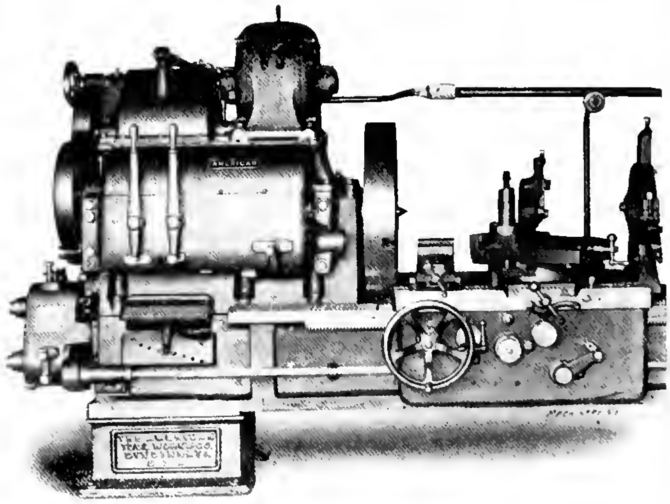
The Gorham Revolving Furnace.

THIRTY-INCH AMERICAN ENGINE LATHE.

The cut herewith shows a 30-inch engine lathe equipped with an interesting method of motor drive, and built by the American Tool Works Co., Cincinnati, O. The drive is designed for a constant-speed motor, either direct or alternating current. The various spindle speeds are obtained mechanically through the gear-driven headstock, the mechanism of which consists of a patent clutch and gear arrangement employing the minimum number of gears and shafts for such a device.

Through manipulation of the levers at the front of the head, and the one at the lower right corner of the head, sixteen distinct and positive speeds to the spindle are provided, in geometrical progression, ranging from 3.8 to 246. Thus a wide range is obtained entirely through mechanical means, sufficient to cover the ordinary work of this lathe. As the construction is simple, all gears and shafts can be made of large diameters. The whole is neatly incased, and all parts are accessible for lubrication.

A non-reversible constant speed motor may be used if desired, because the reverse is obtained mechanically, by means of the rod shown mounted above the lathe, out of the way,



Thirty-inch Engine Lathe, American Tool Works Company.

yet convenient to the operator. The good feature of this construction is that the motor is at no time reversed, but runs at continuous constant speed, all starting, stopping and reversing of the machine being accomplished without interference with the motor.

The motor is substantially mounted above the all-gear headstock, and the lathe may be at any time converted into a belt-driven machine by replacing the motor by a single pulley mounted on the upper shaft.

SPECIAL HIGH-SPEED LATHE.

The lathe shown in the cut, Fig. 1, has recently been designed by P. Blaisdell & Co., Worcester, Mass., to meet the demand for a powerful tool, with a wide range of geared speeds, created by the increasing use of high speed steels. With two ratios of back gearing, 3½ and 12 to 1, and the three-speed countershaft, 27 spindle speeds are obtainable, 18 of which are geared. There are 90 positive feeds ranging from 8 to 288. The feed mechanism is shown, in detail, in Fig. 2. The change of feed is effected by the lateral movement of a rod which slides in the hollow shaft that carries the lower cone of gears. This rod, which is actuated by the lever at the right-hand side of the feed box, is fitted with a spring feather-key, which is hinged at one end of the slot milled to receive it. The projection on the free end of this key has a bevel on either side of it, so that when being shifted from one gear to another, it is depressed flush with the shaft and snaps into the keyway in the gear as soon as that matches with it. This is a novel form of feather-key and gives a simple and strong construction, free from the jolt and wear that are so objectionable in the usual form of sliding feather-key. The feeds are reversed from the carriage by means of the lever at the right of the apron in Fig. 1. This motion imparted by this lever to the lower one of the two shafts on the front of the lathe, is transmitted, through the arm on the opposite end of this shaft, to the reversing gear, which is contained within the headstock. The carriage is fitted with a graduated, compound rest, and the power cross and angular feeds have graduated adjustment.

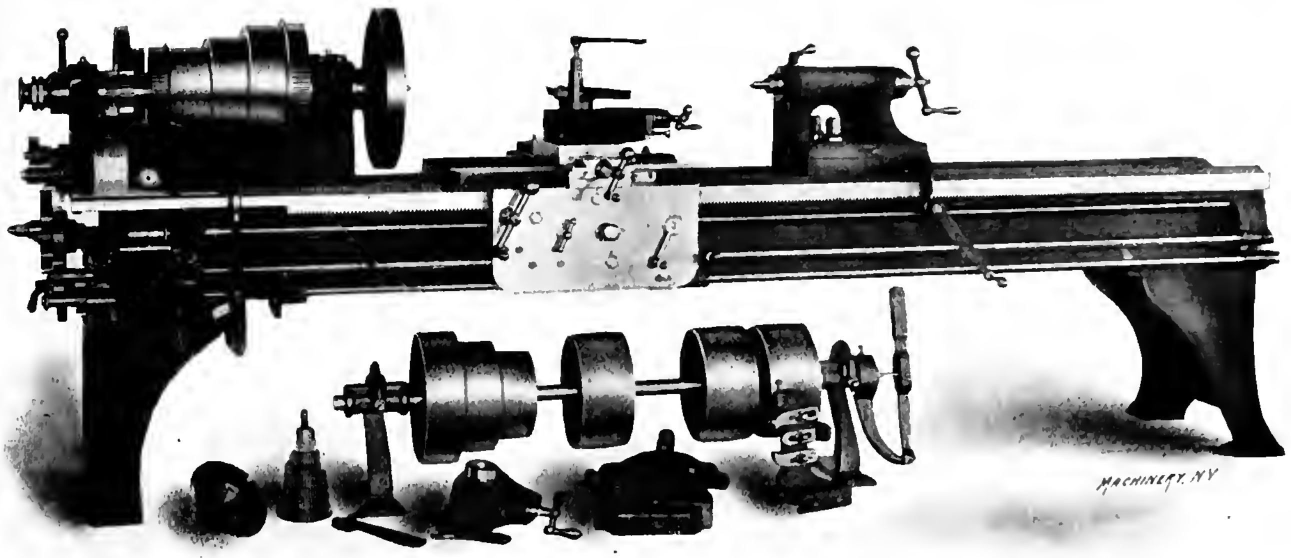


Fig. 1. High-speed Blaisdell Lathe.

The lathe shown in the half-tone swings 22 inches clear of the shears. The front spindle bearing is 3½ inches in diameter by 5½ inches long, and the hole through the spindle

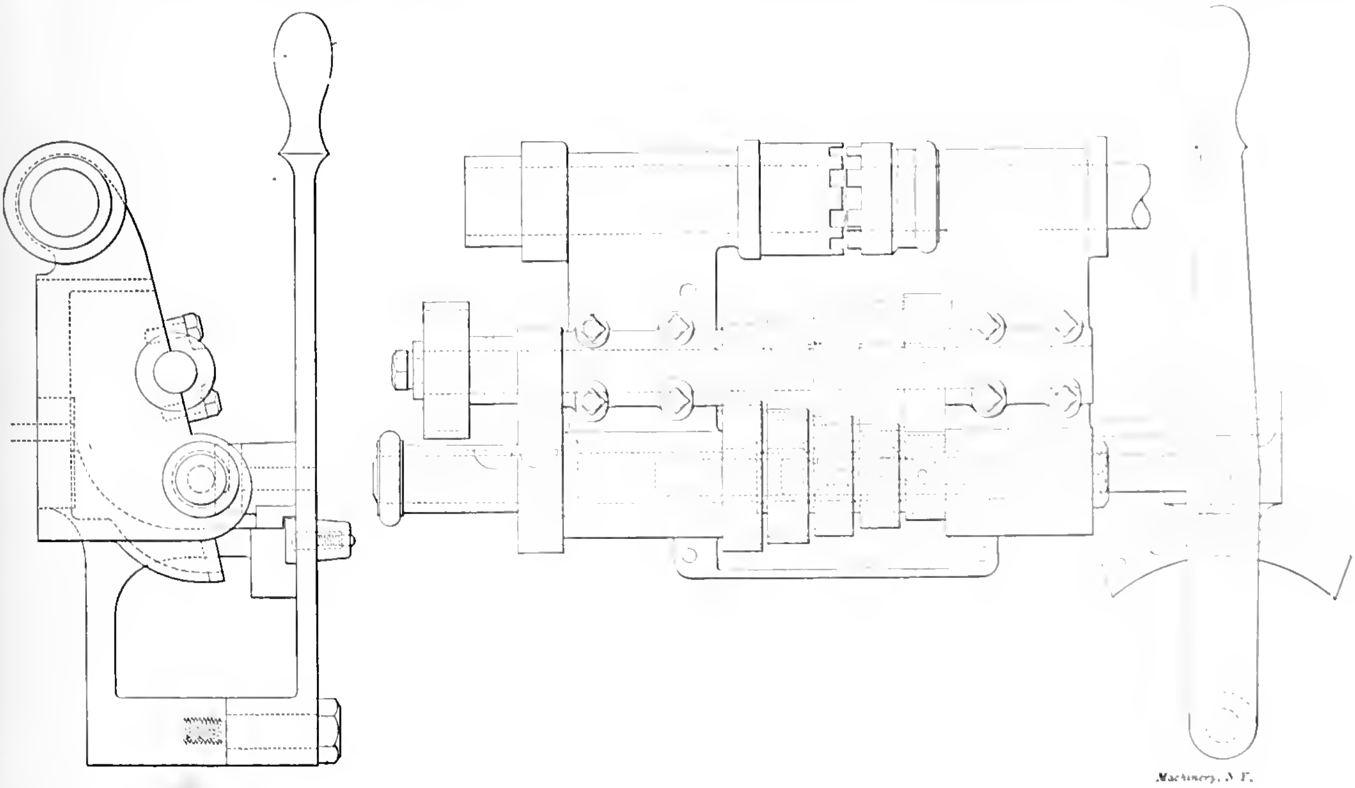

Fig. 2. Details of Feed Mechanism.

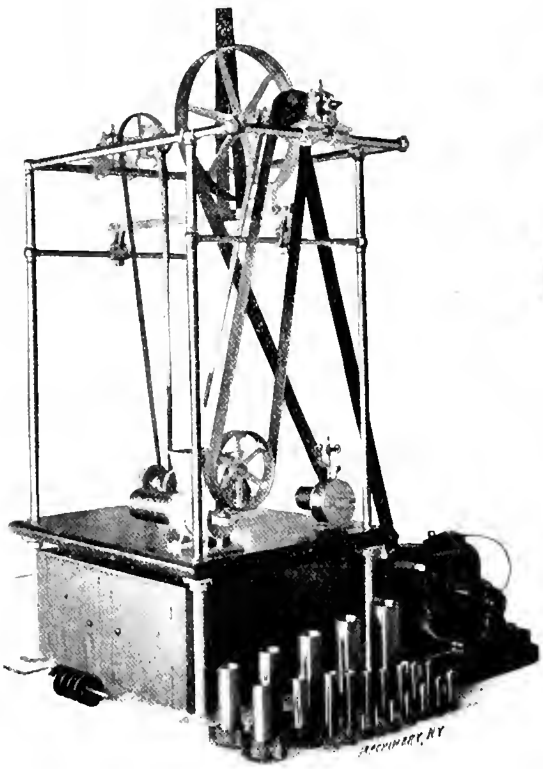
1 7-16 inches in diameter. The cone steps are: 9¼ inches; 11⅝ inches and 14 inches by 3⅞ inches face. The tail-stock spindle has a diameter of 2⅜ inches. A pulley-turning attachment is furnished, if desired, and it is claimed for this machine that it will turn out 100 pulleys, 12 x 5 inches, in 10 hours. In manufacturing shops, particularly, where heavy cuts and cross feeds are the rule, the lathe will be favorably received.

CORE-MAKING MACHINE.

A machine for making cores, the invention of Mr. G. H. Wadsworth, and now being built for the market by the Falls Rivet and Machine Co., Cuyahoga Falls, O., is shown in the accompanying illustration. The vital principal of this machine is new only as applied to the making of cores, being simply the screw, or helical conveyor, such as is used in the sausage mill and in some brick machines. Mr. Wadsworth's machine, however, has many features to recommend it to foundrymen. It will make properly vented cores, of uniform density in round, square, hexagon, oblong, T-shaped, or in fact, in any shape for which the proper dies are made. The cores produced by this machine are very smooth and do not require blackening or slicking, and as they can be made in long lengths, there is a saving in oven room. The range of work produced by the machine embraces 24 sizes of perfectly round cores, ranging from ⅜ inches to 6 inches in diameter, and almost any length desired; 6 inch cores having been made 10 feet 6 inches long. The venting is done by a stationary rod, which passes through a hole in the center of the shaft which carries the screw. Contrary to expectation the wear on this venting rod and on the disks is so slight as to be hardly noticeable. The cores are coned at the ends by being held against an emery wheel at the proper angle, in a device similar to that used in the twist drill grinder.



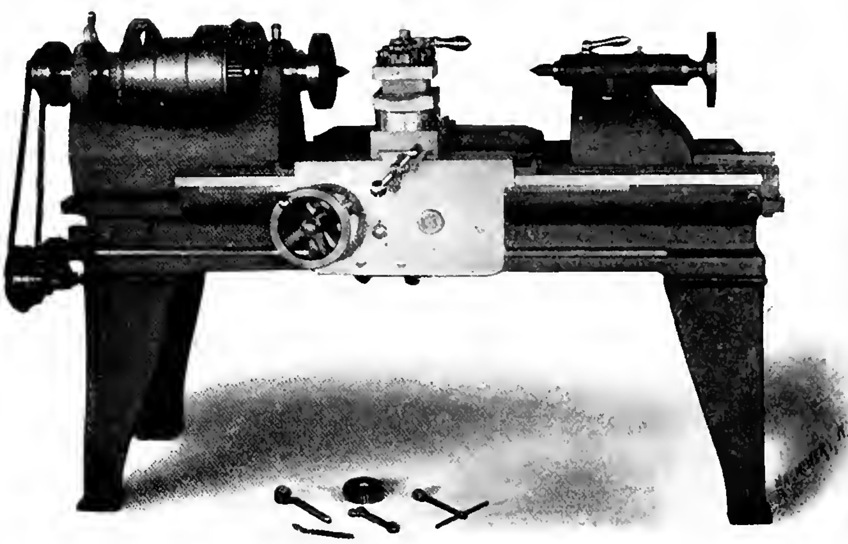
Wadeworth Core-making Machine.

We are informed that upon a basis of an expenditure of 10 cents for wages and a production of from 200 to 600 feet of core per hour, the Wadsworth machine will make from 20 to 60 feet of finished core for one cent.

ACCURATE TAPER TURNING LATHE.

A lathe for turning positive tapers on work of different lengths, without resetting, has recently been put on the market by Fay & Scott, Dexter, Me. The head and tail-stocks of this lathe are fitted to a swivel plate, which is contained within and is independent of the sheaves upon which the tool carriage travels. As the lathe centers always remain in line, and the tool carriage travels perfectly free, without the interference of the usual taper attachment, the work turned out by this machine is very accurate. A point which will, no doubt, make the tool popular with the men in the shop is the absence of back lash in the slide rest, and the consequent trouble in adjusting the tool to turn the size desired, as is the case when lathes are fitted with the usual taper attachment. The carriage is fitted with an automatic stop motion for throwing out the feed, allowing the carriage to be run back without loosening any friction device. This lathe is well adapted to toolroom use, where accuracy in turning taper reamers and taps is essential.

The accompanying illustration is from a photograph of an 18-inch lathe of this pattern. The swivel plate projects beyond the shears at the tail of the lathe. The principal specifications are: Ratio of back gearing, 11 to 1; swing over bed, 18½ inches; swing over carriage, 12 inches: cone diameter, 5 to 10 inches; width of steps on cone 3⅞ inches; hole through spindle, 1⅜ inches; front bearing of spindle, 2 11-16 inches diameter by 5 1-16 inches long; diameter of tail stock spindle, 1⅞ inches, and with a 6-foot bed it will take 30 inches between the centers. The spindles are chucked for Morse taper No. 4.

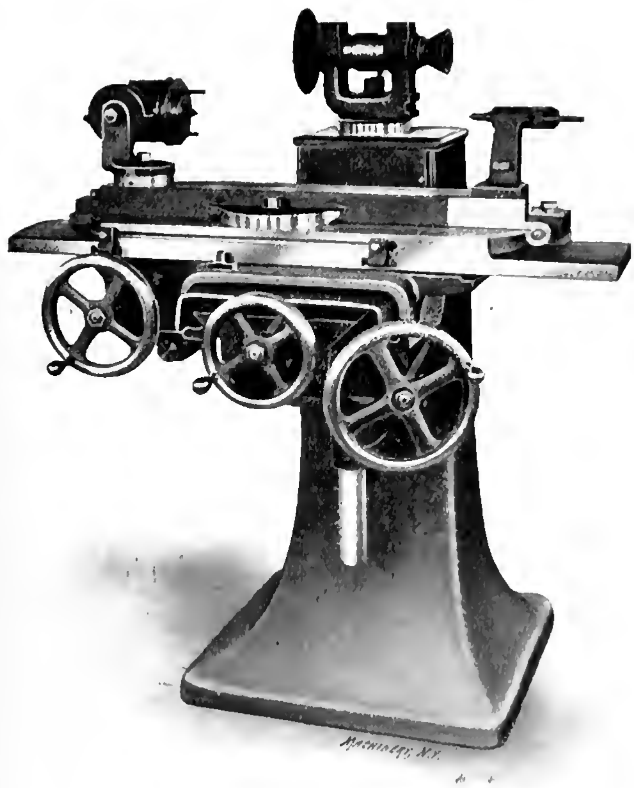


Fay & Scott Taper-turning Lathe.

UNIVERSAL CUTTER GRINDER.

The half-tone herewith shows a newly-designed universal cutter and tool grinder which will grind all work within its range to a great degree of accuracy. Taking the fact into consideration that a grinder must be absolutely rigid and free from vibration if it is to do accurate work, special attention was given in designing this machine to attain this end. The column, as well as knee, saddle, slide and table, are of box form with internal braces. The wheel spindle frame can be swiveled 180 degrees; the base is graduated and locked in any position, it is dust-proof and can be adjusted to compensate for wear. All the bearings, slides and screws are covered. The adjusting hand wheels are of large size and are graduated on the outside, reading to a thousandth. The table is swiveled on a central stud and clamped in any position, has graduated arc in front, reading to degrees, and there is a scale on the slide which reads to 3-inch taper per foot either way. One end of the table is formed to a wormwheel, into which engages a worm by means of which the table can be readily adjusted either way to the desired taper.

For all operations there is but one tooth rest used; it has a micrometer adjustment and can be set in any position. The dimensions of the machine are: Table movement, longitudinal, 15 inches; cross movement, 8 inches; vertical movement, 7 inches; swings between centers, 9 inches, with raising blocks 12 inches by 20 inches long; grinds 16-inch face mills, 36-inch saws. Many operations can be done on this grinder for which other grinders require special attachments such as grinding gear cutters, face of teeth in taps, formed cutters, hobs, etc.



Oesterlein Cutter Grinder.

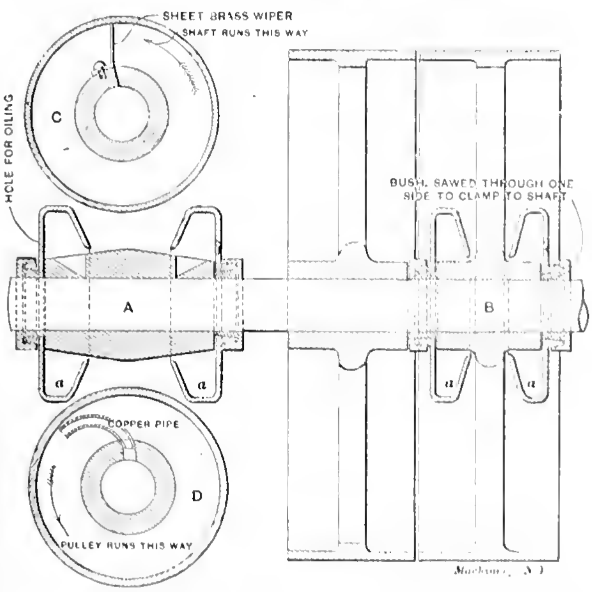
With this machine is furnished a 3-inch chuck, swivel vise, main and drum countershaft and a set of grinding wheels.

It is being built by the Oesterlein Machine Co., Cincinnati, O.

THE ALLMOND OIL CUP.

A type of oil cup is illustrated herewith which has been applied successfully to the loose pulleys of countershafts and the main bearings of countershafts, line shafts, etc. It is manufactured by Charles H. Allmond, 804 First avenue, So., Seattle, Wash.

At *A* in the illustration is shown the oil cup as applied to a stationary bearing, and at *B* as applied to a loose pulley. In both cases the cups which retain the oil are secured to the shaft by a clamp bushing, the construction of which will be

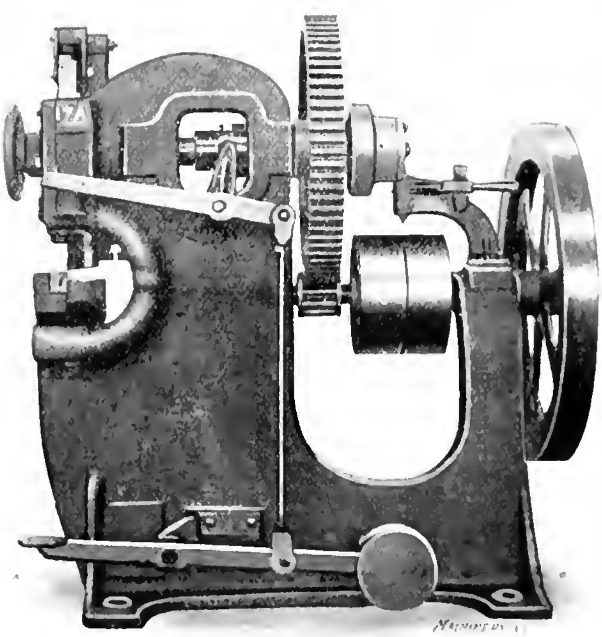


Allmond Oil Cup.

evident from the sketch. The part of the bushing that fits the shaft is split, and, by screwing the two threaded portions together, the outer part of the cup is drawn over the inner taper bushing which securely clamps the latter to the shaft. When the shaft is stationary the oil simply remains in the lower part of the cup at *a a*. When the shaft rotates, the oil is thrown out by centrifugal force to the outer periphery of the cup where it would remain except that it is impeded in its motion by a suitable wiper which carries it back to the bearing. The kind of wiper that is used depends upon whether the cup is applied to a stationary bearing or to a loose pulley. In the former case the construction shown at *C* is used. Here the oil, as it revolves with the cup, is caught by the piece of sheet brass and caused to flow inward to the bearing. At *B* and *D* are shown the construction for the loose pulley. When the loose pulley is running the cup is stationary and the oil remains at the bottom. A bent copper pipe inserted in the hub of the loose pulley, however, scoops part of the oil at each rotation of the pulley and carries it to the shaft. Mr. Allmond writes that the countershaft illustrated in the sketch is one applied to woodworking machinery, and that it has run 16 days with one oiling and that there is no drip or spatter of the oil. He has also applied the cups to the top wheel and loose pulleys of band saws. Another instance is on a line shaft running 550 revolutions. With cast iron boxes it was found that the shaft runs without heating. Mr. Allmond has a shop fitted throughout with the oil cups, which, he writes, require attention but once a week and give entire satisfaction.

NEW T-IRON NOTCHING TOOL.

The accompanying cut illustrates a tool which will prove of interest to any one requiring T or angle iron with leg notched or cut away flush with the remaining leg. The knives are so arranged that the leg can be cut away either at the end or at any point in length of the bar, and length of cut can be varied

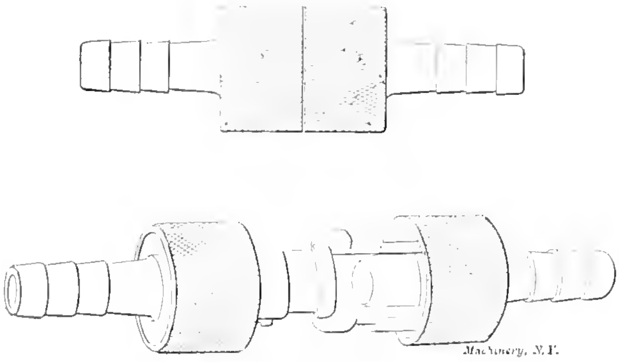


to suit requirements. The side knives are so arranged that either a straight or angular cut can be made on the leg being notched.

For work of this kind the makers claim it to be a very efficient and labor-saving tool. This machine was recently built by the New Doty Mfg. Co., Janesville, Wis.

AIR HOSE COUPLING.

A simple, strong and quick-acting hose coupling, for use in connection with pneumatic tools, known as the "Giv't-a-twist" air hose coupling has recently been placed on the market by the Ingersoll-Sergeant Drill Co., 26 Cortlandt Street, New York. As will be seen from the sketch, no wrench or spanner is required to either couple or uncouple the parts. To make a coupling it is only necessary to push the halves together by hand and slightly twist the locking rings in opposite directions. To uncouple, the operation is reversed. Both halves of the coupling being identically the same, the usual necessity of mating the ends is obviated. There are no projections to catch or break off by the hose being dragged from place to place. The rubber sleeve is entirely encased when the coupling is made, and will withstand any working pressure without leakage. The parts are made of brass, extra heavy, to stand rough usage, and are machined throughout.

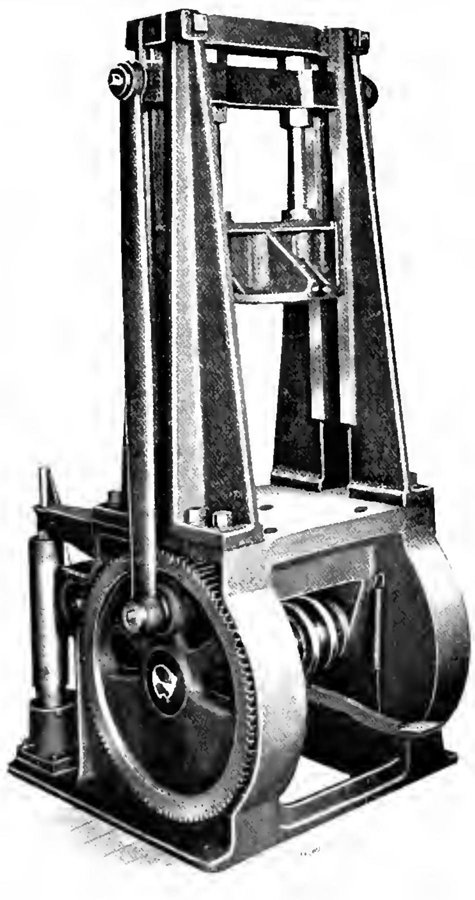


The Giv't-a-Twist Air Hose Coupling

This coupling is manufactured in all standard sizes for connection: Hose to hose, hose to pipe, or pipe to pipe with male and female shanks.

NEW WIRING PRESS.

The illustration herewith is of a wiring press recently completed by the E. W. Bliss Co., Brooklyn, N. Y. It was designed to obviate the slow and laborious handling of large and heavy dies. The stroke of slide is sufficiently long to raise the punch high enough to permit of insertion in the die of the article to be wired, or its removal, without disturbing the die. A good



Wiring Press, E. W Bliss Company.

operator can catch every stroke of the press. The slide plate generally used on a wiring press for moving the die back and forth to insert or remove the article to be wired is not used on this press; the long stroke makes it unnecessary to handle the die. This saves much time and labor and increases considerably the output of the machine.

The press is provided with a powerful friction clutch and the slide is counterweighted. The principal dimensions are: Weight, 3,600 pounds; it will wire up to (diameter and depth) 15 x 12 inches; distance from bed to slide, stroke down and adjustment up, 16 inches; distance between gibs, 20 inches.

FRESH FROM THE PRESS.

ANNUAL OFFICIAL DIRECTORY OF THE TEXTILE INDUSTRIES AND THE YARN TRADE. 1904 Edition. Published by the Lord & Nagle Co., 299 Devonshire St., Boston, Mass. Bound in cloth. Standard size, 6x9. 528 pages. Price Travelers' edition, $2.00; office edition, larger size, $2.50.

This work is divided into five parts, as follows: Part I., Textile Manufacturers; Part II., the Yarn Trade Index; Part III., Classified Lists of Commission and Order Mills, Dyeing Establishments; Part IV., Dealers in Raw Materials and Stock; Part V., Agents and Buyers of Textile Fabrics. Very full information is given on the subjects included under these various headings, and about 20 textile maps, showing the location of cities and towns where there are textile industries are to be found. The work has been thoroughly revised and brought up to date.

DIRECTORY TO THE IRON AND STEEL WORKS OF THE UNITED STATES. Sixteenth edition, 1904. Published by the Iron and Steel Association, 261 South Fourth street, Philadelphia, Pa. Bound in cloth. 468 pages. Corrected to August 1, 1904. Price, $10.00.

This book, which is compiled and published by the above named company, embraces a full description of the blast furnaces, rolling mills, steel works, tin plate and terne plate works, and forges and bloomaries in the United States. Also classified lists of the wire rod mills, the structural mills, plate sheet and skelp mills, black plate mills, rail mills, steel casting works, Bessemer steel works, openhearth steel works and crucible steel works. This has been thoroughly revised and brought up to date and the publishers call attention in the preface to the fact that inquiries submitted to manufacturers were even more searching and more comprehensive than for previous editions, so that the information on the above-mentioned subjects is complete and reliable. A very full table of contents and complete index are also to be found in this edition.

FORGE PRACTICE. By John L. Bacon, Instructor of Forge Work, Lewis Institute, Chicago, Ill. 257 pages, 4¾x7¼ inches, and 272 cuts. Published by John Wiley & Sons, New York. Price $1.50.

Although this work is dubbed an elementary one by the author, being the outgrowth of a series of notes given to the students of Lewis Institute on forge work, it is eminently practical and contains much that should be helpful to the working smith. The text is free from padding and is right to the point, being expressed in language remarkably clear and easy to comprehend. Following a general description of the forge and tools is a chapter on welding, and then in order are chapters on calculation of stock for bent shapes; upsetting, drawing out and bending; simple forged work; calculation of stock, and making general forgings; steam hammer work; duplicate work, metallurgy of iron and steel; tool steel work; tool forging and tempering, etc. The sketches are well drawn, many of them being in perspective which is best for illustrating work of this character. The book is one that should be popular in trade schools and similar institutions giving instructions in practical forge work.

BEVEL GEAR TABLES, by D. Ag. Engstrom. 66 pages, 5½x7¼ inches with eight cuts. Published by the Derry-Collard Co., 256 Broadway, New York. Price, $1.00.

This little book is not a treatise on bevel gears, but is intended to help the practical man who has little knowledge of trigonometry, or who is too busy to resort to the calculations involved. In the preliminary explanation of the terms and use of the tables a very clear conception of the elements of bevel gears is conveyed to the reader. The tables are successively calculated for gears of 12 to 47 teeth, inclusive, mating with gears of 12 to 47 teeth, inclusive, thus making thirty-six tables in all. These tables give without calculation the outside diameter, placing distance, outside cone radius, face angle, edge angle, cutting angle and number of cutter, all for a diametral pitch of 1. Other diametral pitches are simply obtained by dividing the given distances by the required pitch, the angles, of course, remaining the same. For circular pitch, the values in the tables are multiplied by the "diameter" pitch which is the reciprocal of diametral pitch, and a table of diameter pitches is given for circular pitches from 1 1-16 to 3 inches, inclusive.

AIR BRAKE TESTS, compiled by the Westinghouse Air Brake Company. 323 pages, 4½ x 7 inches, and 130 cuts. Bound in limp leather. Published by the Company at Wilmerding, Pa.

This book is a compilation of the principal tests of air brakes that have been made in this country and abroad to determine the factors that affect braking efficiency. The opening chapter is a brief resume of the history of braking, leading up to the introduction of the "Straight-air" brake by Mr. George Westinghouse in 1869, which was the forerunner of the automatic air brake now in general use on railway trains throughout the world. Then follow the three papers read by Capt. Douglas Galton before the Institution of Mechanical Engineers, describing the now historic Galton-Westinghouse air brake trials made in England in 1878-79, on the London, Brighton and South Coast Railway, and the North Eastern Railway. The Paris and Orleans Railway tests were made in 1879, and following the description of these is that of the Burlington brake trials in 1886-87, which are treated at length, 116 pages being given over to these famous tests. Then follow the Westinghouse freight train tests, made in 1887; the Karner tests on the New York Central, in 1892; the Sang Hollow tests on the Pennsylvania Railroad, in 1900; the Shiproad tests on the same railway in 1894; the Nashville locomotive tests; the Absecon tests; and the Atsion tests. The book is one that will interest the advanced air brake man and the mechanical engineer.

MACHINE DESIGN, by Charles Lewis Griffin, S.B. Published by the author, Syracuse, N. Y. 183 8-vo pages. Illustrated. Price $1.50.

Mr. Griffin is experienced as an instructor in machine design, but has recently again taken up engineering work along commercial lines. The matter in this book is the result of his experience both in designing machinery and in teaching. It comprises matter that he has proposed to publish for the benefit of his students, but which he has not had an opportunity to publish until recently. It is practically the same as was prepared by him for the use of the American School of Correspondence, Chicago, and which we have already referred to in these columus.

The book is along strictly original lines and its distinguishing characteristic is that it teaches the method of designing rather than giving a great quantity of data and leaving the student in the dark as to the method of applying the data. It takes up, in the first place, the design of a simple but complete machine and shows how the draftsman would go to work to gather his data, make preliminary calculations, lay out the work on the sheet, and finally detail the work to the draftsman under him for making the finished drawings. This whole process is worked out clearly by means of freehand and finished sketches, calculations as they would be made by the draftsman in his notebook, etc. In the second part of the volume the elements of machine design are treated, such as belts, pulleys, shafts, gears, friction clutches, bolts, keys, etc. If a student wishes to really learn how to design machinery, by home study, or if an instructor wishes to lead his students along correct paths in machine design, we think that either will find this treatise unusually well adapted for the purpose.

AMERICAN SMALL ARMS, by Edward S. Farrow, late Instructor of Tactics at the United States Military Academy, West Point, etc. 408 pages, 7x10¼ inches, and 500 cuts. Bound in green cloth with gilt top. Published by the Bradford Company, New York. Price, $5.00.

Mr. Farrow was led to the compilation of this interesting work by noting the great variety of American small arms found in the possession of a tribe of Indians which he captured some twenty-five years ago while in the U. S. Army service; and the fact that there is, or was, an almost complete absence of writings on the subject. This

MACHINERY.

November, 1904.

A REVIEW OF STEAM TURBINE PATENTS.—2.

Hoehl, Brakell & Gunther, 1863.

The turbine produced by this aggregation of inventors has as its only novelty an arrangement of passages by which the steam returns on itself and so is utilized twice by the same wheel, although an additional set of wheel blades is required.

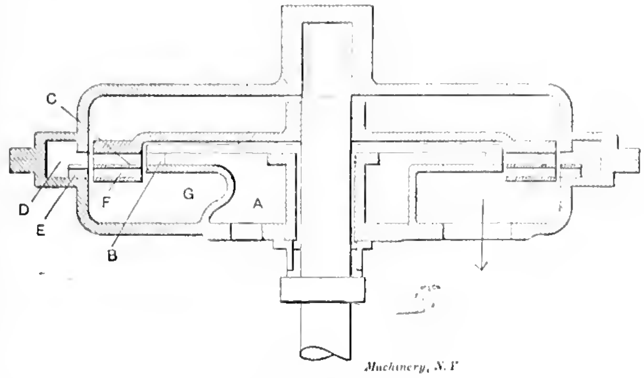

Fig. 19. Hoehl, Brakell & Gunther.

Steam enters the chamber *A*, passes radially outward through the guide passages *B* to the wheel blades *C*, then discharges into the annular chamber *D*, where its motion is reversed, and escapes through *E* to another set of buckets *F*, and finally to the exhaust chamber *G*.

Perrigault & Farcot.

The type of turbine here exemplified is in principle like Wilson's turbine, in Fig. 13 of the September number, the latest representative of which is found in the compound turbine of Messrs. Riedler and Stumpf, to which reference will be made later. The inventions of Perrigault & Farcot took several forms, but the general principle is well illustrated by Fig. 20 herewith. Here steam enters through the pipe or nozzle *A* and impinges against the wheel buckets, passing through the other side of the wheel where it discharges into pipe *B*. This pipe brings the steam around

Fig. 20. Compound Turbine with only one Wheel

again to the inlet side of the wheel, allowing it to discharge a second time against the buckets of the same wheel, when it is again picked up by a second pipe *C* and so on. The exhaust is finally through pipe *D*.

The arrangement consists essentially in a bundle of bent pipes having openings *a*, *b*, *c*, through which the steam impinges against the wheel buckets; and openings on the other side, *x*, *y*., etc., which gather up the steam flowing from the wheel and bring it round again to the inlet side. The object is to utilize the steam over and over without necessitating a series of rotating wheels. It is a system that has been tried with various modifications, but without much success. Its obvious disadvantages are: Large losses from friction and leakage, and the wide range of temperatures through which the same buckets must pass, thus causing condensation and re-evaporation as in the steam engine.

Hannsen, 1870.

Among the most successful types of turbine is that having a succession of chambers in each of which is a single impulse wheel. There is only a slight drop in pressure from chamber to chamber, so that the velocity of the steam does not become excessively high at any point. The latest turbine of this description is the Hamilton-Holzwarth, built by the Hoovens,

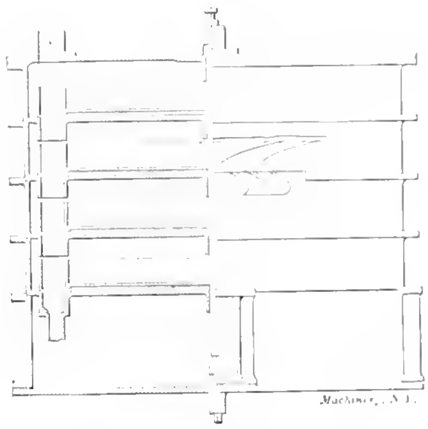

Fig. 21 Compound Impulse Turbine.

Owens, Rentschler Co., Hamilton, O., and the earliest one of which there is any record is the invention of Real & Pichon, 1827—the first patent referred to in this series. The invention of Hannsen, shown in Fig. 21, is almost precisely the same, except in regard to structural features. This is a vertical turbine, steam entering at the bottom and rising to the top.

Moorhouse, 1877.

Of far greater importance, however, is the patent of James Moorhouse for a turbine on the same plan. As shown in Fig. 22 *a*, *a*, *a*, etc., are the nozzles, and *b*, *b*, *b*, etc., the wheel buckets. Steam flows radially outward at each wheel until near the exhaust end, where there is a different arrangement owing to a smaller drop in pressure between the successive chambers.

Moorhouse realized what previous inventors of this type of

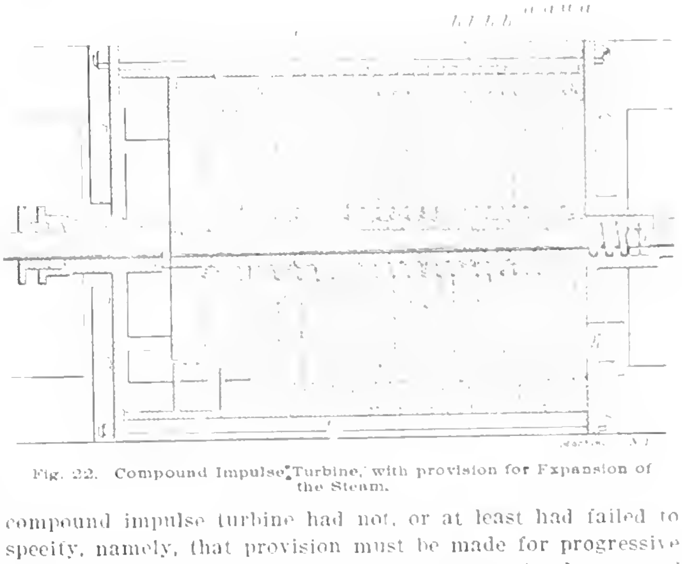

Fig. 22. Compound Impulse Turbine, with provision for Expansion of the Steam.

compound impulse turbine had not, or at least had failed to specify, namely, that provision must be made for progressive expansion of the steam by a gradual increase in the area of the steam passages. His patent is a broad one and fully covers this requirement as a general principle, apart from the

exact method used in its application. In his specifications he says that his invention consists of a cylinder built in sections, each section composing a separate compartment. Through the center of the cylinder passes a revolving driving shaft upon which is fitted a series of turbine wheels, each having, at or near its circumference, a sufficient number of buckets. These wheels are as many in number as the compartments into which the cylinder is divided. Each compartment contains a turbine wheel, and is separated from the adjoining compartment by means of a dividing plate or diaphragm. The foregoing is condensed from his specifications but correctly represents their meaning. He then goes on to say:

"Openings are made in the dividing plates which separate each compartment from the adjoining ones, and the area of these openings is proportioned to the pressure of the steam or other driving fluid, and to the number of compartments and turbine wheels, and to the extent to which it is desired that the driving fluid should be expanded before being finally discharged from the engine. By this means the driving fluid, admitted at its highest pressure into the smallest compartment, passes into the second compartment through openings of such area that it expands to a calculated extent. The same process is repeated, etc."

He says that various forms of turbine may be used, and his first claim is as follows:

"In combination with a rotary engine, the dividing plates between the compartments provided with openings forming communications respectively of varying area between said compartments, the turbine wheels in such compartments, and a driving shaft, substantially as and for the purpose set forth."

Cutler, 1879.

This is a radial outward flow turbine in which the compound principle is used. Steam enters at the bottom, passes to the center and then flows radially outward through the passages between the guides *c c c* and the wheel vanes *d d d*. The rotating wheel *A* has vanes attached to each of its two

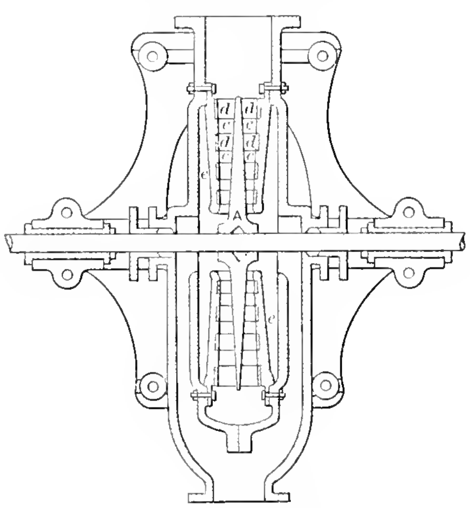

Fig. 23 Radial Outward-flow Turbine.

faces so the pressure is balanced on each side. Expansion of the steam is allowed for in part by the increasing width of the passages and in part by the fact that the steam is constantly flowing from a smaller to a larger diameter of wheel, so that the circumferential area of the passages constantly increases from this cause as well.

Imray, 1881.

This is another attempt to apply the compound principle to a single wheel, having a single set of vanes, but differs somewhat from the turbines of Wilson and Perrigault and Farcot. Steam enters at *A*, passes through the nozzle and impinges against the buckets *C C C*. These buckets are semicircular in shape, as indicated in the sectional view in the upper left-hand corner of the illustration. The steam enters at one side of the bucket, follows the curved surface of the bucket, and discharges into the opposite side of a semi-circular stationary bucket or guide *D*. Here the direction of flow of the steam is again reversed. The steam, as before, flows around the stationary guide surface and discharges against one of the buckets *C*, whence it is carried along to the second stationary bucket, and so on, alternately entering the successive wheel buckets *C C C* and the successive stationary buckets *D D D*. It finally discharges on the opposite side of the turbine casing, at *E*. In the meantime steam enters at *A* on the

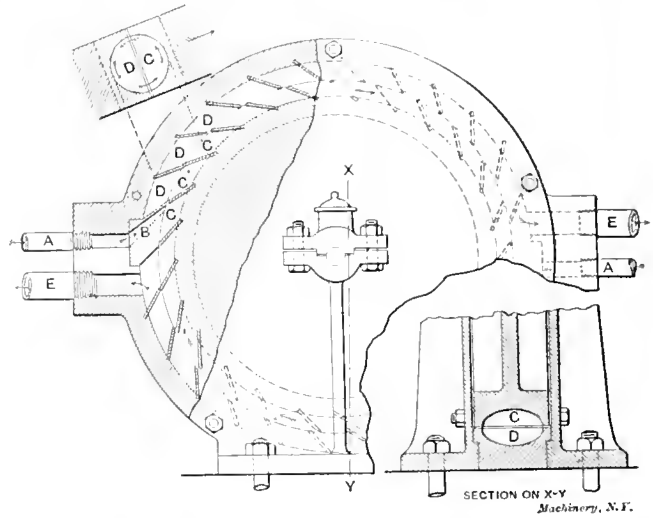

Fig 24. Another Compound Turbine with only one Wheel.

right-hand side of the casing and zigzags through the lower half of the wheel in a similar manner, exhausting at *E* on the left-hand side.

De Laval, 1883.

The first patent of this noted inventor was for a reaction turbine and was taken out in 1883, in several countries. As it was illustrated in the De Laval article in the last number the cut is not reproduced herewith. According to the specifications, steam (or other fluid) enters the wheel at the center through a nozzle, and passes outward through hollow curved arms, escaping at their ends, and causing the wheel to rotate at high velocity. The wheel shaft drives another shaft at a slower speed, by means of friction wheels, the requisite pressure between the friction surfaces being obtained by the axial thrust of the turbine wheel. The principle of this turbine is no different from that of the first American patent by Avery in 1831, but its application to centrifugal cream separators, for the extensive development of which Dr. De Laval has been responsible, was successful and marks the beginning of an important career by this inventor in the manufacture of steam turbines.

Babbitt, 1884.

B. T. Babbitt, besides acquiring fame as a manufacturer of laundry soap, was both an inventor and a mechanic, and one of his inventions related to a steam turbine of the type shown in Fig. 25. This is an inward-flow turbine with two wheels,

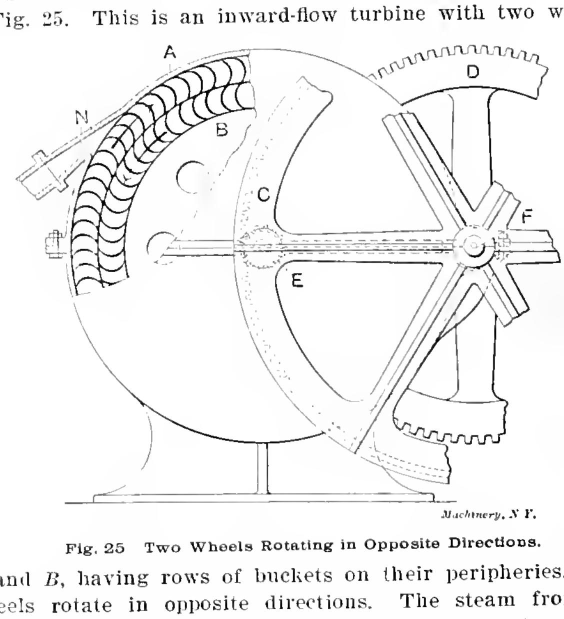

Fig. 25 Two Wheels Rotating in Opposite Directions.

A and *B*, having rows of buckets on their peripheries. The wheels rotate in opposite directions. The steam from the nozzle *N* impinges against the buckets of the outer wheel, which it is supposed to leave with a considerable residual

velocity, and gives up its remaining energy to the buckets of the inner wheel. The chief novelty of the invention is the method of transmitting power from these two wheels to the slow speed shaft F. The turbine wheels are mounted concentrically on two separate shafts, one end of which is shown at E. There is a pinion on the outer end of each of the shafts. One of these pinions gears with the internal gear C on one end of the slow speed shaft F, and the other pinion gears with the spur wheel D on the other end of shaft F.

Isaac Last, 1885.

This is another example where the steam is caused to return upon itself, first flowing radially outward then reversing and flowing radially inward, just as in the Hoehl, Brakell & Gunther turbine, Fig. 19. In the Cutler turbine, however, compounding is carried further than in the former, there being a series of wheels placed side by side on the same shaft. In the sketch, $A\ B\ C$ are the different chambers in which the wheels rotate; $a\ a$ are the guides for directing the steam against the wheel buckets and $b\ b$ are the wheel buckets. One drawing in the patent specifications of Last has a very modern appearance, in that he shows a compound turbine built up of two parts, the high pressure and the low pressure, in each of which is a series of compound wheels like that shown in Fig. 26. The high-pressure and low-pressure sections are connected by a pipe, and their arrangement resembles that of some of the turbines built to-day.

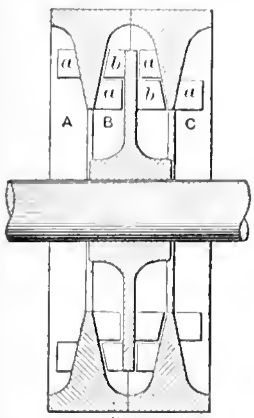

Fig. 26. Combined Inward and Outward Flow.

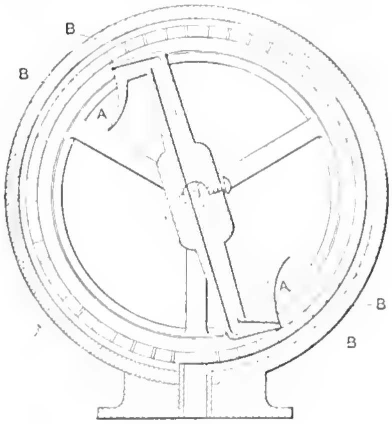

Fig. 29. Denke's Modification of the Reaction Wheel.

Parsons, 1885.

With a patent issued in several countries in this year, the Hon. C. A. Parsons, who was the first to place the turbine on a commercial basis, enters the field. In all his work he has adhered to the reaction turbine and is responsible for the successful development of the compound reaction motor. In Fig. 27 is a section of one of his patent drawings. Steam enters at the center A, and passes right and left between the series of guide vanes attached to the outer casing and the rotating blades attached to the inner drum, which rotates on shaft $B\ B$. Steam escapes to the exhaust passages $E\ E$ and finally to the exhaust pipe shown by dotted lines. The following paragraphs are extracts from his description:

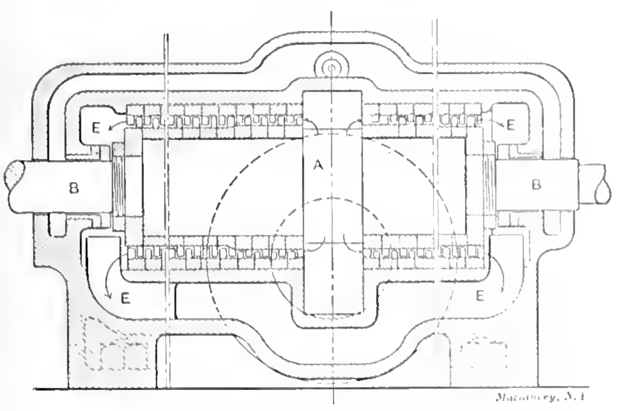

Fig 27. Parsons' First Turbine

"I arrange the portions of the motor to form an approximately cylindrical figure, the whole being mounted upon the same shaft, the first delivering into the second, the second into the third and so on. Each portion comprises a set of fixed and a set of moving vanes, the direction of motion of the actuating fluid being generally parallel, or approximately so. To balance the end pressure upon the cylinder, I mount two similar sets of rotary parts upon one shaft, one set being so placed at each side of the inlet for the actuating fluid that the entering stream divides right and left, and the exhaust takes place at both ends.

"As the speed of the motor will be necessarily high, and perfect balancing of the moving parts would not be practicable, I give to the bearings a certain very small amount of elasticity or play combined with a frictional resistance to their motion."

This refers to the well-known Parsons construction shown in Fig. 28, in which there is an annular space, between the shell of the bearing and the pocket for the shell bored out in the frame, filled with a series of metal rings. Every other ring is bored to fit the outside of the shell, but its outside diameter is smaller than the bore of the pocket, as in $a\ a$. The alternate rings $b\ b$ are turned to fit the pocket, but are bored larger than the outside of the shell. The rings are forced together by a spring s, so that they offer considerable resistance to any lateral movement of the bearing.

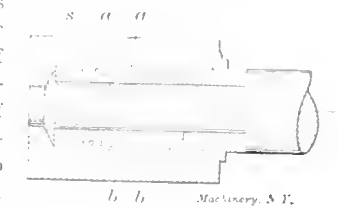

Fig. 28. Bearing of Parsons' Turbine.

He says: "The lubrication is effected by forcing lubricant through pipes to the parts to be lubricated and for this purpose a pump can be employed. To prevent leakage past the shaft at the end covers of the casing, which, when steam is the actuating fluid, would be inconvenient, I form annular recesses in the covers around the shaft ends, and place these recesses in communication with a pipe in which a partial vacuum is maintained by suitable means, such as a steam jet."

In the next year, 1888, Parsons took out a patent in which the turbine wheels are arranged in groups, each successive group being of larger diameter than the preceding one, to allow the steam, as it expands, to flow through larger spaces, as required by the increase in the specific volume of the steam. He also proposes to secure steam-tight joints at the bearings by admitting water under pressure to an annular groove passing around the bearing. He suggests cutting a spiral groove on the shaft, at the section where this annular groove occurs, with the idea that when the shaft is revolving at high speed, the spiral will diminish the quantity of water forced into the turbine casing by the air pressure, when the turbine is running condensing.

A. Denke, 1890.

A simple and interesting though inefficient scheme for taking advantage of the residual velocity of the steam as it leaves the nozzles of a reaction turbine of the Hero type was invented by A. Denke and is shown in Fig. 29. There are two diametrically opposite hollow arms rotating in a casing, on the inner periphery of which is a series of vanes marked $B\ B$. The ends of the arms are bent at right angles, forming nozzles, and the steam which enters at the center flows radially outward and escapes from the nozzles in a tangential direction. The steam impinges against the stationary vanes of the casing and its direction is reversed so that it flows radially inward and strikes the curved horns $A\ A$ attached to the ends of the rotating arms. A simple reaction wheel of this type does not make a practical device because of the high speed at which it must necessarily rotate; but the arrangement shown might possibly be so designed as to somewhat improve the operation of such a wheel.

Altham, 1892.

A compound turbine consisting of two rotating wheels, one inside of and concentric with the other, is the invention of George J. Altham. The buckets of the inner wheel are arranged in its outer periphery and those of the outer wheel in its inner periphery, so that steam will act alternately on the inner and outer wheel, and successively on the different buckets of both wheels, the arrangement being such that the wheels rotate simultaneously in opposite directions. Fig. 30 shows at

the left a cross-section of the rims of the two wheels in which the buckets are cut. The other sketches show longitudinal sections of the rims. Steam is discharged from the nozzle into one row of buckets of the outer wheel, whence it passes to the first row of buckets of the inner wheel, thence to the second row of the outer wheel and finally to the last row of the inner wheel, from which it discharges into the turbine casing. In the smallest sketch, Fig. 30, the construction is indicated where

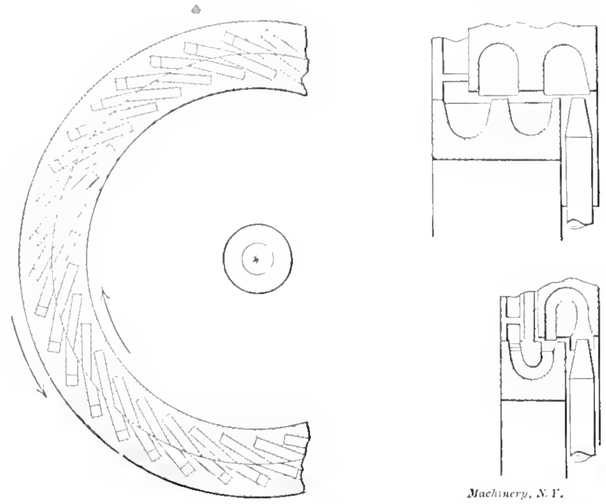

Fig. 30. Compound; two Wheels Rotating in Opposite Directions; no Guide Vanes.

there is only a single row of buckets in each wheel. The course of the steam in this turbine is similar to that in the Imray turbine, 1881, except that in the latter the outer set of buckets is stationary instead of rotary.

Dow, 1893.

When turbines first began to come into prominence in this country the one invented by J. H. Dow was one of the three or four that were most frequently mentioned. His first patent was issued in 1887, and later several others were taken out, but the one showing the most completely worked out design was issued in 1893. All of the Dow turbines are of the radial

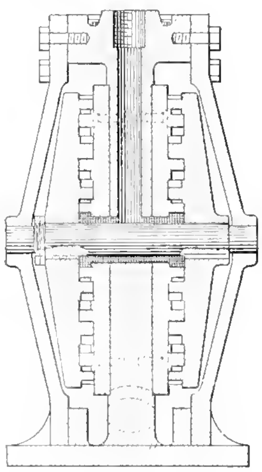

Fig. 31 Section of Origiual Dow Turbine

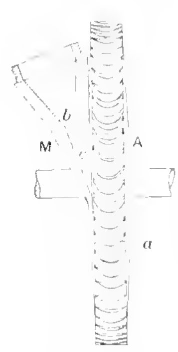

Fig. 34. De Laval Expansion Nozzle.

outward-flow type, consisting of alternating rings of rotating stationary vanes, and in this respect resemble one of Wilson's inventions of 1848. In Fig. 32, taken from his latest patent, *A* is the ring of stationary vanes directing the steam against the ring of rotating blades *B*, and *C* is another ring of stationary vanes, *D* a ring of rotating blades, etc. A peculiarity of his turbines is that the stationary vanes are not curved at their inlet ends in a way to guide the steam into them in the direction in which it leaves the rotating blades, except as the latter might be designed so that steam would leave them in the direction in which the wheel is turning, which would be an inefficient arrangement. In the patent of 1887 there is a single shaft on which are two disks facing each other, having annular rows of vanes cut on their inner faces. Between these two disks is a central stationary disk with annular rows of guide vanes cut on each of its faces. The arrangement is shown in Fig. 31. Steam enters at the center, and flows radially outward between the vanes on each side of the central disk. In his latest patent Dow compounds his turbine still further by providing several rotating and stationary disks ranged along the shaft on each side of the center. Steam enters at the center and gradually works outward toward both ends of the turbine. In his compound turbine he also uses a pair of disks at the center, so designed that they serve as pressure balances and hold the shaft and wheels in an endwise direction.

Parsons, 1893.

In this year Parsons took out a patent on a compound reaction wheel shown in Fig. 33. This is exactly similar in principle to the one already illustrated, invented by Monson in 1862. Later, in 1867, one of the same type was patented by T.

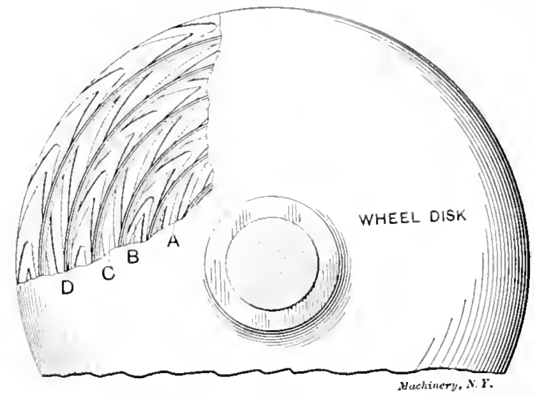

Fig. 32. Dow Turbine.

Banta. This patent of Parsons, therefore, is merely a construction patent and does not cover any principle not previously patented. Steam enters in the steam chest, at the left, passes through the hollow shaft to the first pair of arms, where it flows radially outward, then escapes, through openings at their extremities, into the first chamber. It then passes through a sleeve encompassing the shaft to the second pair of arms, and so on to the end of the turbine. The chief difference between Parsons' and Monson's is the shape of the arms, which Monson made curved and Parsons straight, and the arrangement of the steam channels through which steam passes from one chamber to the next. At one time or another Parsons has patented most of the feasible arrangements for a compound turbine. In 1890 he secured a patent similar in principle to the one issued to Moorhouse in 1877 except that he arranged to have the steam flow radially inward at each wheel and used the reaction principle. In 1891 he secured a patent for a reaction turbine consisting of a series of disks upon the same shaft

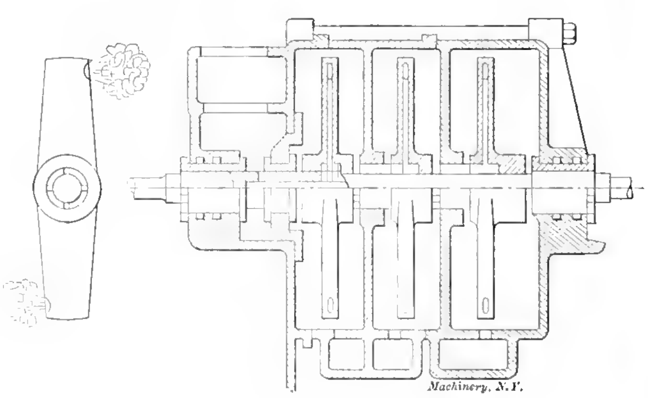

Fig. 33. Parsons Compound Reaction Turbine.

on the faces of which were several rings of blades. The steam flowed radially outward between these vanes instead of passing longitudinally through the turbine, as in the case of his earlier patent.

De Laval, 1894.

De Laval's most important patent relates to his expanding nozzle, in combination with a turbine wheel. It is interesting to note in this connection that the expanding nozzle was patented in this country in 1867, patent 64,539, for steam injectors. De Laval, however, was the first to apply the prin-

ciple of a diverging nozzle for the expansion of steam to a turbine. The two broadest claims of the patent are the following:

1. The combination with a bucket or turbine wheel, of a stationary nozzle opening adjacent to the wheel and having its bore diverging or increasing in area of cross section toward its discharge end, whereby the elastic fluid under pressure is expanded in passing through the diverging nozzle and its pressure is converted into velocity before the jet is delivered against the wheel.

2. The combination with a bucket or turbine wheel, of a stationary nozzle opening adjacent to the wheel and provided with a contracted receiving portion and with a discharge portion having its bore diverging or increasing in area or cross section toward its discharge end.

Maison Breguet, 1894.

Judging from the illustration accompanying this patent, it introduces no new principle that was not included in the invention of Hartman's compound impulse turbine, the patent for which was taken out in 1858. That is to say, the illustration shows a converging nozzle in connection with rotating rings of blades alternating with stationary vanes. This is nothing more or less than what is shown in Hartman's patent drawings. From the way the text of the Breguet patent reads, however, the inventor apparently had in mind the improvement of the De Laval turbine, and if such is the case he evidently intended to imply the use of a diverging nozzle instead of a converging nozzle in connection with a compound turbine. Putting this interpretation upon the patent it is of importance as the first to be issued upon this combination of elements, preceding, as it does, the Curtis patent (which introduced the same principle) by about two years. The description of the invention states that in the De Laval turbine "Even with a circumferential velocity of the turbine of 420 meters, if the steam has a velocity of 1,100 meters, it still discharges from this turbine with a velocity of 440 meters, and this velocity is much higher when the circumferential velocity of the turbine is less. The idea that has naturally come to us is to utilize anew this lost velocity in a second turbine mounted on the same axis, and even in exceptional cases in a third, so as to increase the use of the turbine. We affirm as our property the invention of the compound steam or gas turbine, in which the steam, or gas, after having lost a part of its live force in the turbine buckets, finally loses the remainder in the buckets of one or of several other disks mounted on the same arbor."

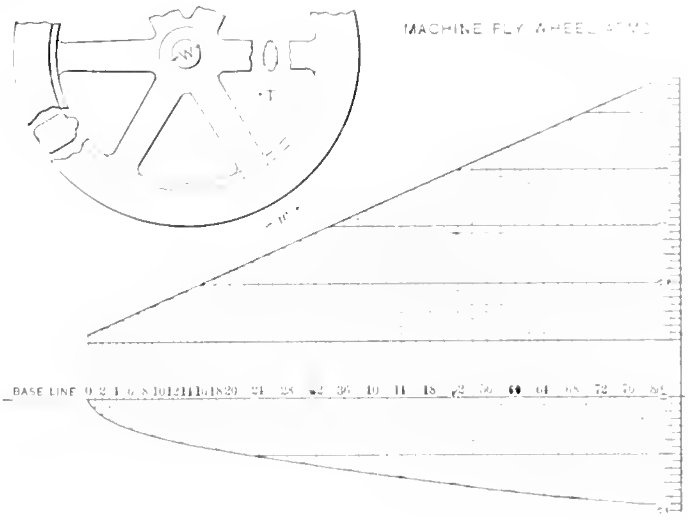
DATA SHEET FOR NOVEMBER.

The data sheet issued with the engineering edition for this month forms another practical supplement giving the results of the experience of several practical men. It contains some more matter upon gear wheels and pulleys, by Mr. Renkin, who has furnished material for the two preceding sheets upon the subject of gear wheels; and in addition gives the proportions for sheave wheels designed for both wire cables and manila rope. Also proportions for machine flywheels or handwheels.

Previous data upon the proportions of handwheels have been issued in the supplements to the November, 1902, and January, 1904, issues of MACHINERY.

We also have on hand another sheet upon the same subject, contributed by W. H. Raeburn, Dundas, Canada. As there is not room to use this in the data sheet supplement for this month, and since it is similar in character to the information contained in this sheet, we reproduce Mr. Raeburn's contribution below. Subscribers will thus have it to compare with the proportions of flywheels given on the November data sheet. The following are directions for using the diagram here given:



Diagrams for Machine Flywheels.

Find diameter of flywheel on base line. Note the distance above this line to inclined line. Call this distance a. Find area of section of rim of flywheel on base line. Note the distance below this line to curved line. Call this distance b. $a + b = W =$ width of arm projected to center; $w = \frac{2W}{3}$; $T = \frac{1}{2}$ width at any point.

Eye surgery in its simple forms must often perforce be practiced in the shop by the men, and many shopmen become very handy in removing foreign substances. Cinders and metallic particles, when superficially imbedded in the cornea of the eye, can usually be removed with little trouble by the skillful use of a toothpick or a match sharpened to a point which has afterward been slightly softened by chewing. But for particles more firmly imbedded so as to require more positive means of removal, a metallic instrument with an end shaped something like an oar and highly polished, may be found necessary. If strongly magnetized it will be of greater assistance in removing steel or iron pieces but will be no better for cinders, brass, or other non-magnetic substances. When metallic particles are of a ragged, irregular shape they may defy removal by ordinary means on account of clinging to the cornea with the barbs. In such cases the use of fine silk waste wound around the end of a toothpick is said to give very gratifying results. The silk threads catch upon the particle and tear it loose by simply moving the toothpick back and forth over the affected spot. Bandaging the eye and occasionally bathing it with a strong solution of salt and water is about the simplest and best after treatment to remove the inflammation.

* * *

A prime consideration in ocean telegraphy is to have a receiving and recording apparatus that works with the least possible resistance. The weak electric current that is necessarily used, is totally inadequate to work a Morse sounder or recorder, being the merest fraction of that required to work the most delicate relays used in land service. In Thompson's galvanometer a small mirror is delicately poised so as to be deflected by electro-magnets, and the deflection of the mirror is multiplied by a beam of light which is reflected on a scale. This delicate, but what is now considered to be a crude apparatus, is replaced by recording instruments of equal or greater sensitiveness which obviously have the great merit of producing a permanent record of all messages transmitted. To indicate what the extreme delicacy of this class of electric mechanism is, the improved Orling-Armstrong electrocapillary recorder may be mentioned. It is worked with a current of one-third volt through a resistance of a megohm or 1,000,000 ohms!

VARIABLE SPEED MOTORS.—7.

THE COMMERCIAL ELECTRIC COMPANY'S SYSTEM.

WILLIAM BAXTER, JR.

The variable speed motors manufactured by the Commercial Electric Company, of Indianapolis, are adapted to operate on any two-wire, or Edison three-wire power and lighting circuit. The variation in speed is obtained mainly by varying the number of wires upon the armature. The motor is provided with a double commutator armature, each commutator being connected with a separate set of armature coils. In this respect the system is somewhat similar to that of the C. & C. Company, but in its operation there is quite a difference; for while in the latter the two armature windings are connected in series to obtain a slow velocity, and in parallel for high speed, in the former the two windings are never connected in parallel. Owing to this fact, the two windings need not be made with the same number of turns; the actual proportion

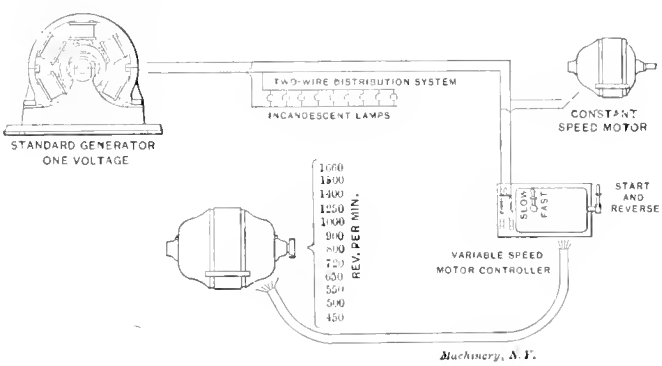

Fig. 1.

used is about two to three. To obtain the lowest speed both the armature windings are used, connected in series with each other. For an intermediate speed the winding having the smaller number of turns is cut out, while for the higher speed this winding is cut in and the one with the greater number of turns is cut out. The speeds obtained with these three connections of the armature circuits are about as follows: Slow speed, with both armature windings in series, 1; intermediate speed with long armature winding in service and short one cut-out, 1.7; high speed with short armature winding in service and long one cut-out, 2.5.

By means of field regulation several steps are obtained between the low and intermediate, the intermediate and high and above the latter speed. The low and the intermediate speeds are increased about 40 per cent. by means of field regulation. and the high speed is increased about 60 per cent., so that the total range of velocities is four to one, which is divided into twelve equidistant speeds.

The diagram, Fig. 1, illustrates the manner in which these motors are connected in an ordinary two-wire system in combination with incandescent lamps and other motors. The controller, which is of the reversible type, can be arranged so as to be actuated by means of a handle mounted directly upon it, or from any convenient point about the machine driven by the motor, through suitable connecting shafts and gears.

Description of the Controller.

The general arrangement of the controller, and the circuit connections between it, the motor and the supply mains, is clearly shown in the diagram, Fig. 2. The construction of the controller can be readily understood from Fig. 3, which shows the working parts, with the casing removed.

In Fig. 2, A A' represent the two armature windings, A being the long one, and A' the short one. As will be seen, these two windings are permanently connected in series with each other, and the operation of the controller is such that when the motor is started, A and A' are both in service. If the intermediate speed is desired, A' is cut out; and to obtain the high speed A is cut out, A' being left in service.

The parts marked from 1 to 21 are the stationary and movable contacts of the reversing switch shown as a rotating cylinder in Fig. 3. The parts marked from 22 to 34 are the contacts of the speed controlling switch shown at the top of Fig. 3. The controller is so arranged that by turning the shaft of the rotating reversing switch the speed controlling switch lever is also rotated; but the latter does not move until the reversing switch has turned far enough to cut out the starting resistance and the series field coils of the motor, so as to leave only the shunt field coils in service, and thus enable the motor to run at a constant velocity for any speed at which

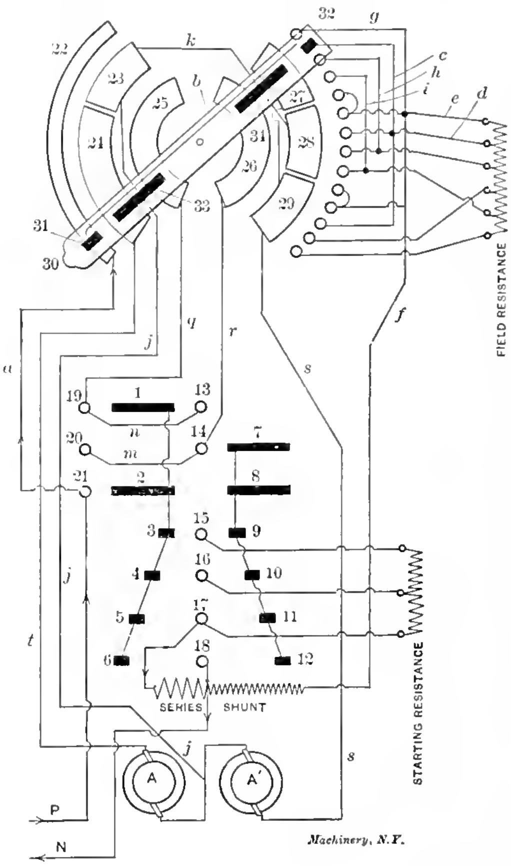

Fig. 2.

the speed controlling switch may be set, regardless of changes in the load. The reversing switch cuts out the starting resistance and the series field coils in four steps.

Circuit Connections and Operation of the Controller.

The circuit connections in Fig. 2 are as follows: The lines P N connect with the source of current supply. If the switch lever 30 is in the position shown, and P N are connected with the mains by closing the main switch, the current from P will flow to 21, thence through a to contact arc 22, and through

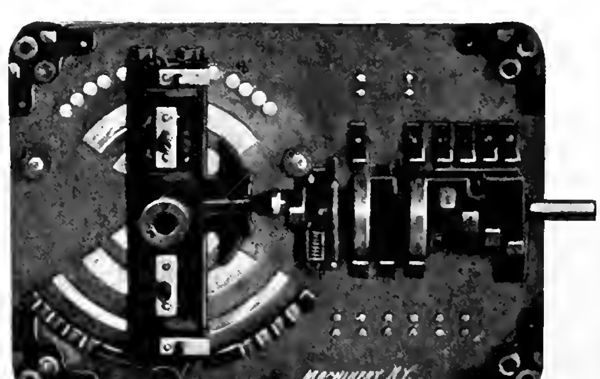

Fig. 3.

contact 31 on lever 30 and wire b to contact 32, and thence through wire c to wire d, and through upper section of the field resistance to wire e, and thus to wire f, which connects with one end of the shunt field coil of the motor. The other end of the shunt field coil is connected with line wire N, thus completing the circuit through the shunt field. If lever 30 were drawn so that contact 32 rested upon the top circular contact, the current would pass directly to wire f, through wire g, and thus avoid passing through the upper section of the

field resistance. This latter is the position of 30 when starting.

If now the reversing switch is turned to the left so as to set the motor in motion, stationary contact 21 will be covered by cylinder contact 2, and 19 by 1. Contacts 7 and 9 will ride over 14 and 15 respectively, and the circuit through the armature will be, from 21 to 2 and 1, thence to 19, to q, to 25 and through connecting contact 33, to 24. From here, through wire t, to armature winding A, through the latter to winding A' and thence to wire s and contact 29. As 29 and 27 are connected by wire, the current will pass to the latter and thence through 34 to 26 and to wire r, which connects with

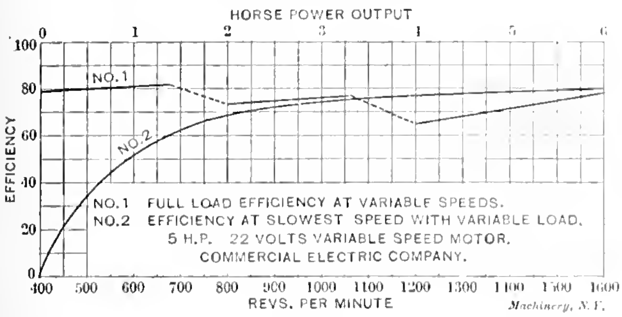

Fig. 4.

14. From 14 through cylinder contacts 7 and 9 the current reaches 15, and then passes through the starting resistance to contact 17, thence through the series field coil to line N.

When the reversing switch is moved to the second step, cylinder contact 10 rides over 16 and cuts out one section of the starting resistance. When the third step is reached contact 11 rides over 17 and cuts out the remaining section of the starting resistance, and on the fourth step contact 12 rides over 18 and cuts out the series field coil.

During all this time the switch lever 30 does not move from its initial position, but, upon the further advance of the controller, 30 rotates clockwise so as to carry contact 32 over the row of circular contacts and thereby cut in sections of the field resistance. While 34 remains in contact with 27 there is no change on the armature winding connections, but the speed of the motor is increased from step to step through the cut-

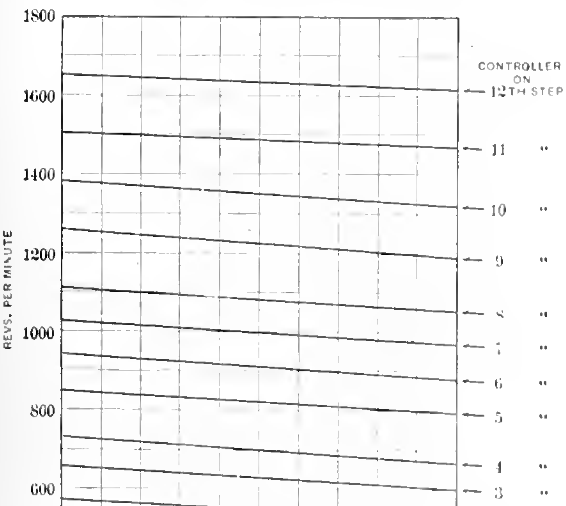

Fig. 5.

ting of resistance into the shunt field circuit. On the first step the current passes through wire g; on the second step it passes through wire c, and cuts in the upper section of the resistance. On the third step it passes through wire h and cuts in the two upper sections of the resistance. On the fourth step it passes through wire i and cuts in the four upper sections of the resistance. In passing to the next step, lever 30 carries 34 over onto contact 28 and at the same time connects with wire c and cuts out all the field resistance. As soon as 34 passes onto 28 the armature winding A' is cut out, because then the current from the junction of the two windings, A and A', can pass through j to 23 and thence, through k, to 28. While 30 is advancing and carrying 34 over 28 the sections of the field resistance are again cut into the field circuit, one at a time, thus increasing the motor speed step by step. When 30 advances far enough to carry 34 over 29, A will be cut back into circuit, and A' will be cut out. As will be seen when this position is reached, 33 will be in contact with 23 instead of 24, so that the current from line wire P instead of

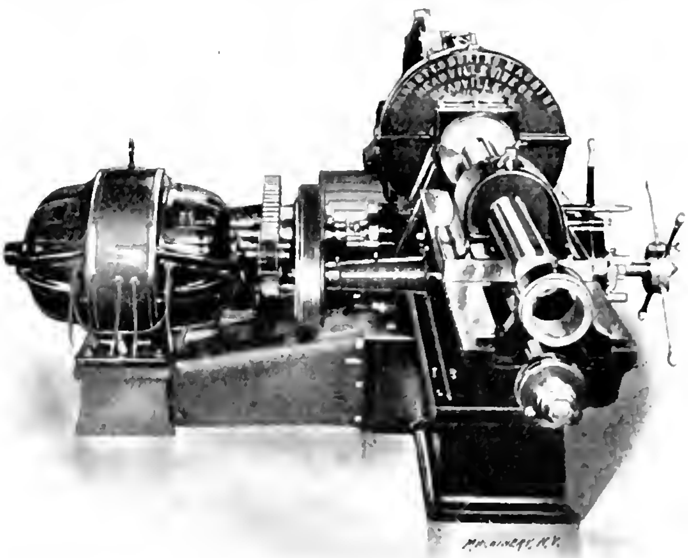

Fig. 6

passing to 24, and thence to t and to A, will pass to 23 and through j to A'; and from the end of A' it will pass to 29 and thence to 26 and out to wire N in the manner already explained.

While 34 is being advanced over 29 the sections of the field resistance will be again cut in, one at a time, and when the final step is reached all the sections will be in service.

In the first two connections of the armature coils only four of the field resistance sections are cut into the field circuit; but in the last connection all the sections are brought into service. In this way the increase in speed obtained by the use of field resistance, for the first two connections is made about 40 per cent, while for the last one it is about 60 per cent.

To run the motor in the opposite direction the reversing switch cylinder is rotated to the right, and then contact 8 rides over 21, contact 7 over 20, contact 1 over 13, and contact 3 over 15. With these changes in the reversing controller connections the path of the current will be as follows: From 21 to 8 to 7 to 20, through m to 14, through r to 26 to 34 to 27 to 29 and through s to and through the armature windings A' A to wire t and to 24. From 24 through 33 to 25, and through q to 19, through n to 13, thence to 1 to 3 to 15 to 17, and through the series field coil of the motor to line N. As the controller is advanced the contacts 4, 5, 6 slide over 16, 17 and 18, one after the other, and cut out the starting resistance and series field coils as previously explained. The further advance of the controller actuates the speed controlling switch 30 in the manner already described.

Torque, Power and Efficiency of "Commercial" Motors.

When the two armature windings are in service the current traverses about two-and-a-half times as many turns of wire as when the short winding is used alone; hence, with the same strength of current, the torque in the two cases will be about in the ratio of two and a half to one. For any portion, or the whole of the armature wire in service, the torque with a given current through the armature will decrease as the field is weakened, or, in other words, as the speed increases. The reduction in torque will be directly proportional to the increase in armature speed. From this it will be seen that the power developed by the motor will be practically the same at all velocities.

When all the armature wire is in service, the loss of energy

in the armature will be greater than when either of the windings is used alone, for the same current strength, but if the armature resistance is small, this difference will have only a slight effect on the motor efficiency. The diagram, Fig. 4, furnished by the Commercial Company, shows that at full load

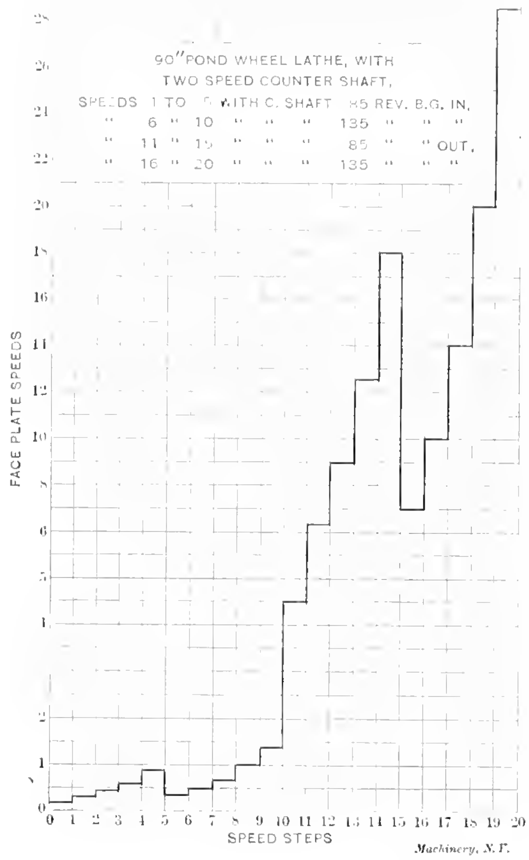

Fig. 7.

the efficiency of the motor changes but slightly for any speed from the lowest to the highest. This diagram also shows, in curve 2, that at the lowest speed the efficiency remains high as the load is reduced to about 25 per cent. of the maximum; below this point the efficiency naturally drops rapidly.

Variation in Speed Due to Changes in Load.

As already explained the motor when running has all the resistance cut out of the armature circuit, and also the series

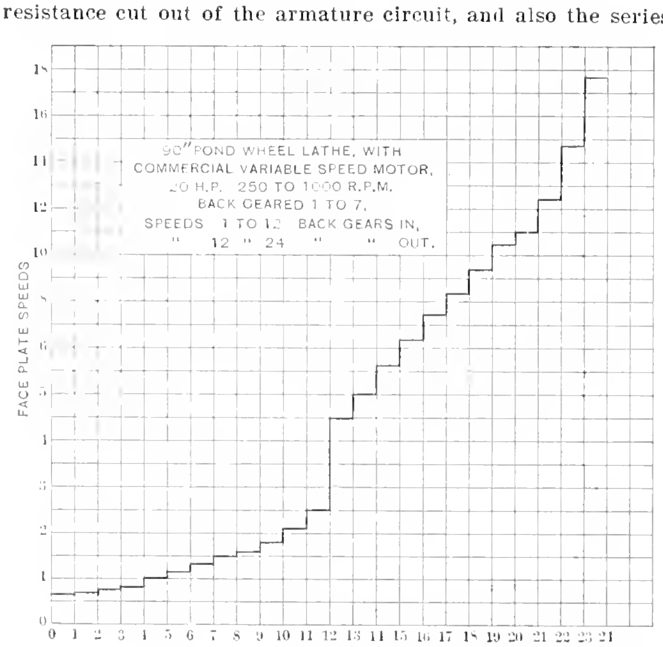

Fig. 8.

field coils; therefore, when the speed controller is set for any given velocity the change in speed effected by varying the load cannot be very great. What this change actually amounts to is shown in Fig. 5. At the bottom of the diagram the power output is marked, and on the left side the revolutions per minute. On the right side the several steps of the speed controller are marked. The speed lines across the face of the diagram show that between full load and no load the change in velocity is about fifty revolutions per minute. Thus on the 10th step the velocity with full load is about 1325, and with no load about 1375.

The way in which Commercial motors are mounted upon machine tools is well shown in Fig. 6.

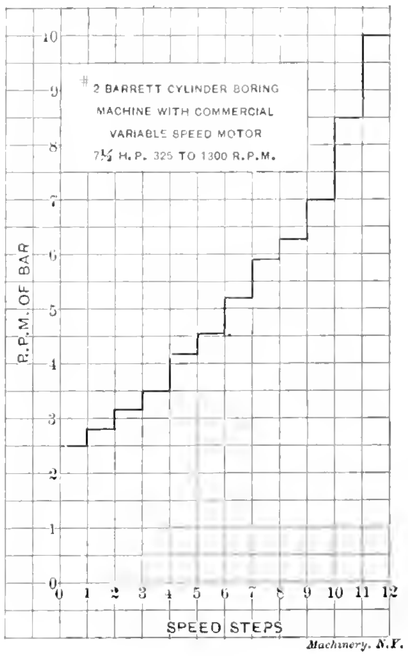

Fig 9.

Some Points on Speed Variation.

Diagrams 7, 8 and 9 show that in some cases the speed variations effected by the mechanical speed-changing devices furnished with machine tools are not as uniformly progressive as they should be, and that in such cases an improvement can be made by using a variable speed motor to produce a part of the speed variation. A perfect speed-changing device would be one in which each step produces a proportionate increase in velocity. In many machine tools, however, the relation of the gearing is such that when the back gear is thrown out and the belt is placed on the slowest cone step, the velocity is materially reduced. This fact is clearly brought out in Fig. 7. In this diagram the speed advances during the first five steps, but here the countershaft speed is increased and the speed of faceplate drops on the 6th step to slightly more than it is on the 2d. The speed again advances uniformly up to the 10th step, when it takes a decided jump in consequence of the change in countershaft speed and the throwing out of the back gear. At the 16th step there is another decided drop in faceplate speed due to changing the countershaft speed.

Fig. 8 shows the same tool driven by a variable-speed motor instead of a two-speed countershaft, and, as will be noticed, the faceplate speed variation is far more uniform; in fact the only break, occurring on the 12th step, is due to throwing the back gear out. If the back gearing were properly proportioned to the range of motor velocities, this sudden rise in velocity when the back gear is thrown out could be prevented. The same result could be obtained by providing a motor with a somewhat greater range of speeds.

Fig. 9 shows the speed variations obtained on the tool of a boring mill by the use of a variable-speed motor alone.

* * *

The artificial corundum, called "cornbin," that is obtained from the slag produced by the Goldschmidt thermit welding process, is much purer than the natural corundum. For this reason it is possessed of a very valuable property to the chemist, and that is the ability to resist sudden great changes of temperature without breaking. Chemical vessels made of fireclay and corubin may be heated redhot and plunged into cold water without breaking or even showing any tendency to crack.

THE DE LAVAL STEAM TURBINE AND ITS MANUFACTURE.

In the Engineering Edition for October was published a general account of the inventions of the noted Swedish engineer, Gustaf De Laval, together with a description of the steam turbine machinery manufactured in this country under his patents, and a description of the De Laval Steam Turbine Works at Trenton, N. J., where the machinery is produced. In this article it is intended to enter more into detail upon the construction of the De Laval steam turbine and the interesting methods of manufacture that have been developed at the American works.

The plant is unusually well equipped with jigs, fixtures and special tools. Micrometers and gages are in evidence, not only for tool room use but for the employes in the shop as well. There is a large tool-making department, which apparently is kept busy, in addition to the tool room where the tools are stored, to be checked out in the usual manner. The drawings are kept in the tool room and an ingenious system is used in giving them out to the workmen. The turbine parts are marked with a number designating the particular part, prefixed by a letter for the size of the machine. Each drawing is devoted to a single part and bears the same character as that part. A board hung in the tool room contains a large number of pins having numbers corresponding to those of the turbine parts. When a workman hands in his check for drawing R-126, for example, it is hung on pin 126 and a small metal clip, lettered R, is slipped over the edge of the check. The number on the check shows who the workman is; and the clip, together with the number of the peg on which the check hangs, shows what drawing has been given out.

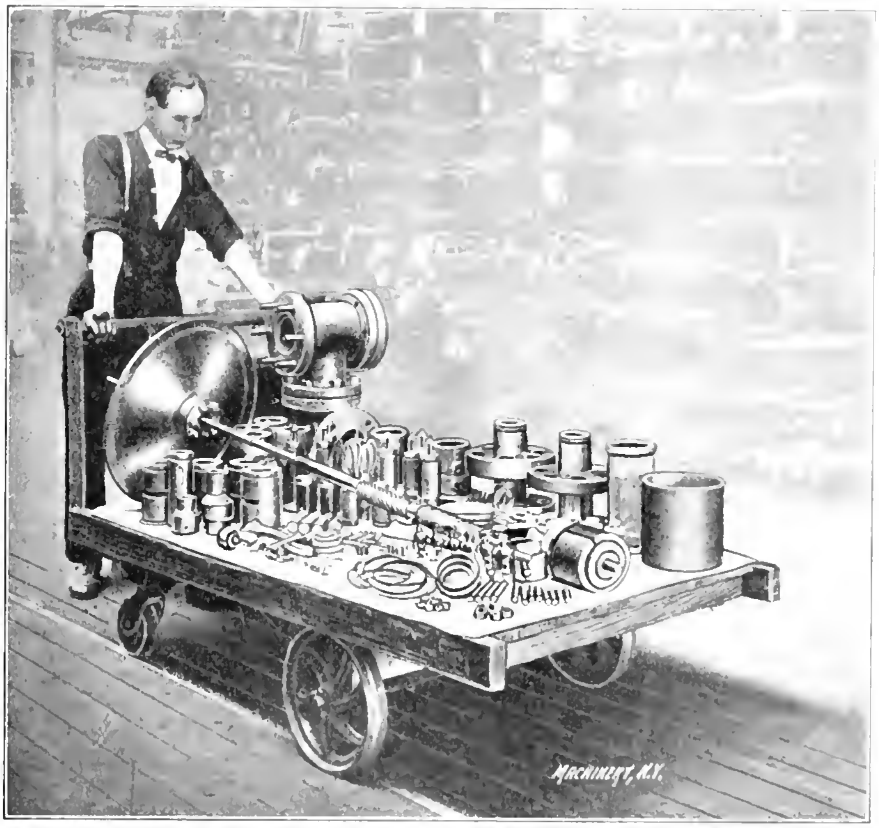

Fig. 1. The Small Parts of a 300 H. P. De Laval Turbine as taken from the Stock Room ready for Assembling.

Another feature of the De Laval works is the stock room for finished parts. All the small pieces are made up in large numbers, carefully inspected and placed in stock. The larger parts consisting of the frames, bedplates, etc., are also made up in lots, though of smaller numbers, and when one or a series of turbines is to be erected, the parts are taken from the stock room, complete, and ready to put together, with the exception of such slight fitting as may be required during the assembling.

In Fig. 1 is shown a truck, loaded with the small parts of one complete turbine, as it is brought from the stock room to be carried to the erecting shop. Here are the wheel and shaft, the gearing, bearings for the several shafts, flexible couplings for connecting the gear shafts with the generator or other machine to be driven by it, the steam nozzles, valves, governor, regulating valve, lubricator, etc.

The line drawing, Fig. 2, is a horizontal sectional view of a turbine, taken through the turbine and gear shafts. Starting at the right, W is the turbine wheel, attached to the flexible shaft which is supported on each side of the wheel by bearings held in the casing by ball and socket joints. The pressure within the turbine casing is practically atmospheric pressure when running non-condensing, and is equal to the pressure of the condenser when running condensing. Under the latter conditions, these bearings should be tight to prevent leakage of air into the casing, and they must at the same time be able to move slightly, in case of flexure of the shaft. They are, therefore, held to their seats by spiral springs N bearing against a collar O made in the form of a socket. At the other end of the flexible shaft are the spiral pinions K, supported on each side by bearings C in the wheel casing. These pinions mesh with the gears I I, as indicated.

The speed reduction between the pinion and gears for all sizes of turbines is about in the ratio of 10 to 1. The speeds of the turbine wheels range from about 30,000 revolutions per minute for a 7-horse power to 10,600 for a 300-horse power turbine; and the speeds of the large gears range from about 900 to 3,000 revolutions per minute. The peripheral speed of the turbine wheels ranges from about 515 to 1,380 feet per second, while the peripheral speed of the gears is 100 feet per second or slightly more, for all sizes. These speeds of the gear shaft are found to be well adapted to driving generators and other apparatus, such as centrifugal pumps blowers, etc. Such apparatus is driven through flexible couplings taking power from the outer ends of the gear shafts. The couplings have a series of pins F, Fig. 2, securely driven into holes in the circumference of the driving disks, and on their outer ends have rubber bushings E, which fit in corresponding holes in the disk attached to the shaft belonging to the generator or other apparatus. These bushings are fitted with an internal steel bushing D, which slips over the end of pin F, to protect the rubber. This brings the wear on the outside of the rubber bushing, which presents a greater area than the inside.

The governor, shown at M, is of compact design and is carried by a short shaft made a taper fit in the end of one of the gear shafts. The governor controls a throttle valve and also, in case of extreme increase in speed, opens a valve admitting air to the wheel casing by means of the lever V.

Nozzles and Steam Chest.

In considering the individual parts of the De Laval turbine more in detail the first to be noted are the nozzles which direct the steam against the wheel buckets and which have been one of the characteristic features of the De Laval system. These nozzles are arranged about the circumference of the steel casting which serves as the casing for the turbine wheel. The inner end of this casting has an annular closed space, separate from the wheel chamber, which serves as a steam chest for the turbine, as indicated in Fig. 2. The inner ends of the nozzles open into this steam chest, as shown in the sectional view, Fig. 3. Here A is the steam chest; B, the nozzle; D, the turbine wheel, and C, the valve for admitting steam to the nozzle. The divergence of the nozzles depends upon the steam pressure to be used and also upon whether the turbine

is to run condensing or non-condensing. If the latter, the turbine is generally fitted with both condensing and non-condensing nozzles, so that in the event of difficulty with the vacuum the machine can be operated non-condensing with a greater degree of economy. These nozzles are turned to gage on their outside and reamed to the required taper on the inside. Over 600 reamers of different tapers are kept in the tool room for this purpose. The nozzles are simply driven into place in the casing, but are threaded at their inner ends to facilitate removal by means of a jam nut. The taper of the nozzles ranges from about 6 to 12 degrees total taper, and they are located with their outlet about $\frac{1}{8}$ inch from the wheel blades.

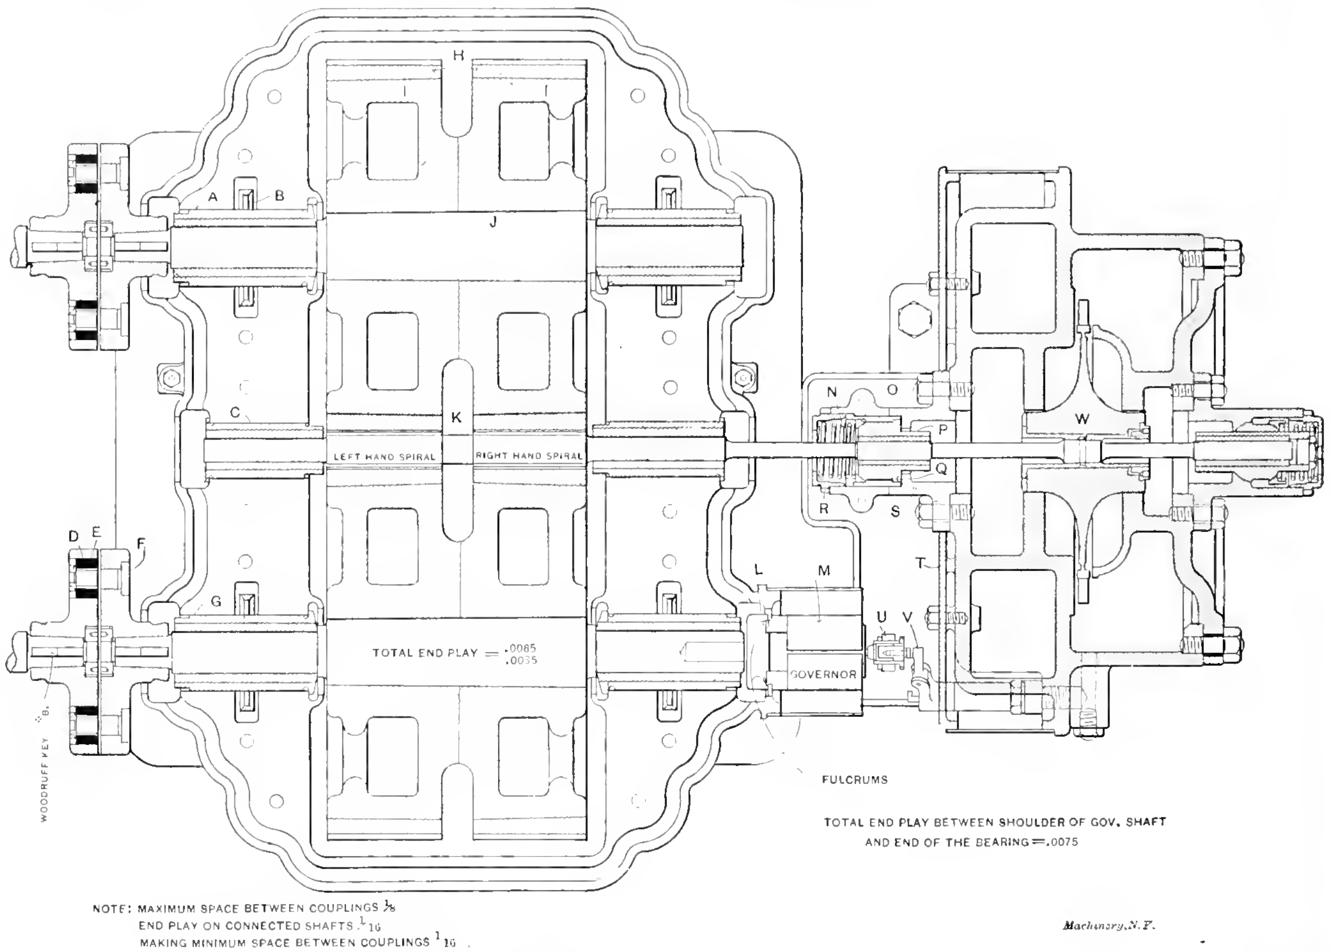

Fig. 2. Horizontal Section of De Laval Steam Turbine.

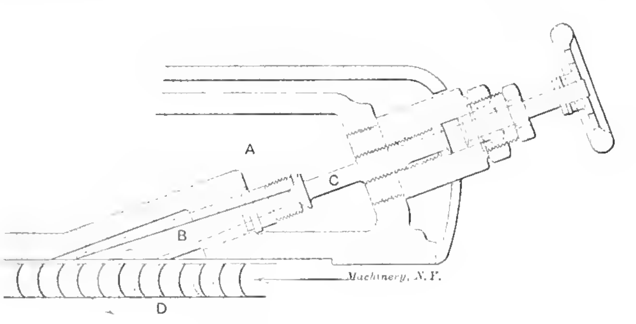

Fig. 3. Section Nozzle and Valve.

Turbine Wheel and Shaft.

The turbine wheels are all made in Sweden, of a special grade of high-carbon steel. They are shaped according to theoretical calculations, so as to offer nearly a uniform resistance throughout to the forces acting; but they are made slightly stronger near the center. A short distance from the periphery annular grooves are turned on each side of the wheel, making this the weak section which would be ruptured first in case of excessive rotative speed. To further guard against danger in the case of a wheel bursting the casing is a steel casting strong enough to sustain the shock due to flying segments of the wheel; and still further, the hubs of the wheel extend into circular openings in the casing, as shown in Fig. 2, in which the hub ordinarily runs without touching. But if the wheel rim should burst, what would be left of the wheel would be out of balance and would cause the hubs to bear against the casing with great force and thus slow down, and perhaps stop the turbine before further damage could be done.

Grooves of the shape shown in Fig. 5 are drilled and milled through the turbine rim in a crosswise direction, and in these drop-forged steel buckets are fitted. This construction enables buckets to be easily renewed, as is sometimes necessary either because of wear or accident.

In the smaller size turbines the wheels are attached to the flexible shafts by the method indicated in Fig. 2. The hubs of the wheels are bored out and a thin steel bushing is drawn into the hub by a nut at one end. The middle portion of the bushing is bored tapering and fits on a taper portion of the shaft, as indicated. This taper is the standard $\frac{1}{2}$-inch per foot used by the De Laval Company. After forcing the bushing on the shaft, it is pinned into place; but the wheel can easily be removed by loosening the nut and sliding it off the steel bushing. The wheels for the larger turbines are made as in Fig. 4. Here the hub is solid at the center, but each end of the hub is recessed and the flexible shaft is made with enlarged flanged ends which fit into the recesses and are bolted solidly in place. The recesses and shaft ends are machined on a taper of $1\frac{1}{2}$ inch per foot, which enables the parts to be accurately centered and fitted solidly together.

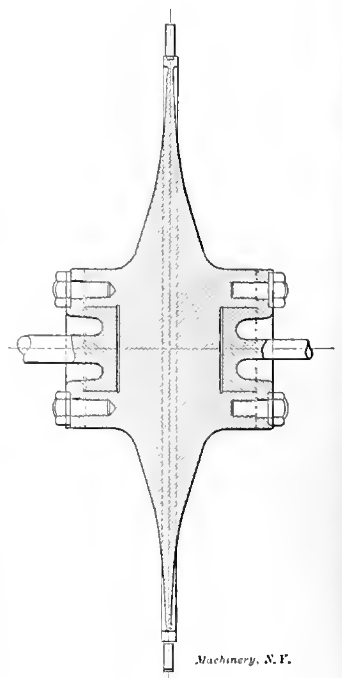

Fig 4. Section of Turbine Wheel.

The pinions are cut directly on an enlarged portion of the shaft. The steps of manufacture are: First, to straighten, turn and square up the various shoulders on the shaft; second, to rough-cut the pinions; third, to finish by grinding, and fourth, to take the finishing cut on the teeth of the pinions. The shaft and wheel are then assembled and tested on centers, where they are run at high speed to determine the accuracy of balance. The flexibility of the shaft, which is an

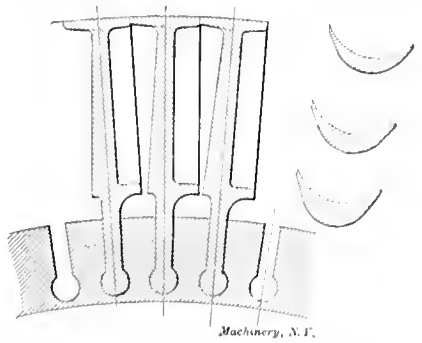

Fig. 5. Showing Construction of Turbine Buckets.

important feature of the De Laval turbine, makes an extremely accurate balance unnecessary since the wheel and shaft reach the critical speed, so-called, at about 1-5 to 1/8 of the normal number of revolutions of the wheel, at which point "settling" takes place and the parts proceed to rotate about their center of gravity instead of about their geometrical center.

Gears.

Next in importance to the turbine wheel, and probably first in importance in so far as the successful operation of the turbine is concerned, are the gears used to reduce the speed of the turbine shaft to a point where it is practicable to utilize the power. It was a radical step on the part of De Laval when he first attempted to run gearing at so high a speed as these gears operate, and it is safe to say that previous to the time when De Laval demonstrated that gears would run at a linear velocity of upward of 100 feet per second, it would not have been supposed possible.

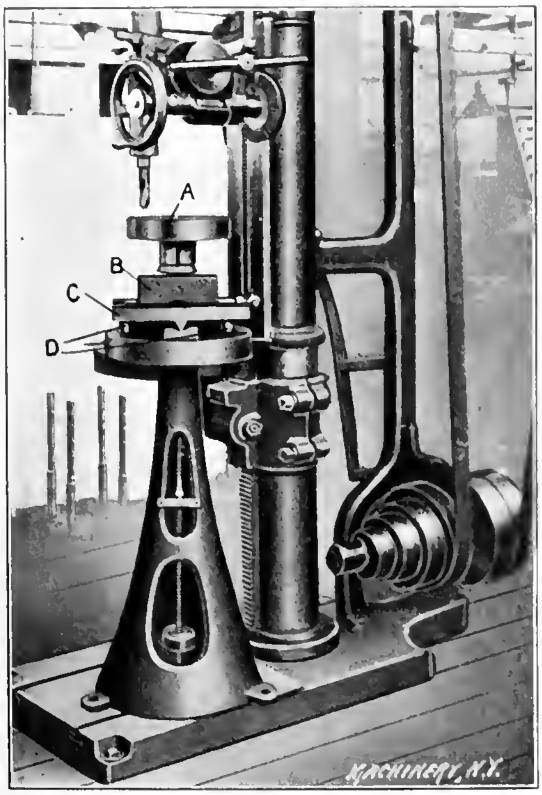

Fig. 7. Machine for Balancing the Rotative Parts of the Turbine.

The pinions are made of 60- or 70-point carbon steel and are a part of the flexible shaft. The gears are of mild 20-point carbon steel of a grade similar to that used for car wheel tires. For turbines up to 30 horse power the gears are of solid steel; but for sizes above that they are made with cast-iron centers with rims of mild steel. The teeth are of fine pitch, ranging from about .15 inch in the smallest to .26 inch in the largest sizes. The success at running these gears at high speed is due, in part, to the fine pitch and the spiral angle of the teeth, which thus brings a large number of teeth in mesh at one time, making the working pressure at each tooth very light, and reducing the likelihood of abrasion. The dimensions of gears and pinions for four sizes of turbines are shown in the accompanying table:

H. P.	Outside Diameter.	Number of Teeth.	Depth of Teeth
PINIONS.			
10	1.077	21	.075
75	1.53	19	.1169
110	1.82	23	.1169
300	2.65	31	.1275
GEARS.			
10	10.1	208	.075
75	15.7	208	.1169
110	18.89	250	.1169
300	29.29	362	.12750

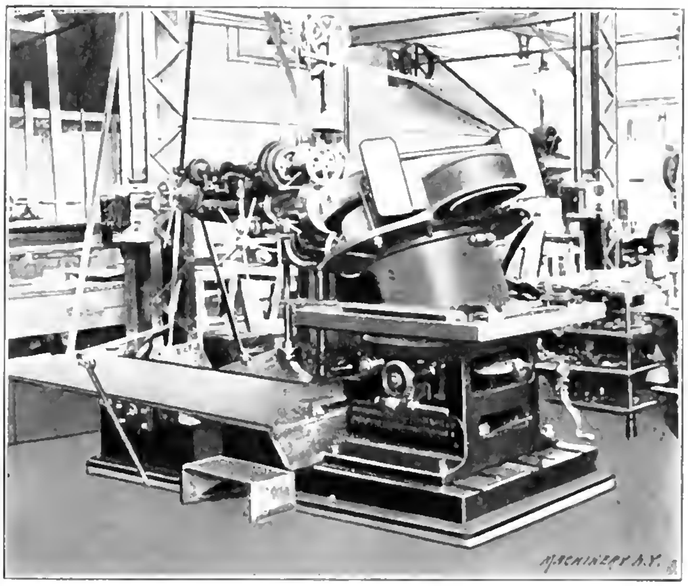

Fig. 6. Boring the Holes in Wheel Casing for the Nozzles, by means of a Special Fixture on the Boring Machine.

A practice somewhat out of the ordinary is employed by the De Laval company in putting together the shafts, gear centers and rims that make up the large gears, as well as in other parts of the turbine, where applicable. This is the use of the 1/2-inch per foot taper already referred to. The angle of this taper is so far below the so-called friction angle, or angle of repose, that pieces turned to this taper and fitted together hold with practically as great rigidity as straight, parallel surfaces would hold and at the same time can be pressed together much easier and without abrading the surfaces. The taper accomplishes the same object as where the surfaces to be pressed together are turned in steps, and on the whole this is a more easily applied system when fitted up for it.

Balancing

Inasmuch as the disks are quite accurately balanced when they reach the factory, and moreover are mounted on a flexible shaft, it answers every requirement to run them on centers in the usual manner, in order to test their balance. The parts of the turbine attached to the gear shafts, however, are not flexibly supported and are better balanced by a more accurate means. The machine shown in Fig. 7 was devised for this purpose, and is shown with one of the flanges for a flexible coupling mounted on an arbor at *A*, ready for balancing. The machine is placed under a drill press and by its aid the heavy side of the casting is located and enough metal drilled out to bring the flange into balance. On top of the stand are located knife edges which carry a table *C* with a movable cross-slide *B*. This cross-slide is fitted with a pendulum in the form of a screw which runs down into the base and has a weight at its lower end. Half way up there is a pointer and a graduated scale for indicating the position of the pendulum. The arbor for supporting the piece to be balanced is at the top of the slide *B*. By adjusting the slide one way or the

other the indicator is brought exactly at the center of the scale and then the coupling is turned around half-way by hand without moving the slide. If the indicator does not move, it shows that the coupling is in balance at this point; if it does move, the coupling must be out of balance and the necessary drilling is done. From eight to a dozen points around the circumference of the coupling are tested in this manner. In order to steady the table and avoid wear of the knife edges when drilling, there are pins *D D* which are raised against the bottom of the table by a cam and which take the strain.

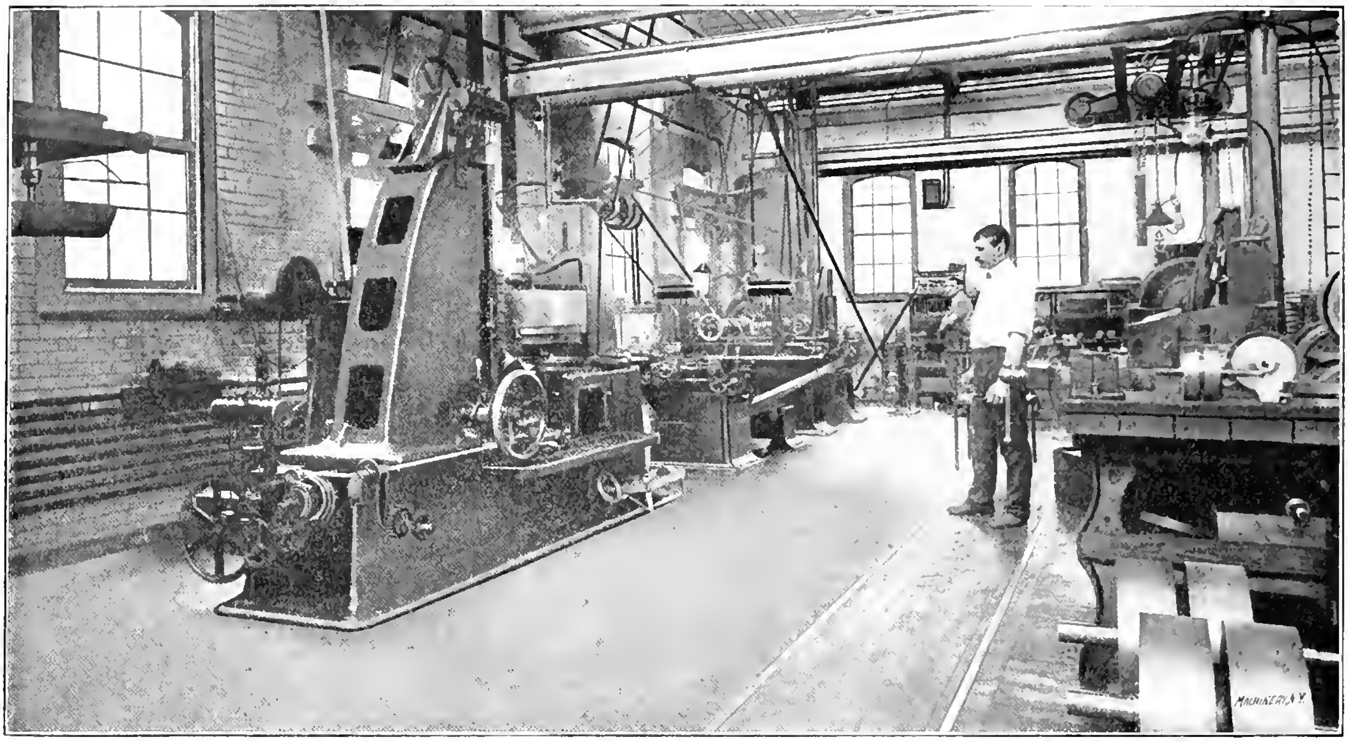

Fig. 8 Gear-cutting Department equipped with Special Machines for Hobbing the Teeth of Spiral Gears.

Gear Cutting

As a matter of course high-speed gears must be accurately cut and their shafts mounted in their bearings so as to be exactly parallel, if smooth running is to result; and unusual precautions are taken to secure a high degree of accuracy in cutting and mounting the gears of the De Laval turbine. Fig. 8 shows the gear-cutting department with its complement of machines built expressly for this work by the Pratt & Whitney Co., Hartford, Conn., in accordance with designs furnished by the De Laval Steam Turbine Co. In these machines the gears are cut by a hobbing process, a spiral cutter being used for a hob. The principle of operation is shown in Fig. 9. At *A* the spiral hob is set so as to cut the teeth of a spur gear. The hob feeds downward across the face of the gear and at the same time the gear rotates as fast as it would be turned around if the hob were a worm meshing in the teeth of the gear. If the hob has a single thread it would have to make as many turns as there are teeth in the gear for each rotation of the gear. At *B*, Fig. 9, the hob is shown inclined still more so as to cut spiral teeth on the wheel. This can be accomplished by giving the cutter either a greater or lesser number of revolutions for each rotation of the gear, according to whether a right-hand or a left-hand spiral is to be cut. In producing a gear the cutting action is continuous from start to finish, so that if the machine is rigid, the best possible results are attained.

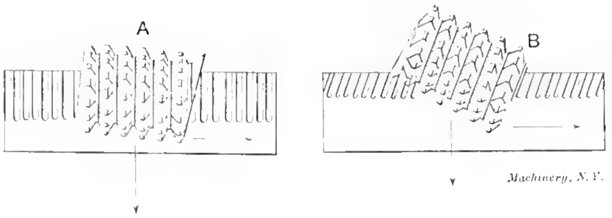

Fig. 9. Illustrating the Principle of the Cutters.

There are two vertical machines and two horizontal machines in the gear-cutting department working on this plan. In order to secure great accuracy in the angle of the teeth, the machines are all provided with an attachment shown in principle, though not in actual detail of construction, in Fig. 10. *C* is the cutter head, which travels downward with the cutter in a vertical direction. *G* is the gear to be cut, mounted on the work spindle which is revolved by a wormwheel. The wormwheel and gear blank are driven by a worm which is given the desired rate of rotation by a system of change gears. Now it is evident that if the change gears used do not produce exactly the right result the correction could easily be made if some means were provided for moving the worm bodily in a longitudinal direction, so that in addition to its driving the wormwheel through its rotation, it also either pushed it ahead or pulled it backward, so to speak. This is what is done by means of a slide shown at *D*, arranged to swivel on a graduated dial which moves up and down with the cutter head. The worm is carried by a sliding frame having a block *R* traveling in the slide *D* so that, when the slide is placed at an angle, any movement of it up or down will give the worm its longitudinal movement. As the slide can be set very accurately by vernier readings, exactly the correct spiral angle can be obtained, independent of the change gears.

Testing the Gearing.

The need for securing so great accuracy of angle will be evident when it is remembered that not only are double spiral

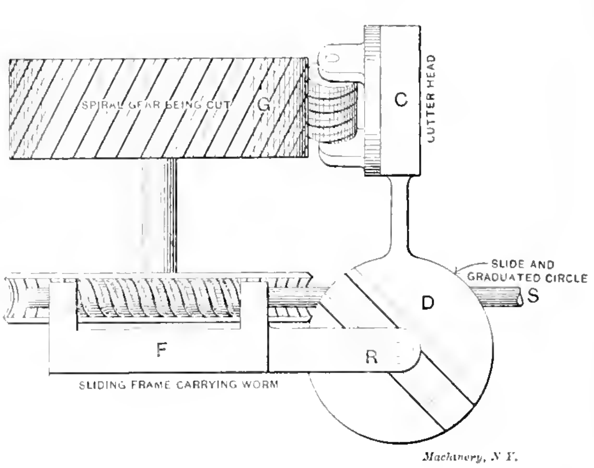

Fig. 10. Diagram showing Method of Securing Accuracy of Spiral Angle of Gear Teeth.

gears used in each turbine, cut right and left, but also that the two right- and left-hand pinions on the turbine shaft lie between two pairs of gears, making what are really two spiral pinions, each of which must mesh with two opposite spiral gears. This will be clear from reference to Fig. 2, which shows the positions of the gears. It goes without saying that

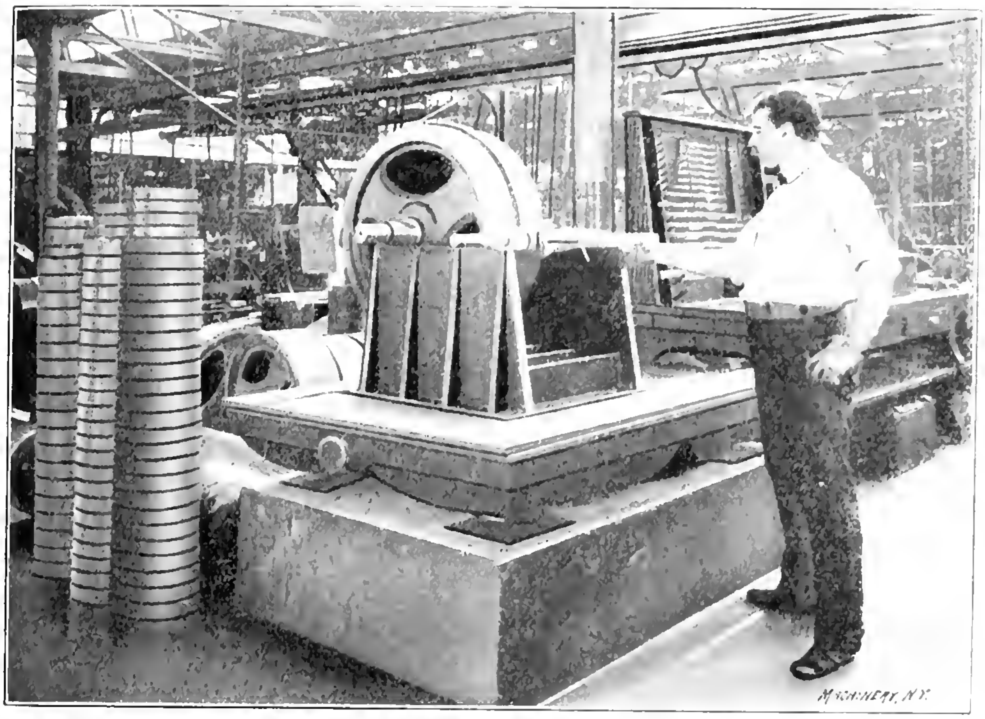

Fig. 11. Testing the Spiral Gears and Pinions to see that Shafts are parallel and in same Plane

it requires rather unusually fine workmanship and painstaking care to have these teeth so correctly cut that they will all mesh in perfect alignment. The method of testing for the angle of the teeth is shown in Fig. 11. There are two parallel straight edges with their top surfaces lying exactly in the same plane upon which the gears are mounted. The gear shafts rest on the top edges of these parallels, and a pair of large gears and a pair of pinions are clamped together, with their teeth in mesh, by an iron band passing around the large gears and arranged with a screw which draws the pinions into contact with the gears. If the two shafts lie in the same plane it is evident that a piece of tissue paper under each end of the pinion shaft would just "draw," and this is the test applied and actually required before the gears are considered to be aligned correctly. A little consideration will show the extreme accuracy of this test, and will indicate how much attention is given to securing the correct spiral angle of the teeth.

The Wheel Casing.

Without correctly aligned bearings the most accurate gear would run noisily, and Fig. 12 illustrates the simple yet effective method used to secure parallelism of the three gear shafts and also to make sure that they are in the same plane. The gear case is first bored out on the horizontal boring machine, being held in a special jig. The bearing pockets are afterward carefully scraped to standard test bars which are brought to their proper center distance by the use of a caliper gage, as shown in the illustration. The gear case rests on a large surface plate and a Brown & Sharpe test indicator, also shown, is employed to bring the test bars into exactly the same plane. This is done by placing the indicator on the surface plate under the shafts at the various points where they protrude past the case. The surface plate is mounted on a heavy foundation and has adjustable legs, so that it can be readily leveled.

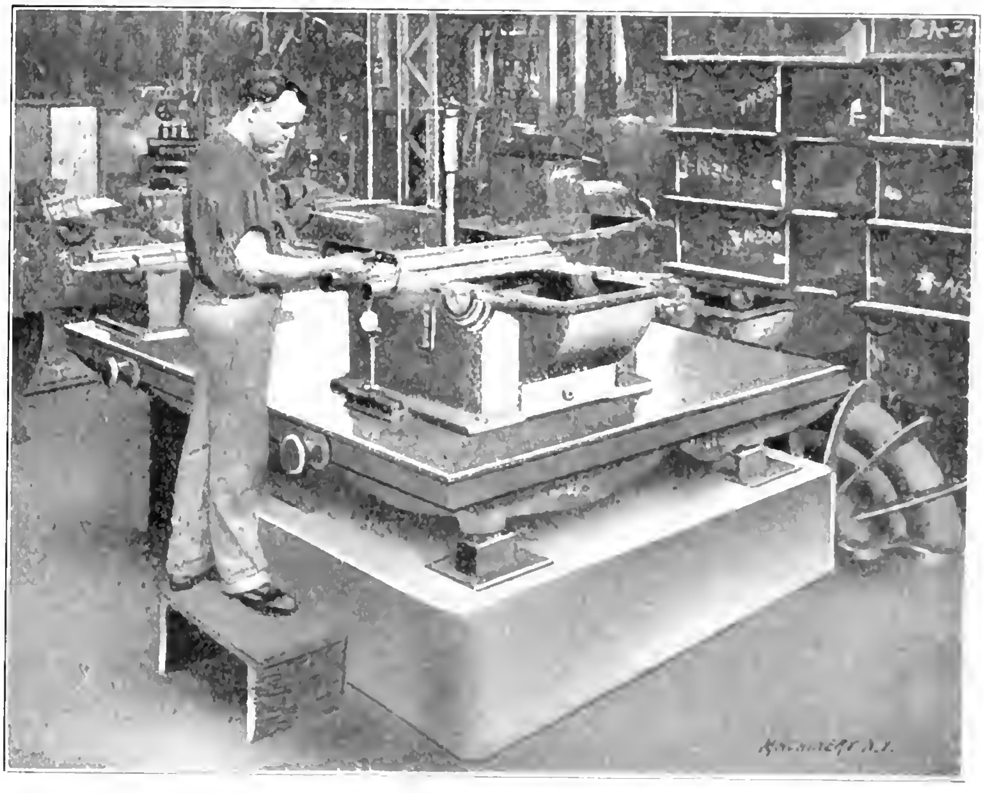

Fig. 12. Testing Pockets for Bearings in Wheel Casing to insure that Gear Shafts will be Parallel and in the same Plane.

Bearings.

All bearings are lined with babbitt and special attention must necessarily be given to their construction to have them adapted to the high speeds of the parts that run in them. The bearings are all in the form of cylindrical shells, either split or solid, excepting those which act as glands in the turbine casing which are turned in the form of a ball at the center and are held in position by sockets. The low-speed bearings are made with cylindrical shells of special composition, lined with babbitt and ring-oiled. Before babbitting, the shells are cleaned in nitric acid. The babbitting is done by first heating the shells and then bedding them in molding sand and pouring in enough babbitt to fill the shell flush with the top. The molten metal is then agitated by means of a stick, which causes the impurities to rise. By this process such impurities reach the center of the bearing, where they are bored out, leaving a solid lining of pure metal.

In the high-speed bearings oiling is accomplished by having a shallow spiral groove turned in the shell, which allows the oil to reach every part of the bearing. In a 100 horse power machine this groove is about 1-64 inch deep of 1/2-inch pitch. The bearings are first milled and scraped together and then bored and reamed under the drill press in a special jig shown in Figs. 15, 16 and 17, before they are turned. Figs 15 and 16 illustrate the drilling of a split bearing, and Fig. 17 the drilling of a solid bearing. The jig is

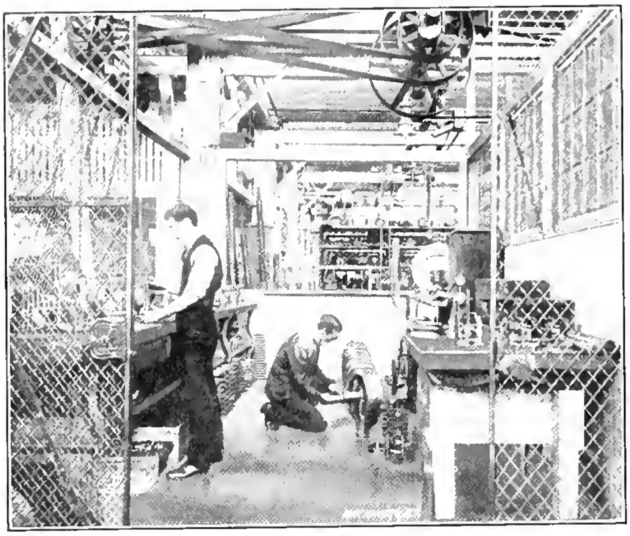

Fig 13 Inspecting Department. This Room is enclosed to Guard against Interruptions that might lead to Errors or Oversight on the part of the Inspectors.

box-shaped with a swinging holder at the top in which the drill bushings are located. Fig. 16 illustrates the method of locating split bearings in the jig so as to insure drilling and reaming of the hole in the exact center of the bearing. The center plate which the man has in his left hand, and which is shown standing beside the drill press in the other views, is inserted in grooves milled in the jig so that one face of the plate is exactly in line with the axis of the bushing through which the hole is to be drilled. The split bearing is then placed with its milled edges against the face of the plate, Fig. 16, and two sliding V-clamps are brought up so as to hold it against the plate, and at the same time align the bearing in a vertical direction. The plate is then removed and the other half of the bearing is placed against the first half, and two more sliding vees are brought up against this second half, on the opposite side of the jig. After this the bushing is brought into position, if it is to be used.

a gage glass, to indicate the quantity of oil in them. The oiling of the various bearings is effected by means of a single sight-feed lubricator having tubes leading to them.

Other Departments.

Fig. 14 shows the machine recently constructed for cutting out asbestos gaskets, which are used chiefly in the pipe joints. They vary from 4 and 5 inches in diameter up to as high as 38 inches in diameter. They were formerly cut out by knives, with the result that considerable material was wasted. The gaskets are now cut out on the top of a table on which is fastened a sheet of zinc and at the center of which is located a center pin on which swings an adjustable cutting rod, which the man in the illustration has in his hand. This

Fig. 14. Device for Cutting out Asbestos Gaskets

rod carries from 1 to 6 adjustable knife rollers. These rollers can be clamped to any point on the rod and fastened by thumb screws. By swinging the rod around very smooth gaskets are cut with one or two turns. Lying on the floor are a number

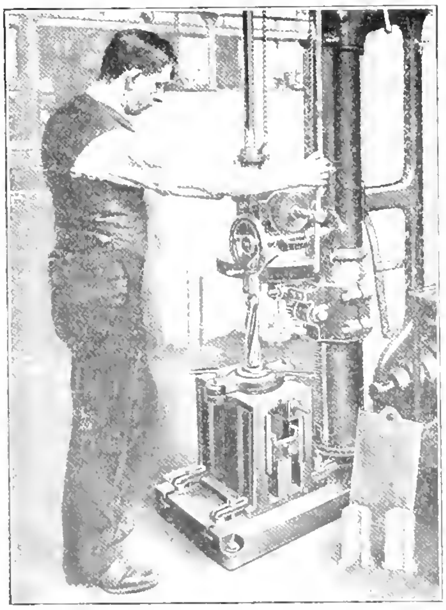

Fig 15

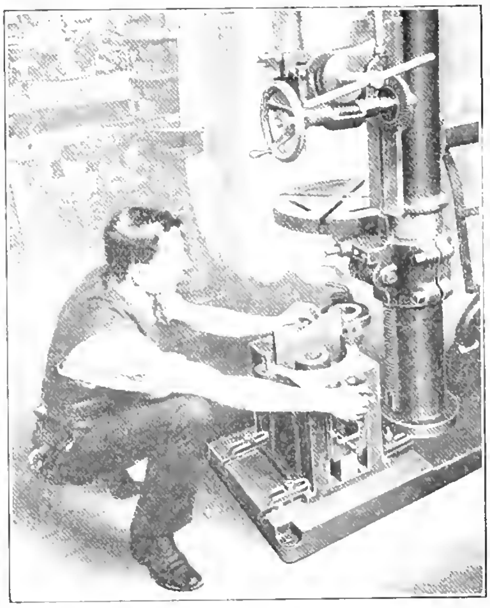

Fig. 16.

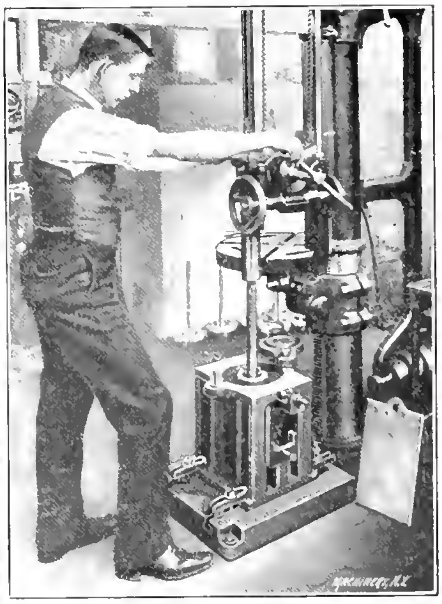

Fig 17.

Fixture for Boring and Reaming the Turbine Bearings

Fig. 17 shows the bearing being bored without the use of the guiding bushings, by means of a bar which runs in a step bearing at the base of the jig.

In connection with the oiling arrangements for the bearings, reference should be made to the design of the wheel casing in which the bearings are located. This casing is in two halves, divided on a horizontal plane, and the upper edge of the lower half has an oil groove running around it, as shown in Fig. 2, to catch any drip that may work in between the two halves. The oil is carried down into pockets in the casting, where the ring oilers reach it, and these pockets are piped to

of gaskets which have been cut out by this device. The gaskets used are about 1-16 inch thick, of asbestos board.

To the right of this gasket-cutting table appears a Pratt & Whitney measuring machine, which reads to one-half of .0001 of an inch by means of a microscope. This machine is employed in measuring gages and is not for shop use.

Fig. 13 represents a general view of the inspecting department. All parts which can be readily handled after being finished in the shop are brought here for inspection. They are accurately gone over by special sets of gages, to see that they are interchangeable. The large parts, such as gear and

wheel cases, are inspected out in the shop. After inspection, each piece is stamped with a designating mark, telling who inspected it, to locate the responsibility for any careless inspection. Every part of the turbine is also numbered in the inspecting department, the number being the same for the

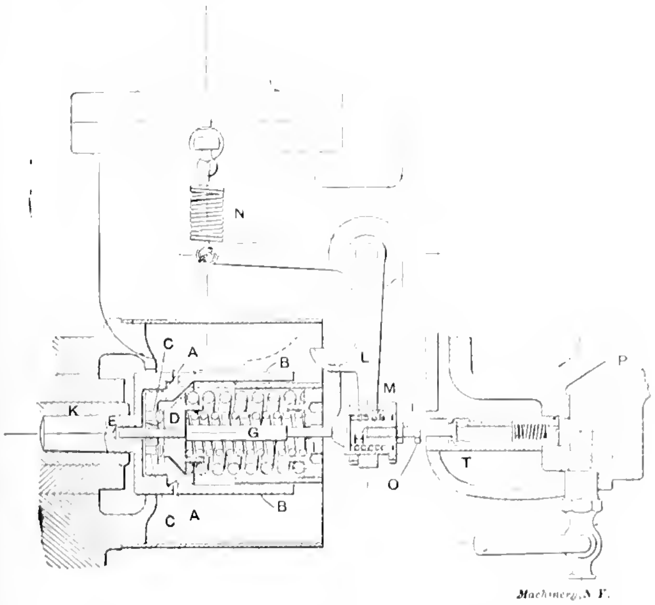

Fig 18. Details of De Laval Governing Arrangement.

same part in the various sizes of turbines, with a letter in front of the number to show the size of the machine. For example, L-429 would represent a 55-horse power gear body, the number "429" being the number of the gear body, and the letter "L" signifying the horse power, which is 55 in this case. The man shown in Fig. 13 kneeling is inspecting with a taper plug gage the hole for the gear shaft in the gear body, which in this case happened to be L-429.

Fig. 20 is a view of the pattern shop, and on the bench in the foreground is an interesting set of patterns used for molding one size of centrifugal pump runner. The particular wheel for which this set of patterns is made is about 21 inches in diameter and is to be used in connection with a 300-horse power pump running at 900 revolutions per minute. At *A* is a half core box inclosing a circular foundation plate on which is the pattern for the spirals located on the inside of the runner. A sweep at *a* is employed for sweeping up the core, which is afterward baked. This makes one-half the core for the inside of the runner; the other half is made on a similar base plate and pattern, shown at *B*. At *C* is the core box for the central hole through the runner, and at *E* is a pattern for one side of the runner, and at its center is the core print for the cylindrical core made in the core box *C*. Pattern *E*, and its mate for the other side of the runner, shown under it, are molded in the foundry, and then the three cores are placed in the mold in the usual manner.

The Governor.

Reference has now been made to most of the principal parts of the turbine, with the exception of the governor and throttle valve which it controls. These are shown in Figs. 18 and 19 respectively. The governor is held in the end of one of the gear shafts by the taper plug *K*, Fig. 18, and is made cylindrical in form, with its outer shell *B B* cut longitudinally into two halves which form the governor weights. These weights are fulcrumed at *A A* and have pins *C C* which press against a collar *D* which takes the thrust of the spiral springs located

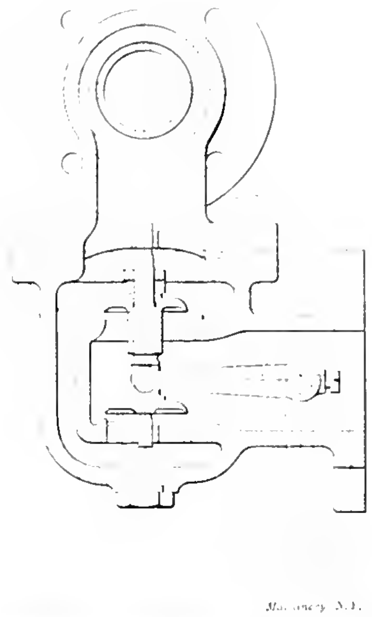

Fig. 19. Regulating Valve.

Fig. 20. View in Pattern Shop showing Patterns for a Centrifugal Pump Wheel

within the governor. The movement of the governor is transmitted through the center spindle G to the bell-crank lever L, which is balanced by a spiral spring N. The shaft supporting this lever passes through the valve casting on the inside of which are a pair of arms connecting with a double-seated throttle valve as shown. In the steam pipe above the valve is a wire cylindrical screen, to prevent any large particles of scale or other material likely to damage the turbine from passing through. It is to be noted that the connection between the center spindle G of the governor and the bell-crank lever L is a flexible connection, and that at the right is a valve T, which connects through the passage P with the wheel casing. In case the throttle valve should stick and the turbine speed go up, the governor would have power enough to overcome the pressure of the spring at the connection H, and the pin O would strike the spindle of the valve T, which latter would admit air to the vacuum chamber in which the wheel revolves. This would immediately put an air brake on the wheel and prevent an acceleration of speed. If for any cause the speed becomes excessive this action takes place.

* * *

WOOD PRESERVATION.

As timber becomes scarcer and more costly the importance of its preservation becomes greater. The decay of timber is principally caused by fungi, but bacteria and insects also play a part. Timber will not decay unless it be subjected to three conditions—air, moisture and warmth; if any one of these conditions is absent there can be no decay. Timber submerged under water so that air is excluded will not decay; neither will it decay if continually dry, or where the temperature is uniformly low. But in ordinary use timber is subjected to all three conditions which favor decay, hence the importance to railways of artificial processes for preserving cross-ties, bridge timbers, etc. The Association of Railway Superintendents of Bridges and Buildings in a committee report submitted at the Chicago meeting in October, outlined some of the methods of preserving timber as follows:

Creosoting.—The creosoting process makes use of dead oil of coal tar which is a distillate of coal tar, a product of the manufacture of illuminating gas. Green timber is subjected to a steaming process 200 to 250 degrees F. for several hours in a closed cylinder to liquefy the sap and to solidify the albumen in the cells. After steaming for some hours the cylinder is exhausted to a partial vacuum to expel the liquids from the interior. After this process is complete the cylinder is filled with dead oil of tar at a temperature of about 175 degrees F. and subjected to a pressure of 80 to 100 pounds per square inch to force the oil into the pores. This is sometimes called the Bethell process.

Burnettizing.—In the Burnettizing process the impregnating fluid used is chloride of zinc which is applied in a water solution similar in method to the creosoting process. After treating, the wood must be thoroughly dried to deposit the salt in the cells, but even when this is done exposure of the wood to water afterward will dissolve the salt and leach it away. While the process is fairly satisfactory for ties it is not good for structural timbers and has been practically abandoned by nearly all European railways.

Kyanizing.—In this process seasoned timber is soaked in a solution of bichloride of mercury (corrosive sublimate) which coagulates the albumen. The solution is very poisonous and corrodes iron and steel, hence is unsuited for structural purposes in which metallic fastenings are used. The process is effective, but dangerous to the health of the workers employed.

Wellhouse.—The Wellhouse process also uses zinc chloride as does the Burnettizing process but adds a small percentage of glue. After the timber has been treated under pressure the zinc chloride solution is drawn off and one of tannin is substituted. The tannin combines with the glue and forms an insoluble substance that effectually seals the pores.

Allardyce.—The Allardyce process makes use of zinc chloride and dead oil of tar, the latter being applied last, and the manner of application being essentially the same for both as explained with the other processes.

Boucherizing.—Sulphate of copper in solution is forced into the timber under heavy hydrostatic pressure. Sulphate of copper attacks iron and is, therefore, objectionable from a structural standpoint.

Thilmany.—Sulphate of copper is first used in the Thilmany process and then a solution of barium chloride, but the process has not shown good results.

Hasselman.—The timber is boiled in a solution of copper, iron and aluminum sulphate to which a small quantity of kainit is added. The results in Germany seem to show that the process is satisfactory.

Creo-Resinate.—In this process the timber is first subjected to a steaming process at 200 degrees F. to evaporate the moisture in the cells; the temperature is then gradually increased to 320 degrees F. and a pressure of 80 pounds per square inch. The pressure is slowly reduced to 26 inches vacuum, and then a solution of dead oil of tar, melted resin and formaldehyde is injected. After this process the timber is placed in another cylinder where a solution of milk of lime is applied at a temperature of 150 degrees F. and a pressure of 200 pounds per square inch.

Vulcanizing.—The vulcanizing process of treating timber consists essentially in subjecting it to a baking process in hot air which is heated to a temperature of about 500 F. by passing over steam coils. The heat coagulates the albumen, expels the water from the cells, kills the organisms therein and seals the cells by transforming the sap into a preservative compound. This method is used with success by the elevated railway systems of several cities.

A QUICK JOB.

The following interesting description of a quick piece of work in replacing a large iron pulley with a wooden pulley, and by this means averting a long shutdown of the plant where the change was made, has been sent us by the Reeves Pulley Company, Columbus, Ind.

On Thursday, October 6, the massive cast-iron main drive pulley, 112 inches diameter, 37 inches face, in the plant of Lafayette Box Board & Paper Co., Lafayette, Indiana, went to pieces.

President Bauer, of the Paper Company, and his superintendent, Mr. Wilson, appreciating the length of time required to get an iron pulley of this size in place, sent their men home, and announced a thirty-day shutdown. They did not know a wooden pulley of this size, and capacitated to handle 600 horse power, could be built, but later in the day Mr. Bauer was persuaded to 'phone Reeves Pulley Company concerning their trouble. The pulley company assured Mr. Bauer that they could furnish him a pulley of the size designated, absolutely guaranteed to carry the load, and the order was placed. Work was commenced on the pulley Friday morning at 7 o'clock, and within eighteen working hours it was completed and en route to its destination. The pulley, accompanied by Superintendent W. S. Jones of the Reeves Company, was taken by Saturday's midnight Pennsylvania Express to Indianapolis, where the Chicago Fast Express of the Big Four was held one hour in order that the pulley might be transferred, and this train in turn delivered it at Lafayette at 3 o'clock Sunday morning. The pulley was here met by a corps of workmen and Superintendent Wilson, who immediately transferred it to the paper plant, where under the direction of Mr. Jones, the installation was completed Sunday afternoon and on Monday morning at 6 o'clock the big mill started as usual.

* * *

A Custodis brick chimney 300 feet high is being built for the New York Steam Heating Company alongside the Manhattan approach of the Blackwell's Island Bridge. It is to have an outside diameter of 29 feet 6 inches at the base, tapering to 17 feet at the top. It will weigh approximately 2,160 tons and will cost $25,000.

* * *

By an error in the engraving, Fig. 1 of Mr. Geo. D. Hayden's letter, "Charts for Forming Tools," in the October issue, .208 was omitted from its place between .192 and .224 under "Given" at the top of the cut. Consequently the quantities to the left as far as the third division space (which was also omitted) are misplaced one space.

ADAMS-FARWELL AUTOMOBILE.

NEW FEATURES AND A NEW TYPE OF ENGINE.

The Adams Co., Dubuque, Ia., have brought out a revolving-cylinder, air-cooled, gasoline motor for automobile use, which possesses many points of novelty. It reverses the ordinary practice, in that the engine cylinders revolve and the crankshaft, which is in a vertical position, remains stationary. The motor is the invention of Mr. F. O. Farwell, superintendent of the Adams Company, and its details have been very carefully worked out during the process of development at the shops of this company. The motor has been tested for a long period under trying conditions and we are informed that its performance has proven satisfactory to its inventor and to the builders, and that it is now placed on the market with the assurance that it will meet any demands that may reasonably be made upon it.

Fig. 1. Automobile with Convertible Front Seat. The Machine can be Controlled from either Seat.

The engine consists of three units, each made up of cylinder, piston, connecting rod, etc. The cylinder castings are bolted together, forming a single rotary element, which acts as a flywheel and is in nearly perfect balance. In a 20 horse-power engine, such as is now built for automobiles, the cylinders have 5-inch bore, the pistons $4\frac{1}{2}$-inch stroke, and the revolving unit, consisting of the three cylinders, pistons, and their connections, weighs only 190 pounds.

The cylinder castings are bolted to a top and bottom cast steel flange which has bronze bushings serving as bearings for the vertical stationary crankshaft. The three pistons are connected to a single crankpin of large proportions by bronze pitmans. Inasmuch as the pistons and cylinders are rotating about different centers, the pistons reciprocate back and forth once during each revolution of the engine.

The light weight of the motor, compared with the usual three-cylinder motor, is brought about by the elimination of many parts found necessary in the engine of the ordinary type. A single central crank case answers for the three cylinders. A single-throw crank, of about one-third the weight of the three-throw crank found in the other type of engine is employed. A single cam operates both inlet and exhaust valves for all the cylinders. Although the engine is light in weight, the rotating parts constitute a flywheel of unusually heavy weight which is conducive to steady running; and the facts that the engine is in so nearly perfect balance and runs on a vertical axis nearly eliminate vibration and adapt the motor especially to automobile driving.

It was determined by experimenting with the engine that the exhaust muffler of the design usually employed could be dispensed with. This is because the rotating cylinders seem to run away from the exhaust gases, as it were, and this action was found to reduce the noise incident to the escape of the burnt gases. The exhaust noise partakes more of the character of the noise of a skyrocket than of the report of a gun. Auxiliary exhaust ports are employed which reduce the pressure before the gases finally discharge to the atmosphere, and we are informed that at low power the exhaust is noiseless, while at full power there is less noise with this system than in the case of an engine of the usual construction working at full power.

Another unlooked-for result brought out in experimenting with the engine was that centrifugal force served to close the valves and that this force was in direct proportion to the requirements. The higher the speed the greater the force and the greater the need for a stiff spring or force to open the valve. The springs actually used are made of light piano wire and are useful only to close the valves in starting the engine when the centrifugal force at the slow starting speed might not be sufficient to overcome the resistance of cold lubricating oil on the valve stems. After the engine is started and has become warmed up the springs are not needed.

One of the most advantageous results of the moving cylinder principle is the effective air cooling accomplished. The cylinders are cast with longitudinal external ribs, to provide a large radiating surface and their rapid rotation draws in the air at the center of the casing which incloses the engine and expels it with a considerable velocity at the periphery, or ends of the cylinders. The air is continuously in contact with every part of each cylinder, and there can be no hot spots in the cylinder walls due to unequal circulation of the air, such as is effected by a fan driving the air against only one side of a cylinder or group of them. The cylinders are found to keep cool and work well in warm weather, and there is nothing to freeze in cold weather.

The foregoing briefly summarizes the most prominent features of the new motor, resulting from the rotating cylinder construction. The inventor has carefully worked out other features, however, which, although they could be applied to engines of other forms of construction, seem to be of quite as great interest to the automobilist as the details already outlined. First of these in importance is that the speed of the motor is controlled by a variable compression system. Ordinarily the speed of an automobile equipped with this engine

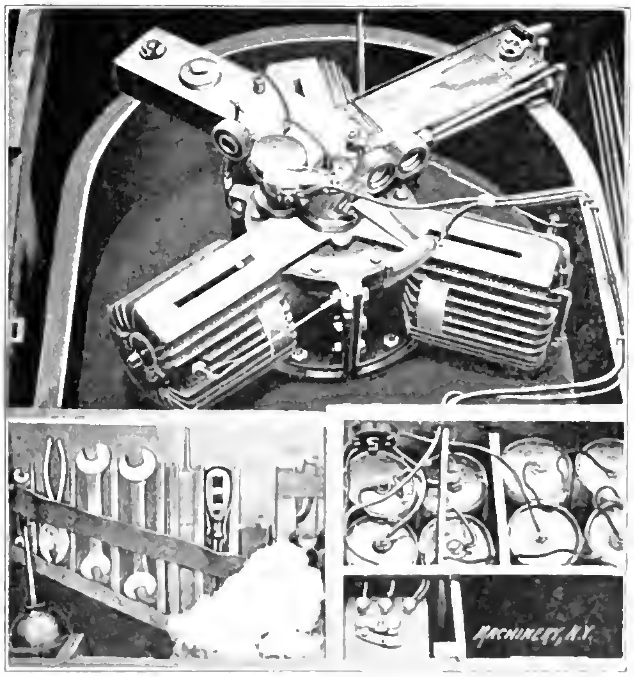

Fig. 2. View of Motor, with Rotating Cylinders, showing it in position in the Vehicle.

may be controlled by changing the speed of the motor, just as in a steam engine; but a speed gear is provided that can be used to pull the machine out of a rut or in climbing an exceptionally steep hill, if found necessary. In the compression system used that part of the charge not needed to give the motor the required power is allowed to escape back by the inlet valve, which is mechanically held open for a part of the compression stroke; that part of the charge so escaping being drawn in by another cylinder. The mechanism is so designed that that part of the charge rejected by any cylinder is first used in the succeeding cylinder, before additional gas is

drawn through the carbureter. There is therefore no waste of gas. When the maximum power is required the inlet valve is closed at the end of the suction stroke and the full charge is compressed to about 95 pounds per square inch. When minimum power is wanted, the inlet valve is not closed until the completion of the compression stroke, and an exceedingly small part of the charge is retained and ignited at atmospheric pressure, giving a gentle expansion.

With this system of control the chauffeur has nothing to do with the point of ignition of the charge by the spark. Instead, the spark is controlled automatically by a device connected with a centrifugal governor and fires the charge at the point producing the highest efficiency at all speeds. It also automatically changes the length of contact of the primary circuit for different speeds, with a view to saving the battery current and contact breaker points. At a speed of 150 revolutions or less the contact is for a period occupying 1-36 of a revolution of the engine; and for a speed of 900 revolutions, the period is during 1-12 of a revolution.

The carbureter is also entirely automatic at all speeds, no attention being required after once adjusting. The proportion of air and gasoline always remains the same, but the quantity of the mixture varies according to the power required and the position of the variable compression cam.

The oiling of all parts of the motor is cared for by a positive-feed oil pump. This consists of a circular barrel in which are four cam-actuated plungers. The barrel is positively driven by a worm gear and will deliver one drop of oil to each of four tubes, carrying the oil to different parts of the engine every 100 revolutions. Two of these tubes lead to a distributing channel in the upper end of the crankshaft and oil the top of each cylinder; one tube leads to the upper end of the wristpin and from thence to the lower crankshaft bearing, a surplus accumulating in the crankcase, which lubricates the valve-operating cams and gears. An opening on each side of each cylinder admits oil from the crankcase to the cylinders, thus oiling each cylinder and piston at three equidistant points. The fourth tube is an extra, and usually is turned to deliver its oil back into the tank. The tank is close to the engine where it is kept warm in the winter time.

Fig. 2 is a view of the motor as situated in the rear of an automobile body. From this position every part of the motor liable to require inspection is readily accessible and exposed to view. Also, the tools required for adjustments, the batteries, spark coils, etc., are all close at hand. In Fig. 1 is shown one of the latest designs of automobile body used by the Adams Company. The fact that the motor is located under the seat makes it possible to adopt the style of convertible carriage illustrated, by which a second seat in front is available in front of the main or fixed seat. The sides and top are removable, and the motor and car can be controlled from either the front or rear seat. The novel features of the car and motor are subjects of patents granted or pending in this and foreign countries.

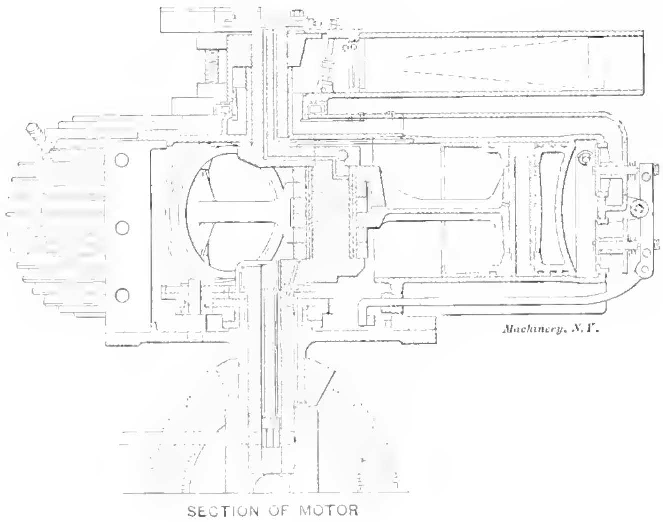

Fig. 3 Sectional Elevation of Engine.

A MODERN PATTERN SHOP AND ITS SYSTEM OF HANDLING PATTERNS.

The new pattern building of the B. F. Sturtevant Co. at Hyde Park, Mass., is divided midway of its length by fire walls inclosing stairs, elevators, etc. One-half the building, with stories respectively 17 and 15 feet, is devoted to the flask and pattern making rooms, while the other half, provided with intermediate floors, making four in all, is utilized for pattern storage. An illustration of the exterior of this pattern building has previously appeared in these columns in connection with a description of the new Sturtevant foundry.

Fig. 1. View in Flask Shop.

The flask-shop measuring about 60 feet by 80 feet is equipped with band, cross-cut and splitting saws, boring machines and lathe, all driven by a 10 horse power Sturtevant motor suspended from the ceiling. The industrial railway runs directly into this room from the foundry, across a distance of about 40 feet and together with an overhead transfer track reduces to a minimum the cost of handling flasks. The lumber for their manufacture is unloaded from cars directly in front of the building. This room includes the metal patternmaker's department equipped with the necessary machine tools. Adjacent thereto is the locker, wash and toilet room for the building.

Immediately above is the pattern shop, abundantly lighted upon three sides and equipped with a full complement of tools. All the power machines are operated by two 10 horse power Sturtevant motors, both being required for ordinary work, but one always serving as a possible relay in case of accident.

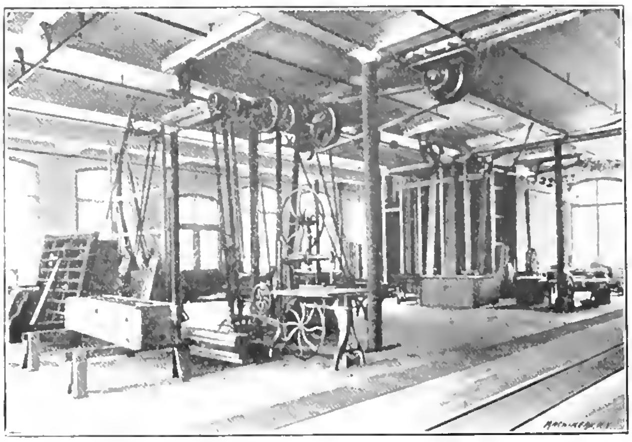

Fig. 2. Pattern Shop.

The benches which accommodate two men each and measure 2 feet 6 inches in width by 16 feet in length are so arranged along the sides of the building that the men all receive a left-shoulder light. Behind each bench is a working table 4 feet wide by 16 feet long. The benches are supported by cast iron legs of special design which were built by the Sturtevant Co.; the same design is used throughout the plant. They are equipped with Emmert vises and their tops are of heavy maple plank. A drying chamber for glued work is provided which receives warm air through the general heat flue from a Sturtevant heating apparatus below.

The first floor of the pattern storage end of the building is of concrete and is designed for the keeping of heavy cast iron patterns. It is served by an industrial railway and turntable which permits of transfer to the elevator and thence to other floors. Communication between the pattern shop and storage department is direct, while the fire risk is reduced to a minimum by a double system of fire doors. Around the pipe columns which support the floors are clamped the pattern shelving brackets which are adjustable to any height. Shelves on the walls afford excellent storage space for the smaller patterns.

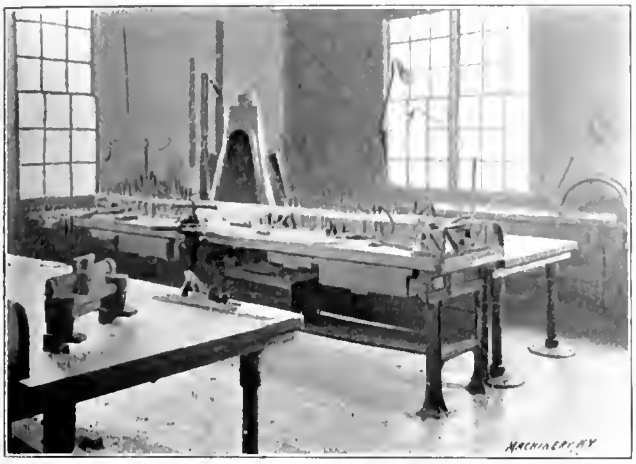

Fig. 3. View of Pattern Shop, showing Benches.

In connection with a description of this shop, the system of handling patterns is of interest. New patterns are numbered consecutively upon the drawings as made. Patterns for gray iron castings take a number without prefix. Patterns for brass castings take a number preceded by 0, those for steel have the number preceded by 00, and so on with a different prefix for each material. The numbers are taken out by the draftsmen in a blotter having columns for data, pattern number, name of pattern and drawing number. This record is afterward transcribed into the "Pattern Record" book by the record clerk in the drafting room.

Fig. 4. Pattern Storage Room.

At the time of taking out a new pattern number a pattern cost card is filled out. This is sent with the drawings to the foreman of the pattern shop and is an order for him to make the pattern described. The time is kept in the pattern shop and entered on this card, as is also the record of stock used. When the pattern is completed, it is inspected by the pattern shop foreman who signs cost card and enters date completed. The pattern is then sent at once to the pattern storage, which is under the supervision of the pattern foreman, and the pattern cost card is returned to the drawing room by the next messenger. The record clerk in the drafting room figures the total cost of the pattern, writing on the card the cost of the labor, stock, etc., and giving the totals. The card is then filed away according to its number. When any work other than pattern work is done a record is kept of the time and material and the pattern shop is given credit. These records give the amount of material and labor chargeable to expense, to which are added a depreciation and fixed charges. The whole is then distributed as a percentage on the hours of pattern labor.

When the patterns are delivered to the pattern storage department proper locations are assigned and records thereof made upon cards, one for each pattern. These cards are filed in the order of the pattern numbers. Four figures, with the addition of a letter, are in every case sufficient to locate a pattern. A given location, for instance, may be 2125B; that is, it is upon the second floor, as shown by the first numeral "2;" it is in the twelfth row of shelves and the fifth division of that row, as shown by the succeeding numbers "12" and "5;" and on the B level, the floor level being designated A and the letters B, C, D, etc., indicating the shelves in their order above.

When the foundry foreman receives an order for castings from the office he issues an order to the pattern storage department. The pattern storage keeper on receipt of same refers to a card index of patterns giving the location of pattern desired. The foreman's order is then attached to the pattern and delivered to the foundry. A metal clip placed upon the card in the card index belonging to the pattern sent out, indicates the pattern is out. When the casting order reaches the foundry a copy is sent to the clerk of the cleaning room, who daily records on the back the number of good and bad castings made from the pattern and keeps the molder informed as to the number of castings required to complete the order. When the required number of castings are made the pattern is returned to the pattern storage, and the metal clip taken from the index card.

LARGE MECHANICAL DRAFT FAN.

In the September number was published a contribution describing the large ventilating fan of the Albespeyre Tunnel of the Langogne-Alais line running between the Atlantic and Mediterranean. This called forth a communication from the Garden City Fan Co., of Chicago, in regard to a large fan for a mechanical draft plant of 500 H. P., showing that the latter is larger than the foreign article, and that we are still sustaining our boasted reputation for big things. The Garden City fan is 20 feet in diameter by 9 feet wide at the

Fan Twenty Feet in Diameter for Mechanical Draft Plant.

periphery, whereas the Albespeyre fan is 6 meters, or 19.7 feet, while the width is 2.5 meters, or 8.2 feet. The weight of the American wheel is 5 tons without the shaft, which is 9 inches in diameter and with its coupling weighs 4500 pounds, making a total weight of $7\frac{1}{2}$ tons on the journal bearings. The fan wheel was incased in a $\frac{3}{4}$ housing of steel measuring 36 feet from the bottom of the bed to the top of the housing, and 26 feet in length. The illustration herewith is from a photograph taken of the fan when in the process of erection in the factory. It is believed by its makers to be the largest fan ever built.

THE HAMILTON-HOLZWARTH STEAM TURBINE.

It has been known for some time that the Hooven-Owens Rentschler Company, Hamilton, O., were developing a steam turbine and that one was being built by them for the St. Louis Exposition. This first machine is now in operation and is direct-connected to a 1,000-kilowatt Bullock generator. The turbine is of the compound impulse type in which there is a series of impulse wheels, each wheel in a separate compartment and driven by jets of steam directed against the wheel buckets by suitably-shaped guide vanes.

The illustrations herewith give a general view of the turbine and show some of the features of construction. For units of 750 kilowatts and upward, the rotating body is divided into two parts, the high- and low-pressure turbine. Smaller turbines are built with the parts inclosed in a single casing. The turbine casings and pedestals for the bearings and the generator are mounted upon a single bedplate, and all steam, oil, and water piping, including the steam inlet, are within and below the bedplate. The steam enters through a separator and passes through the main inlet valve and the regulating valve, all below the bedplate, to the head of the high-pressure turbine. From the steam channel of this head the steam flows through the first set of stationary vanes, forming a complete annulus of steam channels, which direct the steam at the proper angle against the wheel blades, and allow the steam to expand to the lower pressure in the compartment in which the first wheel rotates.

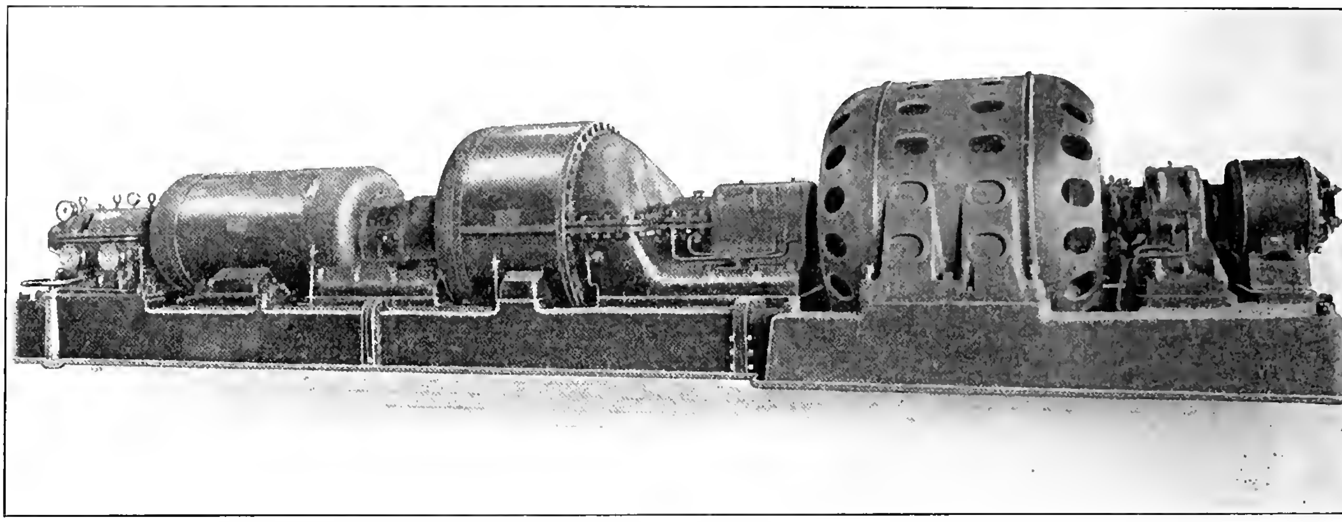

Fig 1. One Thousand K.W. Steam Turbine built by the Hooven, Owens, Rentschler Company, Hamilton, O.

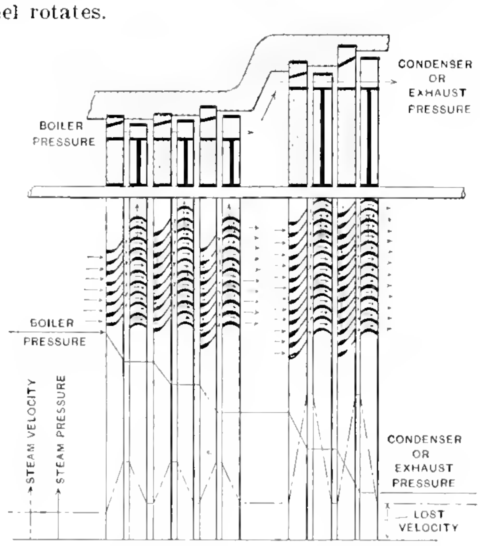

Fig. 2. Diagram showing Principle of Turbine.

From the last running wheel of the high-pressure turbine the steam is led through receiver pipes to the front head of the low-pressure casing, or if there is only one casing, immediately to the condenser. In the low-pressure turbine the steam is distributed in the same manner as in the high-pressure turbine. The low-pressure front head, however, has an additional nozzle through which live steam enters for use in case of overload. The design is such that this steam, which is controlled by the governor, exerts no back pressure upon the steam from the high-pressure turbine. On the contrary, it works like an injector, sucking the steam through the first stationary vanes of the low-pressure turbine. The disks of the low-pressure turbine have guide vanes all around their circumference, as in the high-pressure turbine, and the steam flows through them in a full cylindrical belt, interrupted only by the guide vanes.

The scheme of the turbine and the action of the steam are illustrated in the diagrammatic sketch, Fig. 2. The steam passes through the turbine in the direction indicated by the arrows. The smaller diameter at the left represents the high-pressure turbine, and the larger diameter at the right the low-pressure turbine. The stationary vanes in each disk gradually increase in height, while the vanes are made higher in the successive wheels to accommodate the increasing specific volume of the steam. The wheels receive no unbalanced steam pressure in an axial direction, because the impact of the steam upon the buckets and its reaction in leaving the buckets are equal. If, as in the Parsons turbine, the steam acquired additional velocity in passing through the wheel channels by expanding in these channels, the reaction would be greater than the impact, which would produce an end thrust. In the Hamilton turbine the pressure is the same on both sides of each wheel. The diagram in the lower part of the sketch shows the changing steam pressure and steam velocity so plainly as to need no further explanation.

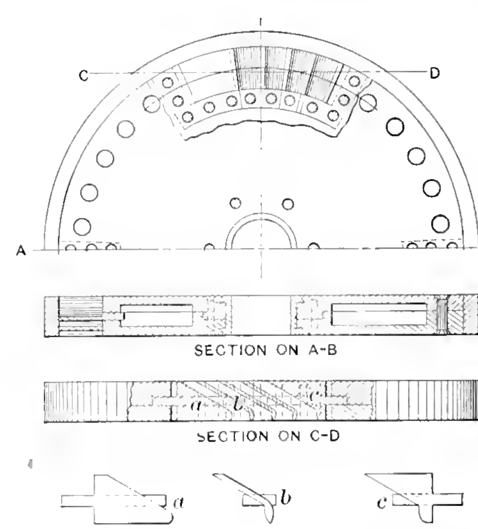

Fig. 3. Details of Stationary Disks and Guide Vanes.

In Figs. 3, 4, and 5 are shown certain details of construction of the turbine. Fig. 3 illustrates the features of the stationary disks, which are built up of two side pieces riveted together. Each vane is a separate piece held by a projection

at its lower end, which fits in an annular groove between the two disks at their periphery. The vanes are of drop-forged steel and are secured by rivets. After they are in position, their outside ends are ground and a steel ring is shrunk on. At *a*, *b*, and *c* are shown three forms in which the drop-forged vanes may be made. In the turbine, as now constructed, however, the vanes extend around the whole periphery, so that the type shown at *b* is the only one required.

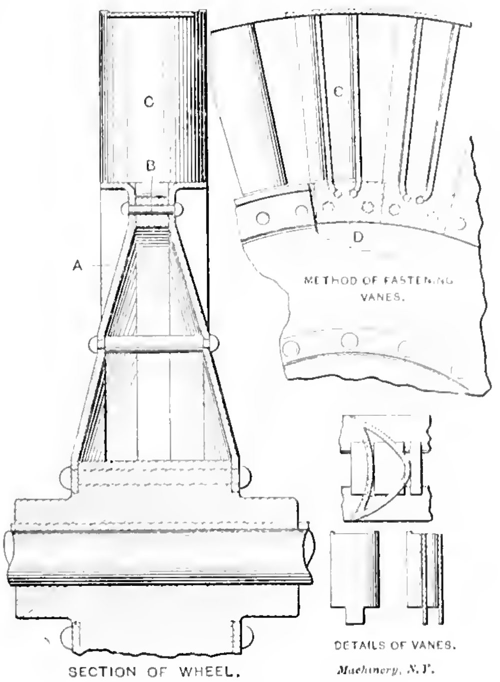

Fig. 4. Details of Turbine Wheel.

Next in importance to the guide vanes and the disks which hold them, is the construction of the rotating wheels, in Fig. 4. These wheels are as light as possible, with cast steel hubs to which are riveted conical disks *A*. There is a space between the disks at their periphery in which are riveted short steel segments *B*. The vanes are attached to these segments, as shown in the sectional view at *D*. The vanes are formed with lips extending downward, and these lips are enlarged at their ends to fit into the enlarged bottom portions of cross channels in the segments *B*. The vanes are so designed that the passages through the wheels have a uniform area from beginning to end, and they are made hollow to reduce their weight. On the outer ends of the vanes a thin steel band is shrunk to give an outside wall to the steam channels. The vanes are milled on both edges to give correct influx and efflux angles.

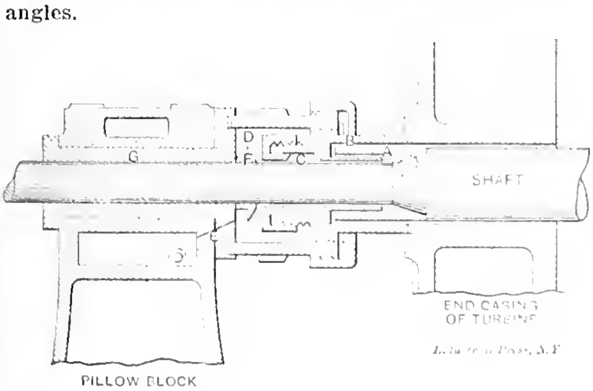

Fig. 5. Gland and Bearing for Shaft.

At Fig. 5 is a sectional view of the bearing and stuffing box for the shaft at the point where it passes through the end of the turbine casing. The shaft is turned to a smaller diameter at its end and runs in a bushing *G*, having a flange bearing against the inner side of the pillow block. At *A* is a cylindrical piece attached to and rotating with the shaft. This piece projects into an annular groove in the piece *B*, but it does not completely fill the groove and a circuitous passage is formed through which the steam must pass before reaching the stuffing box *C*. The object of the passage is to provide condensing surface so the steam itself will not reach the packing. The joint at the stuffing box is thus practically a water-locked joint.

To prevent the oil from working into the turbine a bushing *F* is attached to the shaft which throws off the oil into the space *D* by centrifugal force, where it drips down through a channel *E* into a compartment in the pillow block. Any water escaping through the stuffing box is also collected in the same compartment. The bearing is oiled by a forced oil system, the oil being supplied to the bottom of the bushing.

The high-pressure and low-pressure turbines each have a separate shaft connected by a flexible coupling, and the generator also has its own shaft driven by the turbine through a flexible coupling.

The couplings are a modified form of the familiar disk coupling, having clutch teeth projecting from the face of each disk. The teeth in this case, however, are laminated, which gives them both the necessary strength and flexibility. They are built up of thin steel plates, and the laminated teeth of one disk fit in the spaces between corresponding pairs of teeth in the mating disk.

The governor is of the spring and weight type, adapted to high speed, and controls the turbine by throttling the steam. The throttling takes place at a single balanced valve instead of at the nozzles in the first disk. The governor is constructed on a relay system on the following plan, illustrated in Fig. 6.

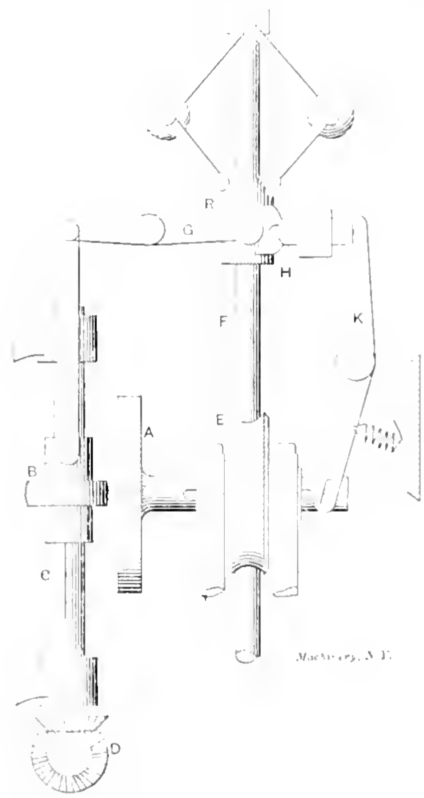

Fig. 6. Diagram of Governor Mechanism.

The regulating valve is controlled by means of a friction disk drive, in which the edge of a small disk or roller is in contact with the face of a continually rotating disk. This disk is driven by a worm and wormwheel from the shaft which operates the governor. In the illustration, *A* is the friction disk, *B* the roller, *C* the splined shaft with which the roller turns but upon which it is free to slide; *D*, bevel gears connecting shaft *C* with the throttle valve; and *E*, a wormwheel driving disk *A* by means of a worm on shaft *F*. At normal speed the governor sleeve is in mid position and roller *B* is at the center of the disk. If the turbine speeds up, however, the governor sleeve will rise, carrying with it the right-hand arm of lever *G*, which will move the roller *B* a corresponding distance downward. At the same time the cam *H* will be thrown to the right by contact with the roller *R* upon the governor sleeve, and this, by means of lever *K*, will move the disk *A* and its shaft to the left in contact with roller *B*, thus imparting a rotary motion to the shaft *C* and closing the throttle valve the necessary amount to bring the speed of the tur-

bine back to normal again, when the several parts will assume their first position. If the speed of the turbine decreases, the action of the mechanism will be entirely similar, except that the roller *B* will be raised instead of lowered and brought in contact with the friction disk at a point above its axis. The disk will therefore rotate shaft *C* in the opposite direction, opening the throttle valve instead of closing it as before. Other features of the governor are that when the angular velocity of the turbine reaches a point $2\frac{1}{2}$ per cent. higher than normal, the governor shuts off steam entirely. Also if the angular velocity falls below a certain percentage of the normal speed, the friction disk is drawn back so that the valve-operating part of the mechanism is inoperative. The methods of accomplishing these results are not shown in the sketch.

This turbine is known as the Hamilton-Holzwarth steam turbine. It is made under patents of Hans Holzwarth, assignor to the Hooven-Owens-Rentschler Company.

CHAIN DRIVE IN A RUBBER MILL.

The conditions of power transmission in rubber mills are probably as severe as found in any class of manufacturing, save perhaps in rolling mills. The nature of the work is very intermittent, causing sudden shocks on the transmission gears; the machines may at one moment be taking the maximum power requirement and in a few moments the power requirement decreasing to zero. For this reason the use of chain drive in the works of the Vulcanized Rubber Co., at Morrisville, Pa., is of much interest because of the severe duty imposed upon it. A prominent mechanical engineer of New York city who rebuilt these works some two years ago, investigated the merits of chain drive and finally adopted the chain manufactured by the Morse Chain Co., of Trumansburg, N. Y., as the one he considered best for the particular service in view. It was used for transmitting power from the main shaft to the line shafts, for transmission from electric motors to line shafting, and to individual machines and tools. The main shaft in the old mill was driven by a spur gearing direct from the engine as is the usual practice in rubber mills, on account of the necessity for a positive drive. In the new mill, however, it was desired to get rid of this method of driving on account of the noise made by the gears, and because clear alleys on each side of the rubber rolls were desired. Moreover, it was desired to group all the engines in one engine room. The plans called for two independent 200 horse-power Corliss engines driving a jack-shaft, and thence the main line of shafting. One engine was a relay to be used in case of breakdown or during repairs. To drive through belting, while possible, was not done because at least 24-foot centers would be required which would make necessary a larger engine room. The reduced center distances possible by the use of chain drive enabled the floor space in the engine room to be reduced some 750 square feet, which amounted to a saving in the cost of the building of $1,000, making the net saving between the cost of the chain and belt drive about $500 in favor of the chain. One engine is connected to the jack-shaft, which is distant from the fly-wheel shaft 7 feet center to center, and which carries other sprocket wheels for connection to the auxiliary engine some 10 feet away. In case one engine gives out, the driving chains are uncoupled and placed on the other sprocket wheels so as to drive with the auxiliary engine. The jack-shaft is connected to the main shaft with Morse chain running on 14-foot centers, making the total distance from the engine to the main shaft about 21 feet. These chains run about 1,150 feet per minute and after a year of constant service, show practically no wear on the rocking joint surface. Besides the main chain drive there are 40 motor drives operating principally individual tools in connection with the work in the factory, and a few of them driving blowers and pumps. The engineer reports that the cost of individual drives from the motors is more with the chain than for leather belting, but that the chain has most decided advantages on account of its positive speed ratio, less space required, shorter center distances, higher efficiency, and greater durability. The efficiency claimed by the makers for a chain is about 99 per cent., and, under the conditions found, the engineer could hardly have expected to have obtained an efficiency of much over 94 per cent. with leather belting. Hence he calculates that the increased cost of the chain drive will be more than offset by the saving in power alone, to say nothing of the other advantages just enumerated.

A Jap Diploma.

President of the Fifth National Industrial Exhibition of Japan, hereby express our thanks for the valuable display of the above mentioned articles, which proved to be special object lessons to our people, in the Foreign Samples Building of the Fifth National Industrial Exhibition held in the 36th year of Meiji." (Signed) Baron Tosuke Hirata, Vice-President of the Fifth National Industrial Exhibition.

* * *

Photography is one of the most valuable means of record, and its use for this purpose is extending into all departments of engineering and mechanical work. A photograph tells its story at a glance, and when dated and supplemented with written notes a series of views makes the best possible record of progress. The cost of making photographs with a proper equipment is not a great expense, and any bright young man can learn to make exposures, develop the negatives and make the prints, in a few days. Some large shops use the camera extensively to show the rate of progress of work, the pictures being taken every few days. To insure accuracy as to the dating it is a practice to set up a small blackboard in the foreground with the date chalked in large letters thereon. Whenever a special job is done a picture should be taken of the set-up of the machine, and of the successive steps taken in the operation. It will often be of material assistance afterward to be able to show just how a certain job was done and what tools were used. In a case of accident or breakdown a record may be of great value, and cases are known where a good picture has been the principal and deciding evidence in a damage suit. With a high-grade lens tracings can be photographed in greatly reduced scale without distortion, and prints made from the negatives may be used in the shop much more conveniently than the large cumbersome blueprints. Lines and dimensions, although of microscopic size, will stand forth with great distinctness even though the tracing is photographed to a scale, say, one-sixth or less of the original size. In fact the usefulness of the camera in the average shop is only limited by the enterprise of those responsible for its application.

CURRENT ITEMS.

The seventh session of the International Railway Congress will be held at Washington, D. C., May 3-14 inclusive. This congress is composed of eminent railway men of all countries, and it meets only once in five years. The coming meeting at Washington will be the first ever held in this country, and it is expected to be of great interest, because of its international scope and representation to American railway men. Unusual efforts will be made by the American committee in charge of the arrangements, to make the meeting a successful one in the matter of exhibiting American railway appliances. The opportunity is one never before experienced by American railway manufacturers for the exploitation of their wares before so many representatives of foreign railways, who are eager to become acquainted at close range with American railway practice. The secretary of the American section of the International Railway Congress is Mr. W. F. Allen, 24 Park Row, New York; the secretary of the committee having charge of the exhibit of railway appliances is Mr. J. Alexander Brown, at the same address.

A meeting of the committee appointed by the American Society for testing materials on standard specifications for iron and steel was recently held in this city. Every step toward the adoption of engineering standards is to be commended, in view of the great convenience of such standards to engineers engaged in constructive work. We think no one would advocate carrying standard construction to the point where individuality would be eliminated. That this point would ever be reached is quite improbable, however, since it has been only with great effort on the part of a few enthusiasts that we now have such few standards as screw threads, pipe threads, etc., and standard methods of testing engines and boilers. Practically the only standard in engineering work up to date is the one adopted two or three years ago by the engine builders and electrical engineers for direct-connected generators, and as far as we know this has not come into very general use.

It is even more important to have standard specifications for materials of construction, upon which safety of life and limb depends, than for any other branch of engineering work. The committee having the matter in charge has already decided upon certain standards for test pieces after conferring with the committee of British engineering standards who are working along the same lines. The investigations of the committee and their recommendations are to extend also to the importance of standard specifications for structural material.

The West Side Young Men's Christian Association of New York City is now offering a course in Advanced Machine Design. This is not merely a course in drawing, but a thorough course in designing. To any young man residing in or near New York City, the course which the association offers will be a rare opportunity. It will consist of the working out of a number of problems, chosen in such a way as to be as helpful as possible to each student. These problems will be worked out by the students just as they would be in a regular drafting-room. Rules and formulas will be used in determining the dimensions of the various parts of the machines. Formulas will be taken, as far as possible, from the standard handbook, such as Kent and Suplee. Only such theory will be introduced into this course as is necessary. This work is intended for men who have not had a technical education, and will be made very practical in its character. The course will not be as extended as in a four-year technical school, but the work will be of inestimable value to men who desire a working knowledge of machine design, at a minimum expense of time and money. Only a nominal tuition fee will be charged. Professor Amasa Trowbridge of Columbia University is to have charge of the work. He is an engineer of wide experience, as well as an able instructor. Each student will receive personal instruction, and, as a knowledge of drawing is required for admission to the course, very rapid progress should be made.

LAUNCHING OF THE CONNECTICUT.

The United States battleship *Connecticut* was launched at the New York Navy Yard, September 29, in the presence of a vast throng of invited guests in the yard, and of a greater multitude on the surrounding piers and every point of vantage from which a view of the vessel could be seen; the promenade of the new Williamsburg Bridge was crowded from shore to shore. She is the first battleship to be built by the Government in several years, and is the largest built by any government to date. The *Connecticut*, with full equipment, will have a total displacement of 15,000 tons, and she and her sister ship, the *Louisiana*, now building at Newport News, will be the two heaviest battleships afloat. The launching was a complete success, passing off without hitch of any kind. The launching ways were greased with 8,500 pounds of tallow, which had been carefully boiled and filtered to remove all grit, to the end that the immense steel hull weighing 6,800 tons should encounter the least possible resistance during its movement into the water. The *Louisiana* was launched by the Newport News Shipbuilding Company some weeks before, and there is a great rivalry between the Navy officials and the private concern to see which can turn out a completed ship first. The outcome will to a large extent affect the future of battleship building in the navy yards. If it is shown that, working under the handicap of an eight-hour day, the navy yards can build battleships as quickly and cheaply as the private concerns, it is probable that most of them will be built by the Government in the future. The large and finely-equipped machine shops of the New York Navy Yard, costing over a million dollars (described in the July, 1902, issue of MACHINERY) were erected for the express purpose of building marine engines and other equipment for new naval vessels. The *Connecticut* is the first vessel built since the new shops were completed.

Further announcement is made of the progress of the work of the committees in planning the Carnegie engineering building. The programme of competition given to competing architects outlined that the auditorium, which is a central feature of the building, should have such capacity only that the voice of an orator or speaker should be distinctly heard in every part of it. It was considered useless to make the auditorium so large that discussions by untrained speakers should become merely a dumb show of moving lip and gestures. It was finally decided that an ordinary speaker could be heard if the audience did not exceed 1,000 on the floor, with the possible addition of 500 in a gallery. There are also to be smaller auditoriums having a capacity of 250 and downward, for monthly reunions.

The main auditorium is to be on the street floor and above this and the smaller meeting rooms will be the office floors, one for each of the societies, with reception rooms, etc. Above these there may be additional floors, if the funds are sufficient. On the top floor which will probably be the twelfth floor from the street will be located the consolidated libraries and the reference and reading rooms. Thus located in the building it will not only be more quiet, but it will be in the better air, above the fly line and will be lighted from the roof. Already the societies are taking up the question of organization and management of the building after its completion.

The engineers' club, which is to occupy a building adjoining that of the three engineering societies, and is to form the social part of the organization, will manage its own building independently as soon as it is completed

* * *

Marine propeller wheels are made right- and left-handed, and the direction of the helix corresponds to that of right- and left-handed screw threads. In other words, the top of a left-handed propeller wheel turns over to the left as the observer stands behind it, when the boat is being driven forward, and right-hand wheel contrariwise. From the point of view of an observer in the boat the water may be regarded as a stationary nut and the direction of rotation in driving ahead is the same as that of a screw thread when turning out of its nut, that is, clockwise for a left-hand screw and contra-clockwise for a right-hand screw

Entered at the Post-Office in New York City as Second-class Matter.

MACHINERY

DESIGN—CONSTRUCTION—OPERATION.

PUBLISHED MONTHLY BY

THE INDUSTRIAL PRESS,

66-70 WEST BROADWAY, NEW YORK CITY.

LESTER G. FRENCH, Editor.
FRED E. ROGERS, Associate Editor.

The receipt of a subscription is acknowledged by sending the current issue. Remittances should be made to THE INDUSTRIAL PRESS, and not to the Editors. Money enclosed in letters is at the risk of the sender. Changes of address must reach us by the 15th to take effect on the following month; give old address as well as new. Single copies can be obtained through any newsdealer.

We solicit communications from practical men on subjects pertaining to machinery, for which the necessary illustrations will be made at our expense. All copy must reach us by the 5th of the month preceding publication.

NOVEMBER, 1904.

NET CIRCULATION FOR OCTOBER, 1904,—22,437 COPIES.

MACHINERY is published in four editions The practical work of the shop is thoroughly covered in the Shop Edition—$1 00 a year, comprising more than 430 reading pages The Engineering Edition—$2.00 a year—contains all the matter in the Shop Edition and about 250 pages a year of additional matter, which includes a complete review of mechanical literature, and forty-eight 6 x 9 data sheets filled with condensed data on machine design, engineering practice and shop work The Foreign Edition, $3.00 a year, comprises the same matter as the Engineering, but is printed on thin paper for transmission abroad. RAILWAY MACHINERY, $2.00 a year, is a special edition, including a variety of matter for railway shop work—same size as Engineering and same number of data sheets

THE CONNECTICUT STILL SAFE.

The authorities at the New York Navy Yard have discovered a veritable "mare's nest" in certain reported attempts to scuttle the *Connecticut*, which was recently launched. While any attempt of this character must mark the perpetrator as a dangerous man and a traitor to his country's interest it nevertheless appears that much more importance has been attached to the discoveries than they merit. The attempts to wreck or injure the vessel, if such they were, gave the newspapers material for many columns of sensational matter, but it seems absurd to give the incident the wild-eyed attention that it has received, because the attempts were so weak and puerile as to be scarcely worthy of attention except as indicating the spirit of the perpetrator. In the natural course of events they could have caused little trouble. In one case, it is alleged that four rivets were drilled through longitudinally so as to make holes one inch or less in diameter through each rivet. "A small leak will sink a ship," but we should not anticipate any serious results from such a trifling leak as caused by four one-inch holes in the bottom of a newly-launched vessel, which must necessarily be carefully inspected from stem to stern immediately following the launching to stop small leaks and to discover other defects that always develop. Another alleged attempt was the fixing of a $1\frac{3}{8}$-inch bolt in one of the launching ways so as to stop the vessel or to rip off plates while on its progress to the water. It is absurd to imagine that such a trifling obstruction as a bolt of this diameter would materially impede the progress of a vessel weighing 6,800 gross tons or over 15,000,000 pounds when once it was under way. It is reported that the vessel acquired a speed of fully fifteen knots per hour by the time she reached the water. Allowing that it was only ten knots, a simple calculation, using the well-known formula for kinetic energy $E = \frac{1}{2} Mv^2$, shows that the energy of a body weighing as much as the *Connecticut* when moving at the rate of ten knots an hour or seventeen feet per second, is over 68,000,000 foot-pounds. This enormous force would be sufficient to shear off nearly 1,000 steel bolts $1\frac{3}{4}$ inches in diameter if they were firmly fixed, but a bolt driven into a timber would simply bend over out of the way, and it is quite doubtful if its presence would have ever been known if it had escaped detection before the launching. As a comparison the resistance of the bolt can be considered to be about the same as that of a ten-penny nail sticking up in the way of a modern locomotive when moving at the same speed as the *Connecticut* down the launching ways. It has been suggested that some of our worthy naval officers, who have so vociferously denounced the dastardly attempts, be granted the degree of E. H. (engineer of hysterics).

* * *

SHOP ARRANGEMENT AND COST OF OUTPUT.

We are wont to "pat ourselves on the back" in self-congratulation anent the wonderful improvements in shop construction and tools, and to "point with pride" to groups of new buildings of great extent, filled with the latest improved machinery and laid out in accordance with the ideas of some so-called expert who has figured all costs down to the sixteenth part of a cent. Unfortunately, however, the anticipated improvement is one of name and appearance only in some cases, especially that of a few railway repair shops which have been sadly disappointing in first results. Instead of showing any marked decrease of the cost of repairing a locomotive, the records may show that the cost is fully as much, or even more, under the new shop roof than under the old one that threatened to fall down at any moment. The work does not go off smoothly, and things are generally highly disagreeable for those in charge and responsible for results.

Railway corporations are notoriously reluctant to pay for competent supervision, and that means good foremen. New shops are often laid out on too broad a scale for the present conditions and the attempt is made to handle the work with the same force of foremen as before. The consequence is that the men are left largely to their own devices because it is physically impossible for the foremen to look after them. A man walking at an ordinary gait will cover a distance of about 300 feet per minute; if he has to exercise general supervision in a shop 600 feet long, a round trip means a journey of not less than 1,200 feet and a minimum time requirement of not less than four minutes. But competent shop supervision means a great deal more than merely walking back and forth. Of course the foregoing is an exaggeration because no competent general foreman chases himself about the shop continually; he depends largely upon the reports of his department foremen, but unless a shop is well-organized there will be a serious lack of coördination unless the general foreman gets out and hustles things along a bit. Again a foreman who has been used to a small shop finds himself utterly lost in some of our modern mammoth structures, and for the time being "loses his grip" on things. If railways must build big shops with the various buildings scattered over a quarter-section, they must expect that one of the offsets to the improved mechanical features will be an increased cost of supervision—but it is money well invested.

In this connection we may mention one bad feature of a new railway repair plant (which mechanically is admirable in every way and leaves little to be desired in the present state of the art) and that is the location of the lavatories. There are only two and they are located nearly 1,000 feet apart. The men consequently must lose considerable time going back and forth, and are exposed to the outer atmosphere while doing so. This is a serious drawback in cold weather as often severe sicknesses are traceable to colds contracted by leaving a warm shop in a state of perspiration. Each shop should have its own lavatory, centrally located, if possible.

* * *

A British patent has been granted for a ball-bearing lathe center which has for its object the reduction of the friction that is put upon tail centers by the weight of the work and the pressure of the cutting tool. The center proper is made with the usual V-point for the reception of the work; the body is reduced in diameter so as to slip within a sleeve in which it turns. The sleeve fits the tail spindle taper socket the same as in the ordinary construction. Races are provided in the center and sleeve for ball bearings of the end-thrust type. Frictional resistance to rotation of the tail center is thus reduced to so little that the center turns with the work instead of the work turning upon it, and thus wear is supposed to be practically done away with.

ENGINEERING REVIEW.

CURRENT EVENTS, TECHNICAL AND MECHANICAL—LEADING ARTICLES OF THE MONTH.

The *Caronia* is a vessel for the Cunard line recently launched at the shipbuilding yard of John Brown & Co., on the Clyde. Her length over all is 678 feet; breadth, 72 feet; depth, 52 feet; gross tonnage, 21,000 tons; draft, 32 feet; displacement at full draft, 29,800 tons; cargo capacity, 12,000 tons; speed, 18 knots. The *Caronia* will have accommodations for 2,650 passengers and will carry a crew of 450.

It is estimated that the New York Rapid Transit Subway will cost complete, $65,000,000; Pennsylvania R. R. tunnel, $50,000,000; New York and New Jersey R. R. tunnel, $15,000,000; Hudson and Manhattan R. R. tunnel, $10,000,000; New York and Queens tunnel, $10,000,000; and New York Central Terminal tunnel, $20,000,000. Total, $170,000,000 for increased rapid transit facilities in Greater New York.

The smallest electric motor in the world has been built by a watchmaker whose work has trained him to handle delicate machinery with the exquisite care required in making a motor that moves with all the regularity of a big machine, and yet is so small that its owner wears it as a scarf-pin. Viewed from a little distance the article has the appearance of a very valuable and rather curiously-designed pin. It is only when standing near to it that its nature can be discovered. The first thing to attract attention is the buzzing of the machine, which, by means of a current obtained from a small battery carried in the vest pocket, is kept in operation at a high rate of speed, with a noise like a bee buzzing. —*Street Railway Review.*

The association of German manufacturers of machine tools, in a report on the condition of the machine-tool industry, complains that sharp competition in foreign markets makes it difficult to obtain orders or remunerative prices, says the consul-general at Frankfort, Germany, under date of September 3, 1904. The importation of American and English machine tools into Germany is notably increasing. During the first half of this year, 1,100 metric tons of foreign machine tools entered Germany, against 450 tons in the same period of the preceding year. The association therefore demands higher tariff rates on imported machine tools, in order to check their importation and thus protect the interests of German manufacturers.

The importance of having light reciprocating parts in engines has been dwelt upon by all authors of works on machine design, but it is quite doubtful if their words have been taken seriously to heart, especially by the designers of locomotives. Many a designer would undoubtedly be greatly surprised if he could be shown the actual results of reducing the weight of reciprocating parts, even so little as 10 per cent. The *Engineer* cites an instance in which the piston of an automobile engine was made of aluminum in order to lighten it as much as possible, and the results are both surprising and gratifying. The speed of the engine was increased 300 revolutions per minute over the maximum that was possible when the heavier cast-iron piston was used.

The use of hot tar or pitch on European highways to prevent dust and to preserve the roadbed from deterioration by water is attracting much attention from those interested in good roads. It appears that ordinary dirt roads, when properly prepared and subjected to the application of hot pitch, can be made practically dustless, and in many respects as good as macadam or asphalt streets, at but a fraction of their cost. The pitch must be applied when the road surface is perfectly dry, and for that reason it must be done during the hot, dry summer months of July, August, and September. The pitch is heated to a temperature of from 140 to 170 degrees F., and thoroughly worked into the road surface, not merely plastered over it. It is poured into the center of the roadway and worked energetically over the surface and into it by means of stiff brooms. This leaves a rough untidy appearance, but a few hours traffic smooths it down, and after that wear is imperceptible for a long time.

We build bridges, skyscrapers, shops, railroads and other engineering structures in very quick time, but for some cause the construction of marine craft appears to be much slower in American shipyards than abroad. This is especially true of the construction of naval vessels; some of our battleships have been five or six years building. During this long period of construction the conditions of warfare, new inventions and improvements in ship construction combine to make a newly-finished battleship of practically obsolete type before she even sees actual service. A writer in *Cassier's Magazine* contends that a battleship could be built in twelve months if its construction was gone at in a business way with complete plans in full detail worked out before construction was started. He says that a large part of the time of building is consumed in making alterations and in finical details of finish which contribute nothing to the efficiency of the vessel as a fighter or as to her seaworthiness.

The committee appointed by the Association of Railway Superintendents of Bridges and Buildings to report at the fourteenth annual convention at Chicago, upon the comparative efficiency of steam hammers and drop hammers for pile drivers, decide in their majority report in favor of the steam hammer. They say that piles can be driven without injury to the pile into almost any kind of earth, and that it is guided home in much better fashion than can be accomplished by the drop-hammer. In Chicago, where perhaps more piles are driven for foundation work than anywhere else in the United States, steam hammers are used almost exclusively. Although the first cost with a steam hammer is much greater than with a drop hammer, its superior efficiency is considered to make the extra cost a good investment. The steam hammer does not require the piles to be banded, and without the bands the heads of the piles are left in better condition than is usually the case with the drop hammer.

The development of the high-powered automobile, capable of running at forty or fifty miles an hour, has brought a train of evil consequences to the users and the public, and it is a matter of grave concern to the automobile industry what the future will bring forth in the matter of repressive legislation if more moderation in speeding on public highways is not displayed by the drivers of these modern Juggernauts. As a matter of fact, however, it is a somewhat difficult matter to accurately judge of the speed of a car and the driver may often believe that he is traveling within the prescribed speed limits when he is considerably exceeding it. A useful device for automobilists who honestly desire to conform to speed regulations is the Warner auto-meter which indicates the rate of progression in direct readings from the slowest up to the highest attainable speeds within the power of the swiftest racers. This device works on the same principle as the cut-meter made by the same concern, and is said to be accurate within limits of one per cent.

A contemporary publishes a picture of a brick chimney 125 feet high which was built from a derrick. The derrick was erected to a somewhat greater height than the chimney, and was built to its full height before the chimney was started. The inside diameter of the chimney is 6½ feet which makes the method of construction from a derrick somewhat puzzling, since the modern method of building chimneys of even smaller bore is to hoist all materials up through the chimney, using the walls of the chimney as a support for the hoisting apparatus and working platform. This method makes falsework unnecessary and considerably reduces the cost of construc-

tion. An analogous method is followed in modern practice in the erection of iron smokestacks. Instead of building a derrick alongside the stack, a short derrick is built around the base to support the stack, as it is being erected. The erection proceeds from the bottom, the succeeding sections being riveted to the bottom of the preceding section, which is held suspended in the air by tackle attached to the top of the derrick.

To even the most casual observer of events, the growing use of cement and concrete in railway and general construction work must be impressive. There are engineers who freely predict that concrete is the coming building material, and that it will supplant wood, brick and stone. When reinforced with iron or steel rods it is used for beams and has the great advantage of high resistance to heat. A sixteen-story office building has been erected in Cincinnati, and this is only one of many complete concrete structures that have been erected in this country and abroad within the past few years. Concrete construction is unique in that its strength increases with age; hence the designer of concrete structures need take no account of the deteriorating effects of age, but on the other hand may rest serene in the knowledge that his allowed factors of safety slowly increase as time passes on. An illustration of this condition occurred in Belgium two or three years ago when a fire occurred in a spinning mill built with concrete floors in 1898. The fire occurred in 1901 and tests made some time after the fire showed that the floors had gained from 130 to 200 pounds per square foot in safe carrying load.

An important change will be made in British patent practice beginning with January, 1905, when no patents will be granted for inventions save only those which stand the test for novelty after a search of the official records for fifty years back. In other words substantially the same practice will be followed as in the granting of German and United States patents. Heretofore in British patent practice, patents have been granted with practically no official search to determine the matter of novelty, so that as a matter of course many worthless patents were granted, but whether in a larger proportion than in American practice where the getting of claims allowed on an exceedingly slender basis has been reduced to a fine art, is doubtful. It is claimed that a large number of so-called "patent agents," "consulting engineers" and other touts have been exploiting the British patent office for their own ends. They have played on human vanity and credulity in getting worthless patents for parties who imagined that their social status was immensely improved by becoming patentees, or whose cupidity was played on by rosy prospects of immense returns for some foolish trifling thing of absolutely no novelty or value.

A consular report from Auckland states that an interesting change has recently been made in the signaling system in New Zealand's railway which it is thought will make collisions absolutely impossible. For a long time, up to a recent date, what is known as the "block" system has been generally used, but the "tablet" system has now been introduced. The essential point in the new system is that no engine driver is allowed to leave a station without a tablet in his possession, and the element of safety rests on the fact that the machines are so made that it is impossible for two of the tablets to be out at the same time. If a driver leaves Auckland for Newmarket with a tablet, that tablet has to be deposited in the machine at Newmarket before another tablet is issued allowing a return train to leave that station for Auckland, and the electrical connection between the two stations makes it impossible to extract a tablet from the Auckland machine until the tablet has been put into the machine at Newmarket. It is claimed by railroad experts that under the new system two trains cannot be on the same section at once, so that the danger of collisions is entirely done away with.

LONGEST PIPE LINE.

The use of the pipe line for the transmission of petroleum over long distances was undoubtedly one of the greatest advances in the handling of a certain class of freight since the invention of the locomotive; the cost of pumping oil is much less than shipping in barrels or tank cars and the danger of fire is minimized. The pumping stations at intervals are the only visible evidences of such a route, and the pipe line itself follows a "bee line" over hill and down dale with absolutely no deviation from a straight line to ease the grades. It lasts indefinitely because of the preservative effect of the oil, and calls for practically no attention save the periodical patrol of the pipe-line walker who covers as much of its length daily as he is able to walk at a stiff gait. Occasionally a leak will spring forth, but it is usually known in the pump stations before it is discovered by the patrol, if of serious proportions. All the pump stations are connected by telegraph or telephone lines, and the amount pumped from each station is transmitted to the next station by wire. This report must tally with the number of barrels received; if it does not it is known that a leak has developed or that an error has been made in the report. The longest pipe line in the United States will be that from Red Fork, Indian Territory, to Bayonne, N. J., a distance of 1,800 miles. The pipe line itself contains thousands of barrels; it requires something like 20,000 barrels to fill the line from Red Fork to Kansas City alone.

TRIPLE VAPOR ENGINE.

The binary-vapor engine using sulphurous acid gas and steam, which was designed and built for Prof. Josse, of the Royal Technical High School, Charlottenburg, Germany, has attracted much attention—more perhaps on account of its theoretical interest than its practical possibilities. Yet when it is considered that this system increases the power production fifty per cent. for the same steam consumption, it must be admitted that there is a powerful advantage in favor of the use of two or more substances having different vaporization temperatures. Another German, Mr. K. Schreber, has shown that with a triple-vapor engine it is possible theoretically to secure a heat efficiency of nearly 38 per cent. He proposes the use of ethylamin, water and aniline. Ethylamin can be advantageously worked between the temperatures of 85 and 180 degrees F.; water in the form of steam between 180 and 360 degrees F.; and aniline between 360 and 600 degrees F. In Mr. Schreber's imaginary engine aniline is heated in a boiler and after passing through the engine, it is cooled in a condenser, the liberated heat being utilized to evaporate water which has already been heated by passing it through an economizer. In the second stage the steam passes through a second engine into a condenser where its heat evaporates ethylamin, also previously heated by the waste gases of the boiler passing through an economizer. The ethylamin works a third engine and is condensed for re-use. If the limits are placed at 70 and 600 degrees F. instead of 85 and 600 degrees, the author of the paper figures that the heat efficiency would be 44.5 per cent.

ALLEGED DISCOVERY OF THE PROCESS FOR MAKING HARD RUBBER.

There was once a machinist named George, who worked at the bench and was always more interested in hearing the quitting time whistle blow than in any other event of the day. One day the first yell of the whistle found him with his hammer in the air, and being alarmed lest it should make even part of a stroke beyond working hours, he permitted the hammer to fall and it broke a bottle containing a certain chemical which happened to be on his bench and the fluid ran over a sheet of rubber that also was on the bench. To wipe up the mass after the whistle had blown was not the way George did business, so he went home. In the morning when he examined the rubber that had soaked all night in the fluid, he found that it was as hard as a piece of board. Here now came in the worldly wisdom of this machinist. Instead of cleaning up his vise bench, and throwing the spoilt rubber and broken chemical bottle into the rubbish box without thinking anything more about the mishap, George reflected that the change in the consistency of the rubber was due to the chemical that had been anointing it all night. Then the question occurred, Would hard rubber have any value as an industrial product? The secret of how to make hard rubber was carefully guarded, a com-

pany was formed to put articles made from it upon the market and the discoverer is now a multi-millionaire.—*Locomotive Engineering.*

RECUPERATIVE POWER OF PEAT.

Page's Magazine, September, 1904.

A good deal has been heard recently about the utilization of peat on a large scale, and it may be interesting to point out that peat differs from coal in that after removal a fresh lot *grows up* again. The rate varies in different parts of the world, but the following are some well authenticated cases:

Lake of Constance—A layer of 3 feet to 4 feet thick in 24 years.

Near Hanover—A layer of 4 feet to 9 feet thick in 30 years.

Valley of Somme—A layer 3 feet thick in 30 to 40 years.

Of course, a great deal depends on the peat-forming value of the mosses, and on various geological and geographical features of the country. Some mosses may only give a foot thickness of peat in 30 years, but taking peat bogs the world over 10 feet in 100 years seems to be a fair average.

Taking these figures and assuming absolutely safe data for working out the horse power, we arrive at rather interesting figures.

Assuming that one cubic foot of cut peat will give 10 pounds of solid fuel, and that 5 pounds of peat fuel are equivalent to one brake horse-power hour, then it can be shown that 640 acres or one square mile of peat bog 10 feet thick, will give:

$$\frac{640 \times 43560 \times 10 \times 10 \text{ lb.}}{5 \text{ lb.}} = 550{,}000{,}000 \text{ B. H. P. hours.}$$

If we assume that the square mile of peat bog grows at the rate of 10 feet in 100 years, then we may say that such a peat bog is good for—

$$\frac{550{,}000{,}000}{365 \times 24 \times 100} = 630 \text{ B. H. P.}$$

for all time. As a matter of fact the working day may very well be taken at 10 hours, so that 1,500 B. H. P. may be calculated as the output of a square mile of peat bog, so worked that it is never permanently diminished.

RELATIVE COST OF CUTTING BY EMERY WHEELS AND BY FILING.

Extract from Paper presented by Mr. T. Dunkin Paret, at the May 12, 1904, Meeting of the Franklin Institute.

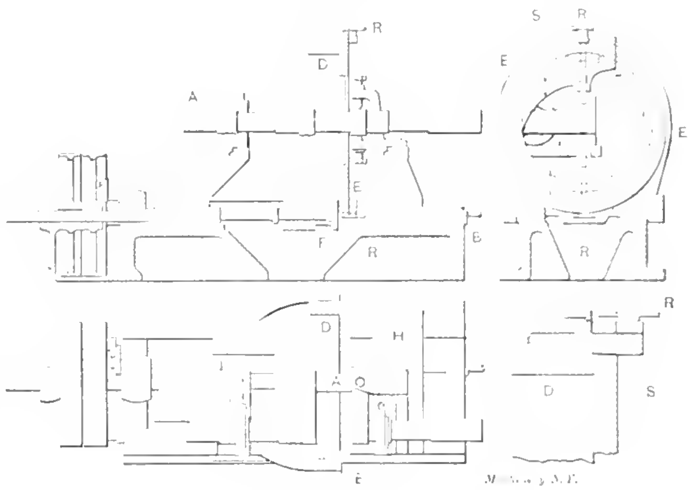
An attempt has been made to arrive at the cost of grinding both on cast and wrought iron, and also at the cost of filing, but it must be remembered that the conclusions which are drawn from very unequal series are not altogether sound. In arriving at these costs, a wheel 10 x 1 is assumed to weigh 7¾ pounds and to cost $1.65—that is, 75 per cent. discount on a list price of $6.60. Labor is calculated at the rate of $1.75 for a day of ten hours. No allowance is made for power. Under these conditions, and counting only the cost of wheel material and the actual time of grinding, at a pressure of 112 pounds, it costs 5 26-100 cents to grind 1 pound of cast iron and 27 53-100 cents for the same quantity of wrought. This cost, so far as it refers to cast iron, is derived from the 214 minutes test of thirty-six wheels. It is interesting to note that the few trials of specially fast cutters show a diminished cost. This diminished cost (on cast iron) is almost the same at 80 and 110 pounds. At 110 pounds the cost of material is greater than at 80 pounds, while the cost of labor is less. At 80 pounds the total cost is 3 40-100 cents per pound; at 110 it is 3 52-100.

A few tests were made with the file on bars furnished for the grinding test, three different machinists being timed. These gave a cost per pound of 29 90-100 cents for cast iron and 74 75-100 cents for wrought. The minute removal by the file for cast iron was 15-100 of 1 ounce; for wrought iron 6-100.

LATHE FOR TURNING CRANKS.

Zeitschrift fur Werkzeugmaschinen und Werkzeuge, April 5, 1904, p. 271.

A lathe attachment made by Emil Capitaine & Co., Frankfort-on-Main for turning cranks and other similar articles is shown herewith. The tools are attached to a rotating ring, that revolves about the center of the part to be turned. In the illustration the device is shown to be formed of two independent parts, that may be separated from each other for the introduction of the work. These two parts *E* and *E'*, when fastened together serve as a support for the rotating ring *D*. The transverse feed is obtained by means of a star wheel *R*.



Crankshaft Lathe.

working through a light spindle *S*. Each section of the ring carries a cutter, so that the work can be executed with two tools at once, thus giving the advantage of having cuts taken on opposite sides which tends to avoid chattering. The crank *A*, to be turned, is fastened to the bolsters *H H*, which are given a longitudinal feed motion by a mechanism not shown.

G. L. F.

KRYPTOL, A NEW SUBSTANCE FOR ELECTRIC HEATING.

Abstract of Consular Report No. 2084 by Frank H. Mason, Berlin.

Among the notable recent German inventions in the field of applied science is an electric resistance material for heating purposes, to which has been given the name "kryptol." The exact method of its preparation and the proportions of its ingredients employed are not disclosed by the specifications of its patent, but it is a mixture of graphite, carborundum, and clay so combined as to form a loose granular mass or powder of four grades or degrees of coarseness, which are severally best adapted to different heating operations.

Electric heat may be developed by two general methods: The electric circuit may be broken, so that a voltaic arc is formed, and the charge in the furnace is thus heated directly, or the current may be transmitted through a conductor that offers enough resistance to generate heat, which is imparted to other substances by contact. This is the indirect electrical heating system, of which kryptol offers the latest and most interesting example.

The two main difficulties inherent in voltaic-arc furnaces are (1) Only very high temperatures are developed, which are difficult to modify or control, and (2) the arc consists largely of incandescent particles of (usually carbon) electrodes, which render the flame so impure as to preclude its use for many important purposes. Both of these defects are remedied by kryptol, which develops heat of any desired intensity from a gentle warmth up to 5,400 degrees F., and is clean and free from dust and other impurities. Moreover, it avoids the use of platinum, nickel, and other metallic wires and foils that have been hitherto used in resistance furnaces, thereby securing important economy and avoiding the danger of short circuiting and other accidents, which is always more or less present when metallic spirals in connection with crucibles are used.

The property of kryptol, upon which its efficiency depends, is the fact that it offers to an electric current the requisite degree of resistance to generate a high degree of heat without destruction to its own substance. The apparatus consists simply of a chamotte or earthenware plate inclosed at its edges in a wooden frame and bounded at two opposite sides

by carbon electrodes which rest upon the plate and are connected by insulated wire conductors with a current supply, forming an electric current when the break between the electrodes is closed. Upon the chamotte plate, which is usually about two feet square, but may be of any convenient size, is loosely strewn the granulated kryptol to a depth of about an inch. When the kryptol is laid continuously across the plate it forms the electrical connection between the two electrodes and closes the circuit. When, however, the kryptol is brushed or scraped aside so that an open, uncovered space is formed through the layer across the plate, the circuit is broken and the apparatus remains, so to speak, dead. If now the kryptol is brushed into the open space, so as to form a connection between the two masses lying against the electrodes on either side, the circuit is at once restored, and the kryptol forming this thin connecting layer begins to sparkle and glow, becoming in a few moments incandescent and generating a heat that will raise cold water to boiling in three or four minutes.

A peculiarity is that the incandescent action takes place only at the places where the layer of kryptol on the plate is thinnest, and it is therefore easily possible to create heat just in the place where it is wanted and not elsewhere, for in this case the thick bed of granular material on other portions of the plate remains cool and impassive and may be touched or stirred by the naked hand with entire impunity. The finer the grains of kryptol the less active is the incandescence, and it is for this reason that the four different grades or numbers of the material are made, to be used as may be required in generating different temperatures.

This extreme tractability, by which the temperature can be absolutely regulated by increasing or diminishing the strength of the current or by altering the thickness of the kryptol layer, one or both, renders it applicable to a large variety of practical uses; it lends itself with great convenience to all the finer smelting operations in scientific and industrial metallurgy. These operations may be carried on by means of a small crucible furnace, which consists of an iron shell with an enamel lining filled with coarse-grained kryptol, in the center of which is hung a movable graphite crucible, in which any temperature up to 3,600 degrees F. may be generated. With a current of 15 amperes, nickel, the smelting point of which is about 2,900 degrees F., may be fused in about six minutes.

Some of the steel and cutlery manufacturers in Westphalia are experimenting with kryptol with a view to its employment for tempering, annealing, and case-hardening steel and iron bars, knives, scissors, and other implements. Such processes would become thereby automatic and independent of the skill of the workman. As the ingredients of kryptol will withstand any temperature up to 5,400 degrees F., its use for heating up to that limit is restricted only by the nature of the material of which the furnace and crucible are composed. Being itself a poor conductor of heat, it retains its warmth for a long time.

For chemical laboratories the new material has already been adopted by the University of Berlin, the Technical College at Aix la Chapelle, the Imperial health office at Berlin, and other State institutions. When used in ovens and heating devices of various patterns it enables the chemist to heat substances to any desired temperature and to maintain an unvarying degree of heat for an indefinite period. In elementary organic analysis it is frequently necessary to heat parts of the substance under examination to different temperatures and to leave another portion not heated at all. For this purpose a simple but effective apparatus has been devised. It consists of an iron frame on which is laid a fire-brick trough or gutter, glazed inside and filled with kryptol. In this is laid the combustion pipe, which may be a glass tube, containing the material to be treated. The current being sent through the whole, even mass of kryptol, heats the tube uniformly throughout its length; but when it is desired to heat one portion to a high temperature, it is only necessary to scrape the kryptol aside and reduce the thickness of the layer under that part of the tube, when it at once begins to glow with accelerated heat, while the temperature of the other parts remains unchanged. If it is desired to withdraw or exclude the heat entirely from the central part of the tube, two copper forks, which slide along a brass conductor, are introduced into the kryptol, which take up the current and pass it by the conductor over the intervening space, leaving the kryptol and that section of the tube cold and excluded from the heating operation.

A NEW PROCESS FOR THE PROTECTION OF IRON AND STEEL FROM CORROSION.

Abstract of Article by Sherard Cowper-Cowles in the Electro-Chemist and Metallurgist, June, 1904.

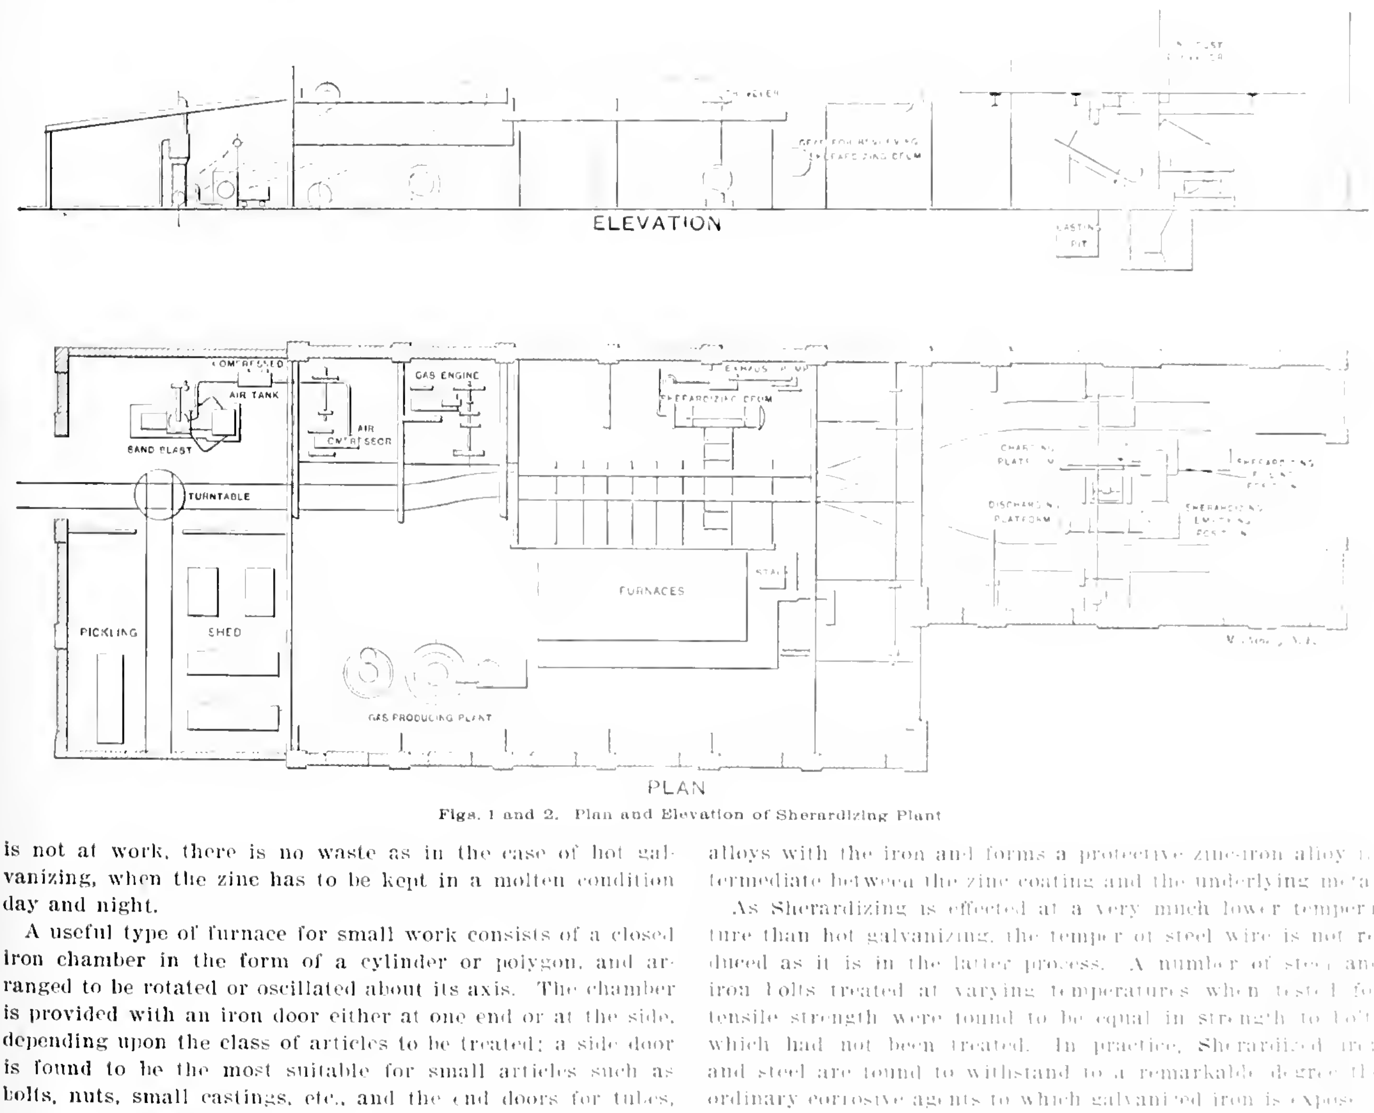
Zinc has proved the most effective coating for iron and steel, and hot galvanizing, with all its attendant disadvantages, is the process most extensively used for applying the zinc coating. Electro-zincing or cold galvanizing is used for special classes of work, and is extensively employed by the Admiralty for giving boiler tubes a thin flashing of zinc for the purpose of detecting flaws and protecting the tubes from corrosion during the time of assembling and erection. Works have just been completed for a new process to which the name of "Sherardizing" has been given. One point of particular interest about the new process is that iron and steel can be coated with an even deposit of zinc at a temperature of several huudreds of degrees below the melting-point of zinc.

The first step in the process is to free the iron from scale and oxide by any of the well-known methods, such as dipping in an acid solution or sand-blasting. The articles to be rendered rustless are then placed in a closed iron receptacle, charged with zinc dust, which is heated to a temperature of from 500 degrees to 600 degrees F. for a few hours and allowed to cool; the drum is then opened and the iron articles removed, when they are found to be coated with a fine homogeneous covering of zinc, the thickness depending on the temperature and the length of time. It will be observed that the temperature required to bring about this result is about 200 degrees below the melting-point of zinc. The low temperature required makes the process cheap as compared to the process of dipping in molten zinc, and has the additional advantage that it does not deteriorate iron or steel of small section to the same extent as hot galvanizing. The whole of the zinc dust is consumed; there is no waste of zinc as in the hot galvanizing process. This new process of galvanizing is not limited to the coating of iron with zinc, it has been successfully applied to coating iron with copper aluminum and antimony. It has also been applied to various other metals, for instance, aluminum and copper with zinc. Copper and its alloys subjected to this process are casehardened on the surface, and can be rendered so hard as to turn the edge of a steel tool.

The zinc powder used in the process is the zinc dust of commerce, and must not be confused with zinc oxide; it is obtained during the process of distilling zinc from its ores. Zinc dust at the present time is used for a variety of purposes, and can be obtained in any desired quantity. The average price of zinc dust for the year 1903 was $95 per ton, (Great Britain) which is slightly below the average price of virgin spelter. The analysis of two samples of zinc dust such as are employed for Sherardizing gave respectively 85 and 85.06 per cent. and 81.86 per cent. metallic zinc. Both samples, when examined under the microscope, seemed to contain small bright metallic beads, unevenly distributed through the dust, and it is probable that this may account for the different percentage given by analysis. One of the peculiar properties of zinc dust is that it cannot be smelted or reduced to the metallic form under ordinary conditions, even when heated to a very high temperature under considerable pressure. This property is very advantageous for the new process of dry galvanizing, as it does away with the risk there might otherwise be of melting the finely-divided zinc by overheating the furnace. The receptacle in which the zinc dust is placed and heated is preferably air-tight and the air exhausted so as to prevent the formation of too much zinc oxide; or, if this is not feasible, it is advisable to add about three per cent. of carbon in a very fine state of division. If the percentage of oxide is allowed to increase beyond certain limits it is found that the deposits become dull in appearance instead of having

a bright metallic luster, although good deposits of zinc can be obtained from zinc dust varying considerably in composition. To prevent the iron receptacle in which the process of Sherardizing is carried on from becoming coated with zinc, it is found advantageous to coat the inside of the drum with plumbago or black lead. Articles coated with grease receive as good, if not a better coating of zinc than those which are free from grease. This fact is of considerable importance, as it enables machined work, such as bolts, nuts, screws, etc., to be thrown direct after machining into the Sherardizing drum without any preparation or cleaning. The articles when they have been heated in the zinc dust for the period necessary to obtain the thickness of zinc required, can be removed, while the zinc dust is still hot; although the better practice is to allow the zinc dust to cool to a temperature at which the articles can be readily handled, as the deposit of zinc is whiter and less oxide of zinc is formed. The new process of dry galvanizing offers many facilities and great economy to those manufacturers who have not sufficient work to keep a large bath of molten zinc continuously at work. Articles can be Sherardized at a few hour's notice, starting all cold, as the drums can readily be heated by gas or coke furnaces, the whole operation occupying only a few hours. When the plant to the back of the furnace. The discharging or charging of the drum is effected by running the truck on which the drum is placed onto a table, the latter being tilted by gearing so that the drum can be discharged or charged with zinc dust from a chute above. After being charged with zinc dust and the materials to be galvanized the drum is brought to a horizontal position, the cover closed and the air exhausted, when it is ready to be charged into the furnace.

The comparison of the surfaces obtained by hot and cold galvanizing and Sherardizing is different in each case, but they can readily be distinguished by anybody conversant with the three processes. In the case of hot galvanizing, the surface is spangled, or has the appearance of cast-metal. In the case of cold galvanizing, the surface is free from spangles and has a matte or frosted surface, uniform if the work has been well executed. Sherardizing is again distinctive from the two former processes; the general appearance resembles more that of cold galvanizing than hot galvanizing, but is more lustrous and metallic, and is uniformly distributed over the whole surface, which is not the case with the hot and cold galvanizing processes. The Sherardizing process, although similar to cold galvanizing in some respects, is also similar to hot galvanizing in other respects, inasmuch as the zinc



Figs. 1 and 2. Plan and Elevation of Sherardizing Plant

is not at work, there is no waste as in the case of hot galvanizing, when the zinc has to be kept in a molten condition day and night.

A useful type of furnace for small work consists of a closed iron chamber in the form of a cylinder or polygon, and arranged to be rotated or oscillated about its axis. The chamber is provided with an iron door either at one end or at the side, depending upon the class of articles to be treated; a side door is found to be the most suitable for small articles such as bolts, nuts, small castings, etc., and the end doors for tubes, oblong or cylindrical articles. In the latter case the cylinder is oscillated and rotated on its axis; in the former case it is rotated and provided with baffle plates to insure the articles under treatment being turned over and thus becoming uniformly coated by bringing all parts into intimate contact with the zinc dust.

Figs. 1 and 2 show the general arrangement of a Sherardizing plant which has recently been completed, comprising four furnaces capable of taking drums 2 feet by 8 feet. These drums will hold about two tons of material, the weight depending on how closely the articles pack. The furnaces are heated by Dowson producer gas, which is led by iron pipes alloys with the iron and forms a protective zinc-iron alloy intermediate between the zinc coating and the underlying metal.

As Sherardizing is effected at a very much lower temperature than hot galvanizing, the temper of steel wire is not reduced as it is in the latter process. A number of steel and iron bolts treated at varying temperatures when tested for tensile strength were found to be equal in strength to bolts which had not been treated. In practice, Sherardized iron and steel are found to withstand to a remarkable degree the ordinary corrosive agents to which galvanized iron is exposed; even after the apparent removal of all the zinc by filing or abrasion the iron is still non-corrosive. This valuable property is doubtless due to the protective action of the zinc-iron alloy formed on the boundary line between the iron and zinc. The dry process of galvanizing is cheaper than hot galvanizing for the following reasons:

1. Less zinc is required to give the same protective coating, as the zinc is evenly distributed. 2. The temperature required is low. 3. The labor is less, as the articles do not require to be cleaned as carefully as in hot galvanizing. 4. No flux is required, no dross or skimmings are formed. 5. There is no danger of explosion or breaking of castings and distort

ing of thin iron work. 6. Sherardizing machine work does not require refitting, as the coating is evenly distributed. 7. There is no reduction in tensile strength as in the case of hot galvanizing. 8. The coating is more uniform and even than that obtained by hot or cold galvanizing. 9. The work can be placed direct in the Sherardizing drum from the pickling vat without drying. 10. The process can be worked intermittently without waste. 11. Iron can be coated with zinc to any desired thickness.

TRADES AND FACES.

English Mechanic and World of Science, August 19, 1904, p. 26.

It is an undisputed fact that a man's trade or profession affects, to a more or less noticeable extent, not only his disposition, but even his physiognomy. That certain faces appertain to certain callings is a matter of everyday observation. The expression of the "horsey" man—be he trainer, jockey, or groom—is quite unmistakable and peculiar. The professional cast of features of the doctor or the lawyer is equally well known, and yet more strikingly distinctive is the face of the actor. Butchers and shoemakers, tailors, publicans, and men-servants all have facial peculiarities which they hold in common with all other members of their trade, and to a keen observer of expression all workers of whatever station bear upon their features the impress of their labor. One specially instructive instance, among many others, has been related by a well-known medical man. In his work as surgeon in the hospital of a shipbuilding town, he was struck with the lowering brows and forbidding expressions of the riveters and boiler-smiths with whom he came in contact. Only by experience did he come to understand that the apparent watchful hostility which each seemed to exhibit was in reality a trick of the countenance merely, and not at all indicative of the actual feelings. And pondering over this he arrived finally at the conclusion that the scowling look, which he maintains is common to all kinds of smiths, is due to the constant automatic contraction of the brow to protect the eyes from the flying sparks, as the heavy sledge descends on the glowing metal. A blacksmith is, as a rule, credited with being a serious and downright man, who "looks the whole world in the face" and stands no nonsense. It has been suggested that the mere act of striking heavy blows, accompanied as it always is with a flush and a frown, has about it so much suggestion of wrath and determination as in time to affect the character to a certain extent. In the case of the shipbuilders also their work is so noisy as to render them all slightly deaf, which infirmity always gives a closely watchful expression to the features. Another curious, and some may think far-fetched, explanation of a "trade expression" has been given in the case of the tailor. Let anyone watch the face of a person engaged in cutting a thick piece of material with a pair of scissors, and it will be seen that the lower part of the face works in involuntary unison with the blades. May not (so it is argued) the constant working of a tailor's jaws concomitantly with his shears help largely toward bringing about that cast of countenance which distinguishes him?

The well-known and recognized type of face belonging to the horsey man has its peculiarity chiefly in the set of the mouth and chin. This is explained from the fact that the muscles which close the jaws and compress the lips are always called into play when we are asserting our will over that of a horse. The incessant manifestations of his own power and will over that of an animal tends to give that firmness of jaw and thinness of lip which a horseman wears. It is somewhat different when the command is exercised over men instead of animals. The firm mouth is still seen in the drill-sergeant; but the commanding eye—which is absent in the groom—is also added, because in dealing with men the higher method of expressing authority is made use of. Generally speaking, it is strenuous contest with ever-recurring minor difficulties which produces thin and compressed lips. Many housewives who suffer the little worries of life to prey upon them, or whose existences are a perpetual struggle to make both ends meet, exhibit this peculiarity, even to extremes. Compressed lips are generally rather a sign of weakness than strength. A strong will is above the perpetual petty strife they indicate. The commanding officer, sure of his men's obedience, lacks the look of tension which his sergeants wear, and that absolute monarch the sea-captain, though his face carries authority and power, has the easily-set mouth of confident assurance. It has been remarked that there is a certain marked resemblance between the types of face, especially the calm lips, belonging to the naval officer and the engine-driver, brought about by the fact that both are absolute masters of the powers they control.

OBITUARY.

J. Ramp.

Mr. J. B. Ramp, one of the men who witnessed the most important years in the mechanical development of this country, died on September 11th, at Burlington, Iowa. During his long career he was continuously engaged in the foundry business. He was born in 1830, in New York City, and began to learn the foundry trade in his thirteenth year, taking the position of foreman when he was 21 in the shop where he served his apprenticeship, at Trenton, N. J.

Mr. Ramp served four years as a volunteer in the Federal Army and returned at the close of the war to accept a position with the Turner & Vaughn Iron Works of Cuyahoga Falls, Ohio, where he was superintendent of the foundry until the time of the erection of the large Mississippi River locks at Keokuk, Iowa. The foundry business at this point needed a man who could successfully produce the large and complicated casting necessary for the construction of these locks and it was this interest that induced him to come West.

In 1882 Mr. Ramp accepted a situation with the Murray Iron Works Co., of Burlington, Iowa., where he spent the rest of his career as superintendent of the foundry department. During his twenty-two years' service there the foundry has grown to three times its original size and capacity, and is to-day said to be the best equipped foundry in the West. During Mr. Ramp's direction there has never been a strike, and not until late years was there any regular organized union. He endeavored to bring the workmen to see that their foreman was their best friend, while able management and energetic, resourceful efforts on his part made his work profitable to the company. Molders who entered the shop for the first time were usually impressed with its orderly appearance and systematic arrangement, and many who served their apprenticeship under Mr. Ramp command first-class positions to-day. Among these are Mr. Ramp's two oldest sons, Herbert M. Ramp, superintendent of the General Electric Company's foundry and iron department, Schenectady, N. Y., and Paul R. Ramp, superintendent of the foundry department of the Wheeler Condenser and Engineering Works, Carteret, N. J.

Seven or eight years ago Mr. Ramp devised a molding machine to do the heavy ramming involved in making heavy castings. The machine has since proved its efficiency and durability and is in operation to-day. Cars are arranged to carry the heavy flasks under an air cylinder press, where the mold is rammed evenly in an instant and then drawn away. The past year the machine was enlarged and improved so that four operators can be at work at the same machine and two whole molds can be made at the same time.

* * *

To get a nicely mottled effect on casehardened work a toolmaker recommends that instead of dipping it all under at once in the hardening bath, the dipping be done jerkily; the result is a series of mottled bars across the work, each of which denotes its position at the surface of the bath as it was momentarily arrested in the plunge.

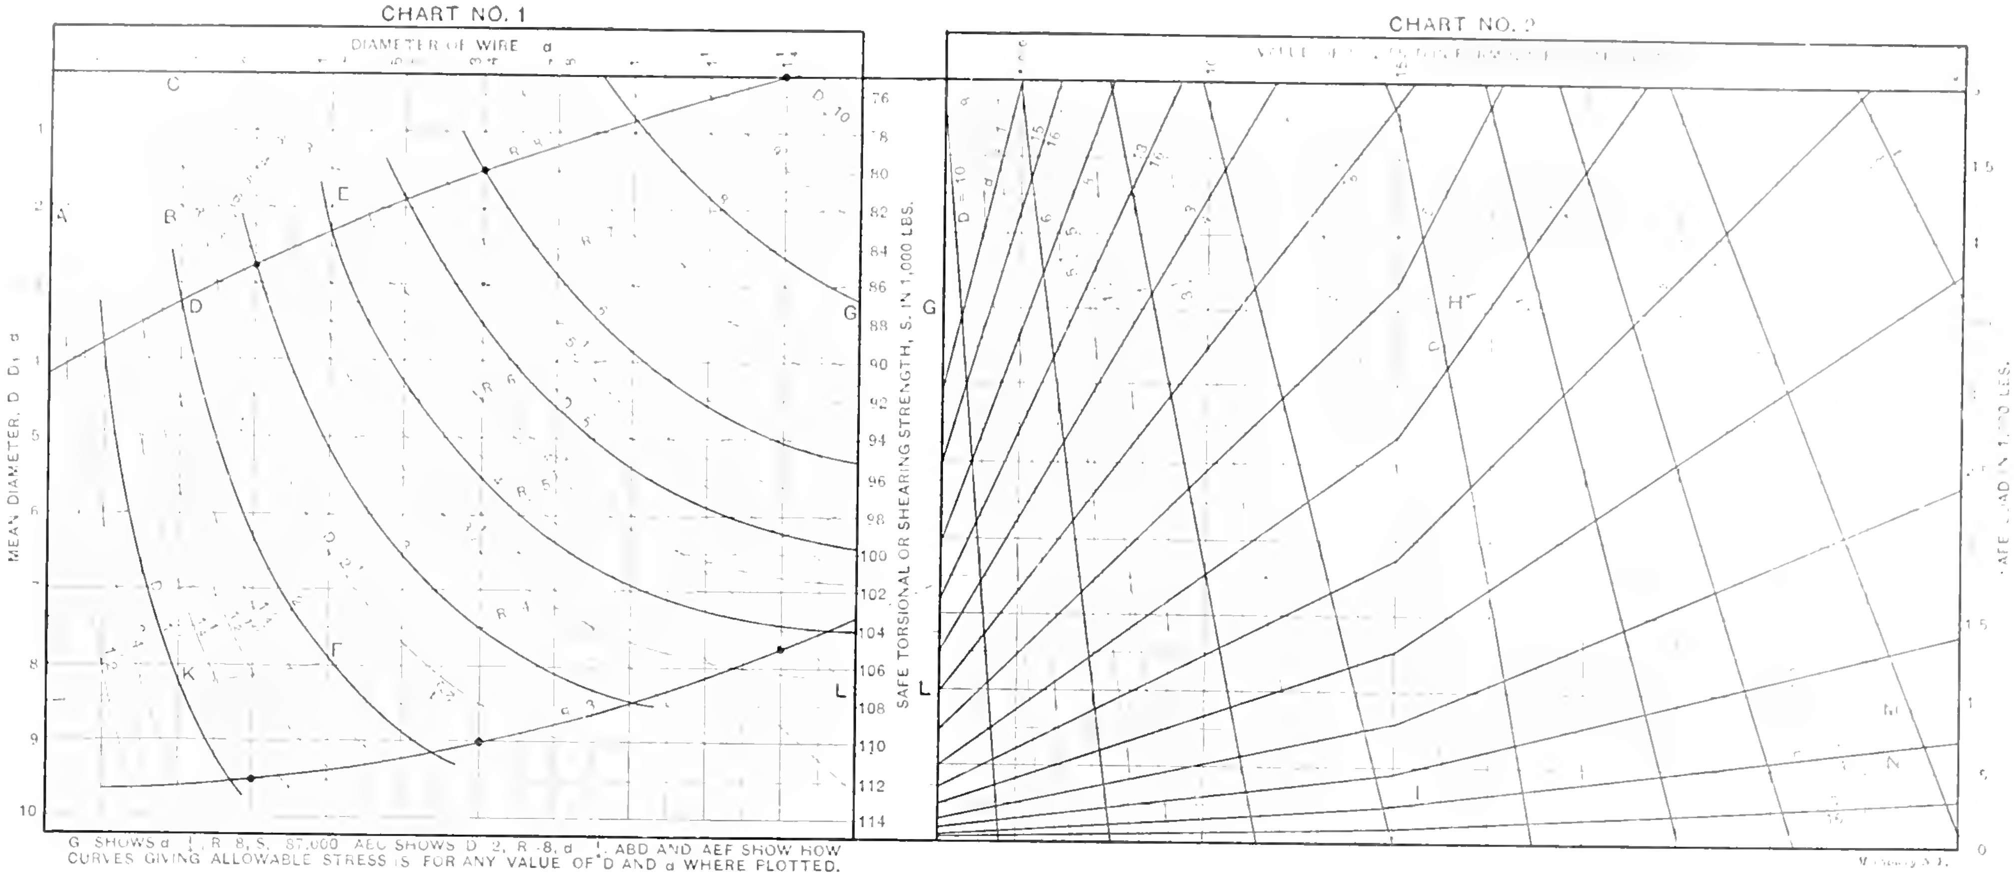
The bridge over the Zambesi River at Victoria Falls on the Cape-to-Cairo railroad in Africa is 420 feet above the low water level.



These two Diagrams show the Method of Constructing Chart No. 3. They are Drawn to the same Scale as the latter.

CHARTS IN DESIGNING.—3.

HELICAL SPRINGS.

JOHN S. MYERS.

Desired: A chart for helical springs of round steel giving the safe load and deflection of same. This series of charts is intended to illustrate the development of curved line charts from straight line ones.

The formula for safe load is $P = \dfrac{Sd^3}{2.55\,D}$, where P = safe working load in lbs., S = safe torsional or shearing strength of bars, and D = mean diameter of coil = outside diameter D_1 —diameter of bar d.

From "Machine Design," by Prof. C. H. Benjamin, the safe value of S as deduced by experiment,* varies with the ratio of mean diameter of coil to diameter of bar, and also with the size of bar used. Safe values are given in the following table, where R = the above ratio.

For bars below ⅜-inch diameter,

$R = 3.\quad S = 112{,}000.$
$R = 8.\quad S = 85{,}000.$

For bars 7-16 inch to ¾ inch diameter,

$R = 3.\quad S = 110{,}000.$
$R = 8.\quad S = 80{,}000.$

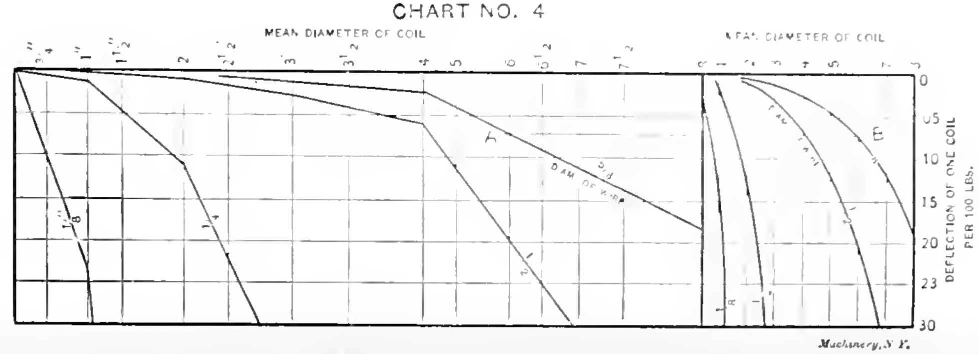
For bars 13-16-inch to 1¼-inch diameter,

$R = 3.\quad S = 105{,}000.$
$R = 8.\quad S = 75{,}000.$

In chart No. 1 the diameter of wire was first laid out on a uniform scale at the top of the chart and values of S ranging from 75,000 to 114,000 on the side of the chart. The stress as given in the table above was then spotted off for $R = 3$ and $R = 8$, on the line corresponding to diameter of bar, and a curve $R = 8$ and $R = 3$ drawn through the points.

The intervening space was then divided into 5 equal parts

CHART NO. 4



Showing the Method of Constructing Chart No 5.

* These experiments were conducted by Mr. Roy A. French and were part of his thesis for a master's degree.

CHART NO. 3

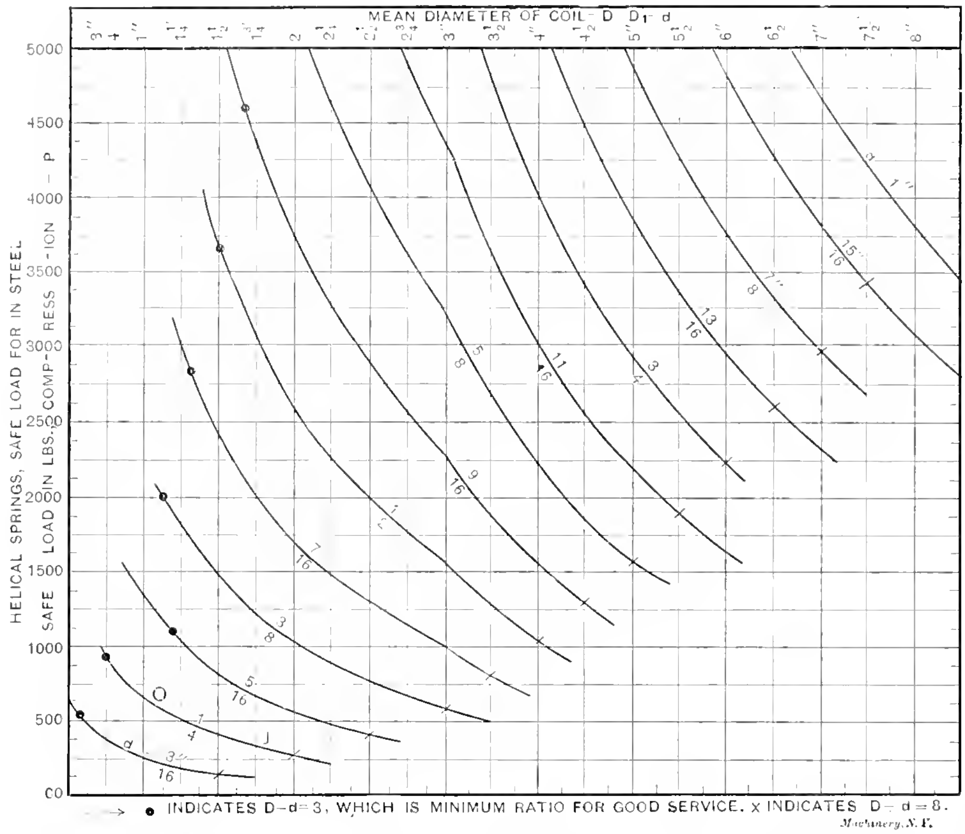


Diagram showing Safe Load for Coil Springs of different Diameters, from Wire of different Diameters.

Notation for Chart No. 3.

D = mean diameter of coil = $D_1 - d$.

d = diameter of wire.

S = safe torsional or shearing strength.

P = safe load.

$$P = \frac{S\,d^3}{2.55\,D}$$

For extension springs $P = 2/3$ of above value. Where springs are subjected to shock use about 2/3 P. The foregoing is for round bars. For square bars safe load = 1.2 × P for round bars.

Let $R = D \div d$; then,

For Bars Below	$R =$	$S =$
3/8" diam.	3	112,000
	8	85,000
3/4" diam.	3	110,000
	8	80,000
1 1/4" diam.	3	105,000
	8	75,000

(From Summary of Tests by Prof. C. H. Benjamin, at Case School of Applied Science. Relations of D, d, R and S are shown in Chart No. 1 on the previous page.)

ERRATA: Chart No. 1, for "G shows, etc." read "C D G shows." Chart No. 3, for "Indicates D−d=3," read "Indicates D÷d=3."

and the curves R = 4, 5, 6 and 7 drawn through. These lines now give values of S for any value of d and R. Thus $C\,D\,G$ shows diameter of wire d = 1/4-inch; ratio R = 8; safe stress S = 87,000. Next the side scale was numbered to represent mean diameter $D = D_1 - d$, and lines drawn to perform an operation of division $\frac{D}{d} = R$, for values of R = 3, 4, 5, 6, 7 and 8. Thus $A\,B\,C$ shows D = 2 inches; R = 8; d = 1/4-inch. The curves representing D were then drawn by projecting, thus $A\,B\,D$ and $A\,E\,F$ being two points on the curve D = 2 inches. These curves now give the value of S for any value of d and D.

Chart No. 2 was then constructed, the side representing values of S being adjacent to chart No. 1, S being taken as the first factor. The second factor is $\frac{1}{2.55\,D}$, thus the top of chart represents $\frac{S}{2.55\,D}$. The other set of sloping lines marked d represent the value of d^3 and perform the operation of multiplication, thus giving value of P in formula, $P = \frac{S\,d^3}{2.55\,D}$.

Chart No. 3 was then constructed by projecting points from No. 2, thus $C\,D\,G\,G\,H\,I\,J$ and $C\,K\,L\,L\,M\,N\,O$ show the projection for points on the curve which represents d = 1/4-inch. Chart No. 3 is thus complete in itself, Nos. 1 and 2 being used only in developing the curves.

Desired: A chart for helical springs of round steel, giving the deflection.

Begtrup's formula is $F = 8\frac{P(D_1 - d)^3}{E\,d^4}$. Taking E at 14,500,000, as stated by Prof. Benjamin, the deflection for one coil per 100 pounds $= \frac{1}{18125}\,\frac{D^3}{d^4}$. Chart No. 4 shows to a small scale the construction and development of curves in Chart No. 5. The top of chart No. 4 represents values of D^3, the sloping lines values of $\frac{1}{18125\,d^4}$ and perform the operation of division, thus the side gives the deflection $= \frac{1}{18125}\,\frac{D^3}{d^4}$. Points were projected into a smaller and more convenient chart on the right giving the curved lines shown. Thus A projected to B gives a point on line D = 6 inches, which curve representing 5/8-inch diameter wire passes through. Chart No. 5 gives these lines to a convenient scale for interpolation.

While the formulas read mean diameter, if it were thought advisable to have the charts read outside diameter this could be readily accomplished by shifting each curve when tracing.

CHART NO. 5

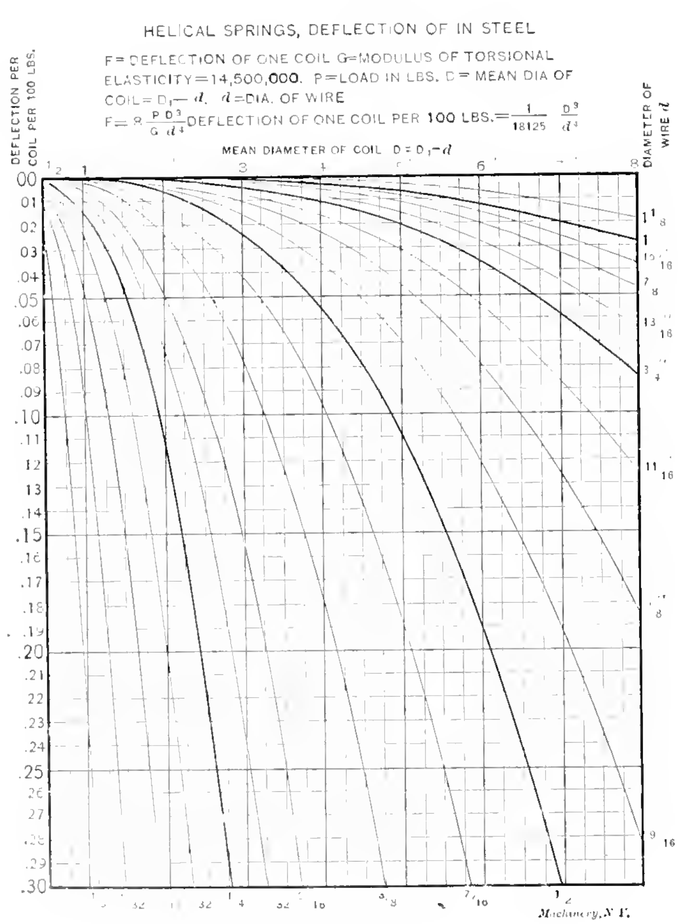

Diagram showing Deflection of Coil Springs.

THE "DE FRIES" PRECISION LATHE.

DR. ALFRED GRADENWITZ.

Dr. Alfred Gradenwitz.

In a precision lathe recently brought out by the firm of De Fries & Co., Düsseldorf, Germany, there is applied a novel construction in place of the usual lead screw by which it is claimed that extreme accuracy is obtained so that screws of any desired length may be cut of very accurate pitch.

Heretofore thread cutting has simply consisted in copying an existing lead screw, the latter being in turn copied from a master screw. There has been a serious drawback in this method, however, for producing accurate threads, because it has been extremely difficult to procure a master screw of uniform pitch, and any error in the pitch would be reproduced in the second screw. Now the De Fries lathe is quite independent of any existing screw, since a *lead nut* cut in halves longitudinally, thus making a long half nut, which is used in place of a lead screw. This nut runs along the bed of the lathe, and a bronze screw forming part of the mechanism of the carriage meshes with the threads of the nut. The screw is driven by change gears and a splined feed shaft located in the usual position, below the lead nut, as shown in the illustration. The thread grooves of the nut are cut singly by means of a special patented apparatus. As soon as a single thread has been made, the tool is moved most accurately as far as the next division by aid of a measuring instrument of precision. Any threads finished by the aid of the lead nut according to the method above are obviously copies of the same; and as the nut is finished with practically mathematical accuracy by means of a precision measuring machine, any thread cut by the novel lathe will also be of nearly mathematical precision.

Other advantages over the old system may be mentioned, *i. e.*, the slide rest drive is placed as near as possible to the shears and the driving force thus acts directly under the tool post, and as near to the cutting point of the tool as it is possible to locate it. This produces the smallest possible twisting moment and gives a very direct drive. Again, whereas with previous lead-screw lathes the lead screw would frequently undergo heating and expansion because of the friction and pressure, this constituting a great drawback to accurate thread cutting, any heat evolved in this part of the mechanism of the De Fries lathe is conducted to the bed of the lathe and thus dissipated. Still another point is that in gap lathes, which are so much used on the continent, it was necessary to locate the lead screw in a very low position in order to clear the gap, and thus the driving force acted upon the slide rest at a great distance from the cutting tool. In the De Fries lathe this is avoided, as shown in the second illustration, since the lead nut does not have to extend across the gap and the splined driving shaft is located low enough to clear the gap. On account of the wear of the lead screw being obviously the greatest in the neighborhood of the face plate lathes of the old type lost their accuracy after a brief use, since there would be a change in the pitch in passing from a point near the face plate to a point where the lead screw had retained its original accuracy. In the De Fries lathe the lead nut is made up in several sections, any one of which may be renewed so as to correspond exactly with the other section. In this way the ability of the lathe to cut threads of accurate pitch can be maintained with no great trouble or expense.

In its general design and construction the lathe is built with the utmost care, every refinement of modern workmanship having been made use of. Special points have been made of neatness of construction, easy handling, beauty of appearance, and stability. The lathe is, by the way, heavy enough so that it is especially adapted to the use of high-speed steels. The lathe bed has T-shaped walls of extraordinary breadth and height, joined by means of hollow braces. The shears are broad and rectangular and special provision is made for oil-

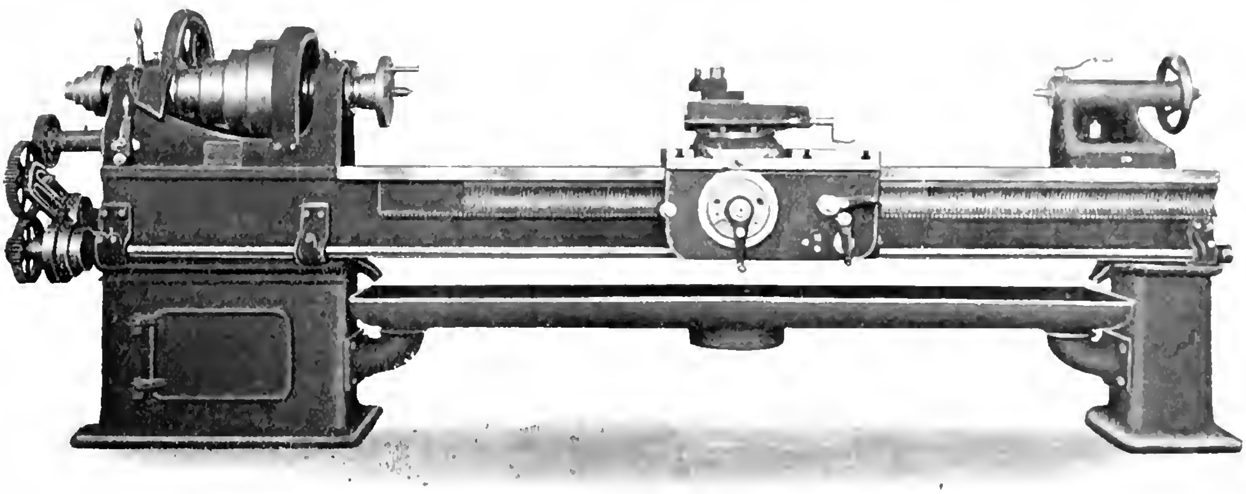

Fig. 1. De Fries Precision Lathe with Lead Nut, extending the Length of Carriage Travel, in place of a Lead Screw.

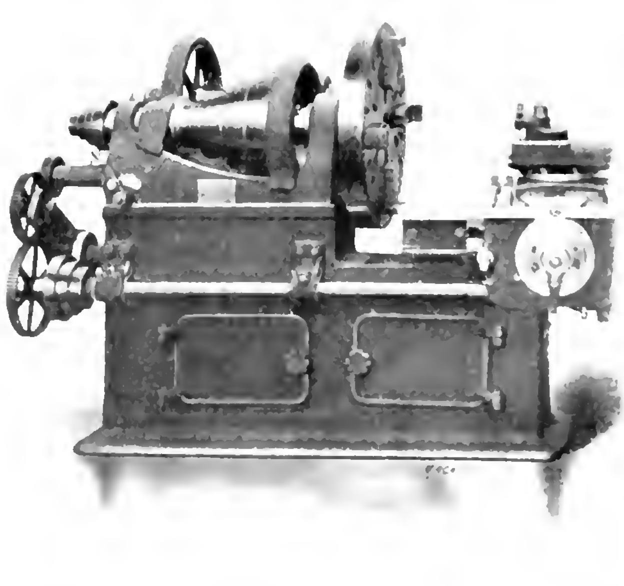

Fig. 2. The "De Fries" Principle applied to a Gap Lathe. With a Lead Screw on a Gap Lathe the screw has to be dropped below the gap, but not so with the Lead Nut.

DR. ALFRED GRADENWITZ was born at Breslau, Germany, May 18, 1875. He was educated at the König Wilhelm's Gymnasium (Preparatory School), Breslau, the Technical High School, Charlottenburg, and at the universities of Breslau, Freiburg, and Geneva. Dr. Gradenwitz has made a special study of science applied to industry and the progress of science and industry. Hence he has naturally become a contributor to the technical press; his contributions have been published in the leading trade papers of Germany, France, Spain, Norway, Denmark, Great Britain, and the United States.

ing automatically, the oil coming in contact with the friction surfaces while the slide is moving.

The headstock is of pleasing shape, of strong and massive construction, provided with a four-stepped cone pulley for a wide belt. The gearing is protected by cast-iron covers. There are also tumbler gears located in the headstock by which the direction of feed is changed and there is a shift gear to enable extremely coarse threads to be cut. The lathe spindle is hollow and of crucible steel and the bearings are of phosphor bronze cut longitudinally into three parts spaced 120 degrees each. The thrust of the lathe spindle is taken by several chilled disks, between which are disks of a special composition. This arrangement was chosen after many experiments. The slide-rest and carriage have long, broad sliding surfaces so as to eliminate vibrations, even under heavy strains. Both the longitudinal and transverse feed screws are provided with graduated dials. The feed mechanism is of novel arrangement and either transverse or longitudinal feeds may be worked automatically or by hand, and the screw and rack feeds block each other so they cannot be operated simultaneously.

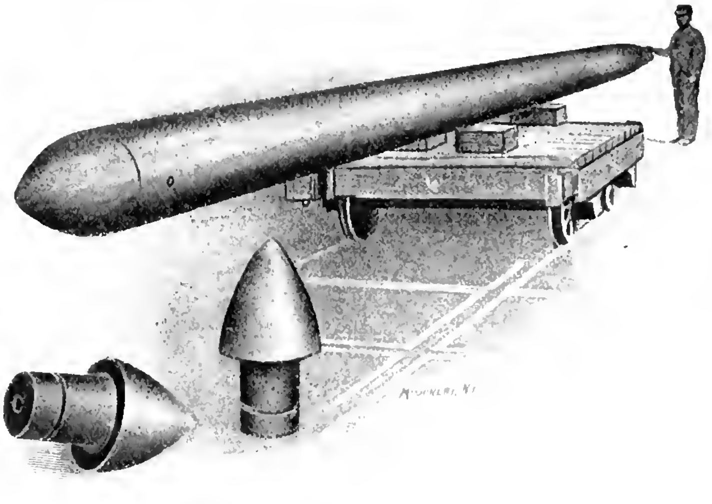
EFFECTS OF WAR ON THE ARTS OF PEACE—LOBNITZ ROCK CUTTER.

However much we may deplore the cruelty and waste of war, it is easy to show, paradoxical as it may seem, that war and the fear of war (and its consequences) have been powerful factors in stimulating inventive genius and constructive arts. The ancient armorers were, in effect, subsidized workmen who received very large sums for their products as compared with the prevailing prices for other goods. Hence the developing effect of war upon the metal-working arts. So in later years the building of battleships, rifled guns, mounts, the manufacture of the munitions of war, have undoubtedly reflected great benefits in civilizing influences, although the making of such is economically wrong. No cost is considered prohibitive by powerful governments in gaining a desired improvement, and the consequent experimenting and constructive work is happily not altogether waste effort—because of its beneficial effect on other lines of work.



Lobnitz Rock Cutter.

An interesting example of the beneficent effect of the arts of war upon the quiet pursuits of peace is shown in the cut which shows a huge rock cutter made by Lobnitz & Company, Renfrew, Scotland. This device is made for breaking up rocks under water as is necessary in harbor dredging operations, canal work, etc., and is found far more effective and cheaper than drilling and blasting operations. The cutter usually weighs from 10 to 15 tons and resembles an elongated armor-piercing projectile. The similarity is further carried out in that the head is made of steel of about the same characteristics as found in armor-piercing projectiles. These immense cutters or breakers are raised to a height of 6 to 10 feet and allowed to drop by a suitable releasing gear, the lifting apparatus being a steam winch or hoisting engine of special design for this work. As the cutter falls, the impact of its tremendous blow is concentrated upon a few square inches of rock surface, and the hardest granite yields readily to such forceful treatment. The fact that is of first importance in this connection is that until steel of the characteristics that make a successful armor-piercing projectile was developed, such a tool would have been a virtual impossibility since no ordinary tool steel could stand the punishment. This tool will probably play an important part in the completion of the digging of the Panama Canal, and this inspires the question: Who knows what the effect of high-speed steel will eventually be upon the peaceful pursuits of the world, and this was discovered and developed in the manufacture of armor plate and the machinery of battleships.

* * *

DRILL SPEEDS TABLE.

The table herewith, contributed by Mr. Walter Brown, Chicago, Ill., gives the speeds of drills in steel, malleable iron, cast iron, brass and tool steel, have been found most practical, in general use, at the Chicago works of the International Harvester Company. These speeds were carefully compiled after thorough trials in the works, and have been

SPEED OF DRILLS.

Size of Drill.	Revolutions per Minute.				
	Steel.	Mall. Iron.	Cast Iron.	Brass.	Tool Steel.
1/16	3650	4200	4380	6950	1790
1/8	1540	1770	1850	2930	755
3/16	1060	1240	1270	2160	520
1/4	740	850	890	1410	362
5/16	570	655	685	1080	280
3/8	460	530	550	875	225
7/16	370	425	445	703	182
1/2	310	356	372	590	152
9/16	270	310	324	513	132
5/8	240	276	288	456	118
11/16	210	242	252	400	103
3/4	188	216	226	358	92
13/16	170	196	204	323	83
7/8	156	180	187	296	76
15/16	142	163	171	270	70
1	134	154	161	255	66
1 1/8	115	132	138	218	56
1 1/4	104	120	125	198	51
1 3/8	92	106	110	175	45
1 1/2	84	96	101	160	41
1 5/8	75	86	90	145	37
1 3/4	70	81	84	136	34
1 7/8	63	72	76	120	31
2	59	68	71	112	29

found to be good commercial practice. It will be noted that the small drills are given a greater peripheral speed than the large drills. To compensate for the greater speed, the feed of the small drills is correspondingly reduced, this being found to give the most satisfactory results.

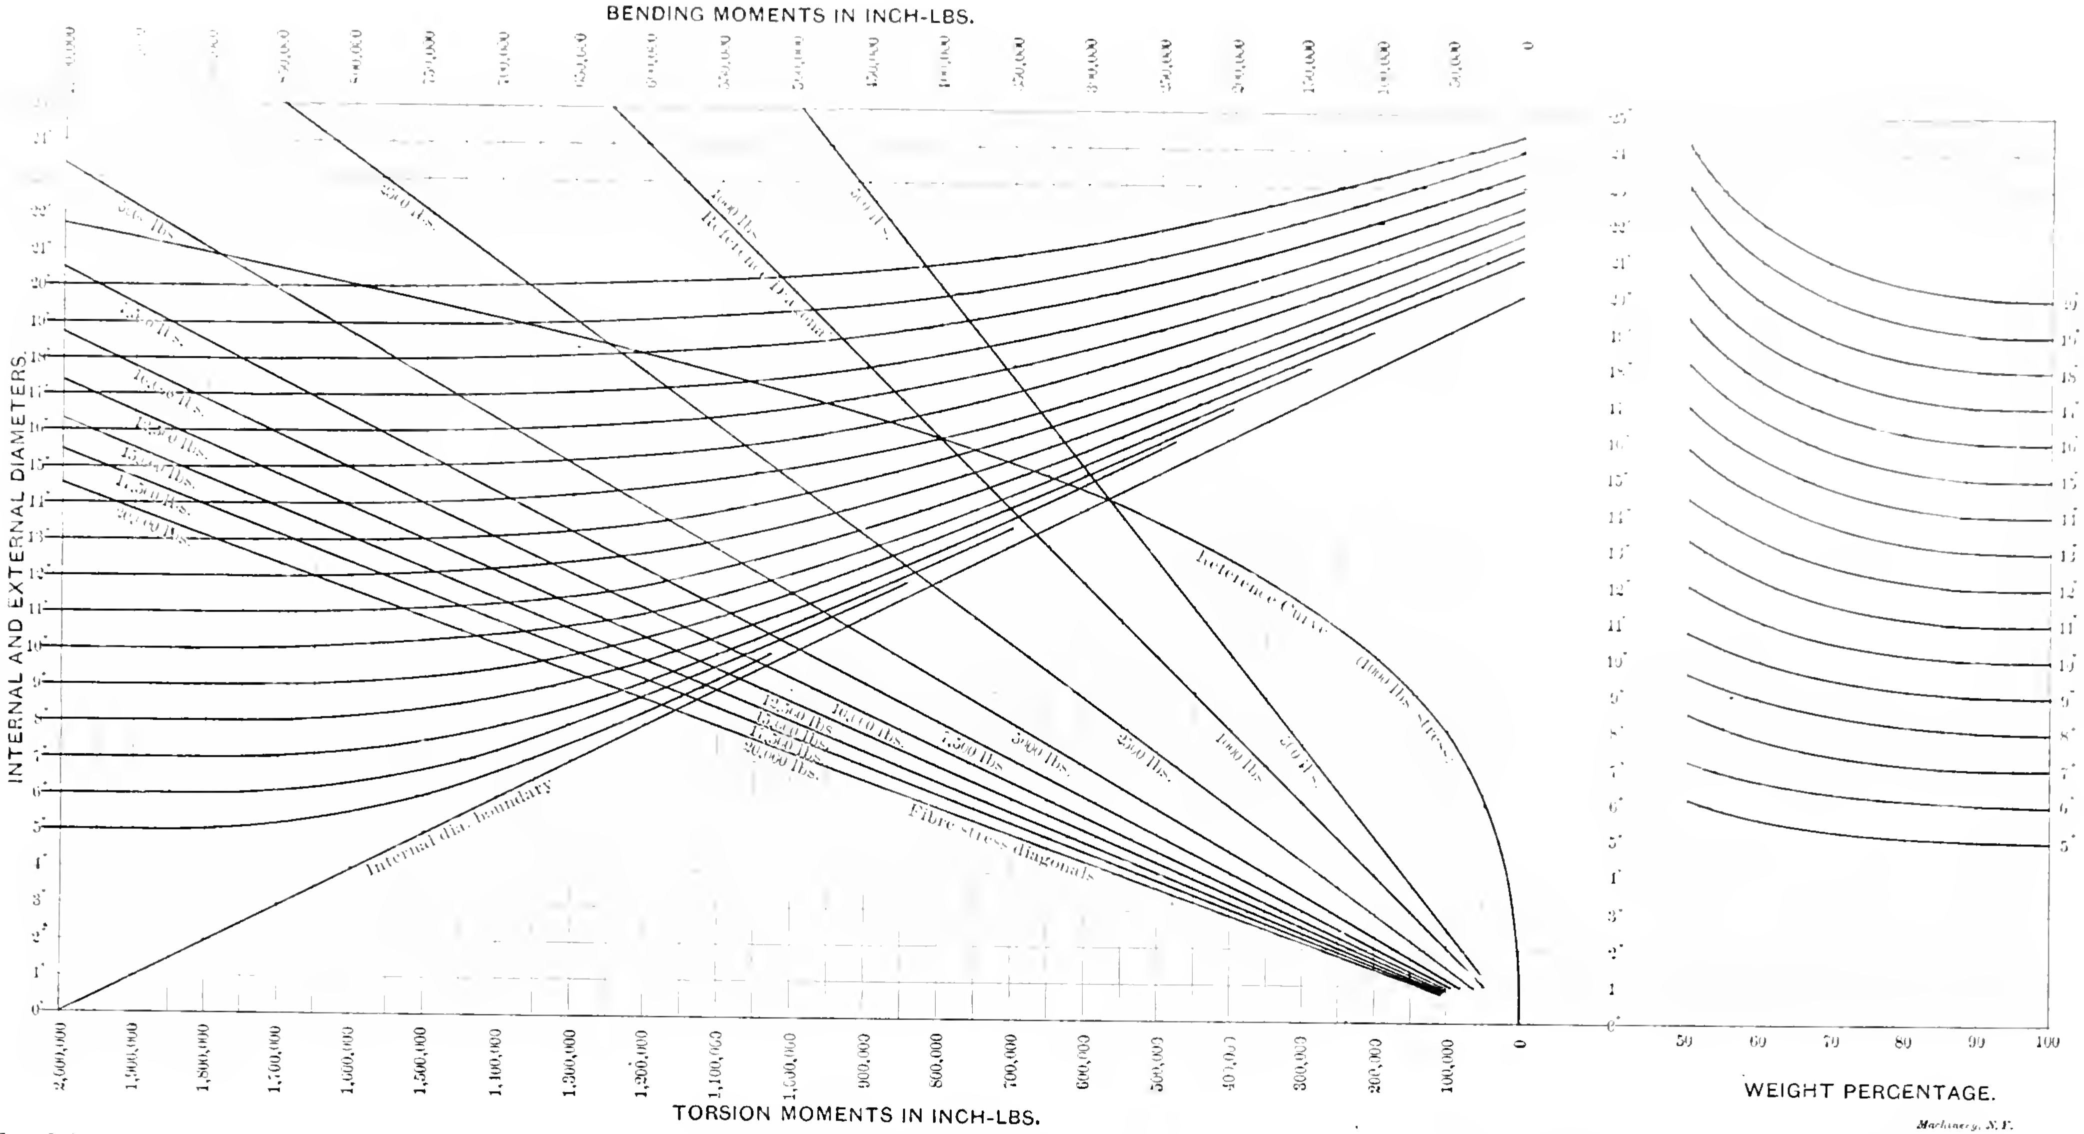
* * *

CHART FOR HOLLOW AND SOLID SHAFTS.

The diagram, next page, is one of the United States Navy standard charts of which several have been published in data sheet form in recent numbers of MACHINERY. The chart is for the purpose of finding the dimensions of shafts, especially of large size, as used in marine and heavy stationary engine construction. It can be applied to both solid and hollow shafts, when subjected to either torsional or bending stresses. The shaft diameters are found by first selecting the bending moment (at the top of the diagram) or the torsion moment (at the bottom of the diagram) which applies in the particular problem, and then proceeding as follows:

Solid Shaft in Torsion.—For a torsion moment of 1,600,000 inch-pounds and a maximum fiber stress of 7,500 pounds, follow the 1,600,000 torsion moment line vertically to the "reference curve;" trace the intersecting horizontal to the "reference diagonal;" trace the intersecting vertical to the 7,500-pound fiber stress diagonal and finally the intersecting horizontal to the vertical scale at the left-hand edge of the diagram, finding 10.27 inches diameter for the shaft.

Hollow Shaft in Torsion.—First find the diameter of a solid shaft to carry the load, as above, and assume some inside diameter. Suppose the outside diameter for a solid shaft is



found to be 10 inches and the inside diameter of a hollow shaft of the same strength to be assumed at 7 inches. To obtain the required outside diameter of the hollow shaft, start at the left at 7 inches and follow the horizontal line until the internal diameter boundary diagonal is reached; then proceed vertically upward until the curve is intersected which starts at the 10-inch point on the scale at the left, and read the diameter corresponding to this point of intersection. The diameter found is 10.75 inches; a shaft of this diameter, and with a 7-inch hole through its center, would have the same torsional strength as a solid shaft 10 inches in diameter. Again, if the central hole were to be 8.75 inches diameter, the outside diameter would have to be 11.5 inches in order to give the same strength as a solid 10-inch shaft. The diagram is so constructed that all shafts having external diameters bounded by the curve starting at 10 inches at the left and having internal diameters bounded by the diagonal starting from 0 at the left, are equivalents, and the same is true for curves starting from other points on the scale at the left. The vertical height from the diagonal bounding the internal diameters to the curve bounding the external diameters, is the actual wall thickness. drawn to a reduced scale, and is useful as giving a graphic comparison of the various equivalent shafts.

Weight Relation of Shafts.—To find a hollow shaft to have 50 per cent. of the weight of its 10-inch solid equivalent: Follow the 10-inch shaft curve in the small diagram at the right to the point of intersection with the 50 per cent. vertical line; then proceed horizontally to the 10-inch diameter curve in the large diagram at the left, which it intersects at the sought-for external diameter of 12.125 inches; and finally, dropping vertically down from the intersection point to the internal diameter boundary line, gives a diameter of 9.75 inches for the hole.

***Shafts Subjected to Bending.*—Proceed as before, but use the bending moment scale.**

LETTERS UPON PRACTICAL SUBJECTS.

WONDERFUL TAPS AND DIES.

Editor MACHINERY:

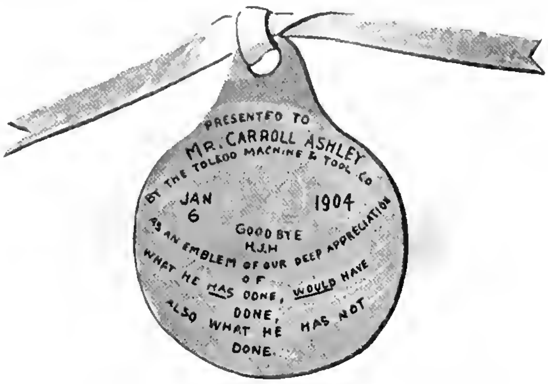
Recently an English daily newspaper of good reputation for reliability announced with befitting seriousness that taps and dies were now made so small that they could tap the human hair. After reading this I pictured to myself the advertisements of future tonsorial establishments: "Why have short hair? Tresses lengthened in any degree by our new process. Threads warranted without backlash and not to strip." Indeed, the prospect seemed so rosy that I thought of going in for the business myself and of getting the necessary kit. But, unfortunately, like the majority of the wonderful announcements in this "something scientific" column, there was neither the price, maker's name, or any practical information given for these useful (?) tools. However, if you know where I can get any of these I should be very glad of the information under "How and Why." When a paper wanders out of its depth it should be careful as to the source of its news.

McANIC.

A LEATHER MEDAL.

Editor MACHINERY:

Since we were "knee-high to a grasshopper" we have often heard the expression: "You ought to have a leather medal," More especially is the expression used in the machine shop, but have any of the readers of MACHINERY ever seen one? Methinks not a great many, not perhaps that some of you have not deserved one many times, but don't it recall to your memories many incidents of shop life—some humorous and some otherwise—just to remember some certain event, when for doing something famous or infamous you were threatened with the bestowal of a "leather medal"?



A Leather Medal given to Mr. Carroll Ashley, as a token of good fellowship, when leaving the Toledo Machine & Tool Co. after a seven years' service.

I take pleasure in sending you a photo of an identical "leather medal"—the real thing—not perhaps a thing of beauty, but it may be a joy forever, to me at least, as whenever I recall the episode of its presentation, I smile. It is made of four-ply unadulterated leather, a neat bow of "belt lace" gives it a machine shop effect. Though the inscription is rather vague it seemed to fill the bill. As much pomp and ceremony were used on its presentation, as if the recipient were going to be presented with a house and lot, and, in the same spirit, I endeavored to answer the presentation speech (which was long and quite flowery) just as if I had received the real estate. However that may be, the fact remains that I am the possessor of a real "leather medal;" if any of the readers of this journal can make a similar boast, I might be tempted to exchange condolences with him.

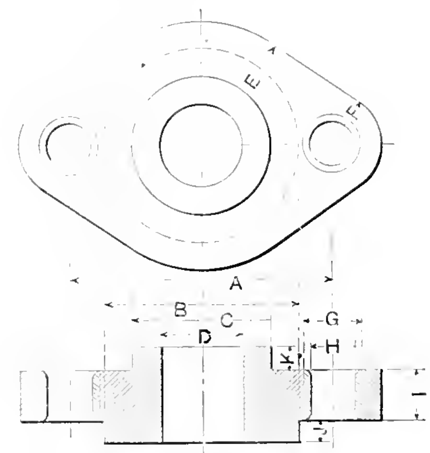
CARROLL ASHLEY.

Rochester, N. Y.

"LABOR-SAVING SCHEME FOR MAKING DRAWINGS."

Editor MACHINERY:

In Mr. C. W. Putnam's article "Labor-Saving Scheme for Making Drawings" in the September number of MACHINERY, I do not think he has chosen a very good illustration of the use of templates in the drawing-room. He was obliged to make a pencil-drawing in the first place. Then, while he was cutting out the template, he could have put a piece of tracing cloth over it and traced it, or this would have been a good job for the blueprint boy. Letters would then have been put on for dimensions, and while he was packing up his five sheets of tracing paper with the carbon sheets between, a row of columns could have been ruled off under the figure. At the head of the first column could be put "No. of Gland," and the letters corresponding to the dimensions at the heads of the others. He would then have something permanent and it would have taken little longer, if any, than for him to make his first five copies. It will take no longer to fill in the dimensions for the different size glands on the tracing than it would on his sketches, and if he printed the same title, as shown, on each sheet he would be left far in the rear before he had made the five hundred. I was about half an hour making the drawing for the accompanying cut; how many carbon tracings of his first five hundred could Mr. Putnam have made in that time?



NO. GLAND	A	B	C	D	E	F	G	H	I	J	K
60	$4\frac{3}{4}$	$3\frac{1}{2}$	$2\frac{17}{32}$	$1\frac{1}{4}$	2	$\frac{7}{8}$	$1\frac{1}{16}$	$\frac{7}{8}$	$\frac{7}{8}$	$\frac{3}{8}$	$\frac{3}{8}$

Machinery, N. Y.

"Labor-saving Scheme for Making Drawings."

I object to putting pencil drawings out in the shop for several reasons:

First, it is my experience that they are so hastily made that many of the important dimensions are often omitted, causing the workman, or perhaps the foreman while he stands around, to run back to the draftsman, or his chief, and interrupt him in some important calculation. Second, mistakes are more common on pencil tracings than on finished drawings. Third, if a workman makes a mistake on the work he can easily change the figure on a sketch, and sometimes does. Fourth, if the sketches are ever returned to the drafting room, which is doubtful, they are covered with grease and dirt and badly mutilated. Fifth, the sketches are generally of all sizes and shapes and are very difficult to file away or put anywhere where they can be readily found when wanted.

While it sometimes becomes necessary to use such sketches let us avoid it wherever possible. While I believe in doing

just as little work as possible, and that in the quickest and cheapest way we can, do not let us do it in such a way as to cause us weeks of sleepless nights and to be "blessed" by everyone connected with the concern we are working for, some time in the future.

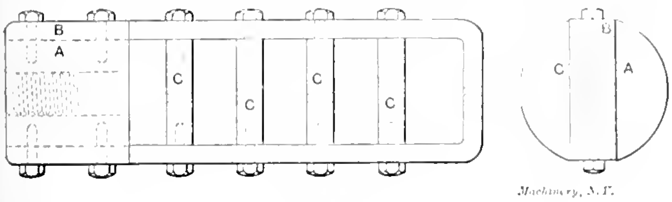
Templates can very often be used to advantage, but great care must be taken to get the work accurate. One cut out of cardboard or sawed from a ¼-inch board, is not good enough for complicated machines, such as a loom, drawn one-fourth size. It should be laid out on zinc under a magnifying glass and then filed up by a man who can work right to a line.

Worcester, Mass. H. A. Houghton.

WIRE STRAIGHTENER.

Editor Machinery:

In reply to inquiry by "Connecticut" for a wire straightener I send sketch and description of one I made about seven years ago to straighten ⅛-inch spring wire. It consists of a cast iron piece, *A*, fitted to the spindle of a speed lathe, and having two slots milled on the side for the piece of machinery steel *B*, which is bent U-shaped as shown. This frame holds a number of tool steel pieces (in this case four), which have



Wire Straightener.

holes drilled through them slightly out of center. After being hardened, drawn and the holes lapped to smooth them, they are assembled on the frame so as to bring the small holes in the position shown. One end of the wire is pushed through the four holes and through the hollow spindle of the lathe until it can be grasped with a pair of pliers, when the lathe may be started and the wire pulled through slowly.

New York. H. J. Bachmann.

HOW BILL CHANGED HIS JOB.

Editor Machinery:

One of my old shopmates came in to see me the other day. He had been away from the shop for two years or more and I had not heard a word from him in that time and I was cordially glad to see him. He wasn't much of a machinist; he never wore overalls or a jumper, and he used to turn his shirt away back from his neck and cut off the sleeves at the shoulder, and he didn't look like a machinist any how. He had been in the shop two or three years and he never got over $12 a week, and one day "he chucked up" his job and lit out—said he was going to see if he couldn't get a living at something that suited him better, or that he was better suited for, and as soon as he came in the other day, I saw at once he had found it. He had on a blue suit, not the "dollar-down-and-a-dollar-a-week style," but one that looked as though he had been melted and poured into it. A nice yellow chain hung out of his vest pocket and I knew Bill well enough to know there was a watch to match on the other end of the chain. He had on a clean collar and he looked like a man who had found prosperity.

"Well, Bill, you look as though you had struck oil," I said as we shook hands.

"No, but I have struck something that is better than oil and that is a hole that fits me," and then he went on and told me what he had been at.

When he "jacked up" he had no idea of what he was going to do and he took a job as deck hand on one of the steamers between Fall River and New York at $20 a month, and put in three months at it. Then went two trips as a coal passer and fireman on one of the big ocean liners at a pound a trip. He made two trips and no amount of money would tempt him to make a third. Then he shipped as fireman on a United States transport to Manila at $55 a month. That was a good thing, and he made three trips on her from San Francisco to Manila and return. Here he found that in order to cut any ice, he must be a union man, and so he joined the Fireman's Union and shipped for the Yukon River at $90 a month. Just before he went, he saw an illustration of the power of a union that will stand repeating.

An English firm had taken a contract to carry the United States mails from San Francisco to some foreign port and by the contract the steamer must be manned by American seamen, so the captain let his "long-haired boys" (Chinese) go and came up to the hall of the Fireman's Union to get a new crew. The captain had but one eye, and he called out the master fireman and says, "I want a crew of eight good firemen and I will pay seven pounds five shillings per month." This was a big price for an English boat, but it did not go at all.

"No you don't, if you want a crew out of this hall, you will pay ten pounds straight.

"What!" said the captain, and the mate who was with him roared, "What! pay a lot of greasy coal slingers two pounds a month more than I get; I won't stand that."

The captain started off and saw the British consul, only to be told that if he had taken a mail contract with that clause in it, he must take union men, and take them he did at ten pounds a month.

After three months on the Yukon, Bill struck a berth as second engineer at $110 a month, and although he had no papers, he held it till he could some back to 'Frisco and get passed. His machine shop training told in the examination and he got his papers and then came East to see some of his old friends and to go out as second engineer with a new boat just being finished.

"And now," said Bill, "if you know of a machine shop where I can earn $110 a month, a clean bunk and three squares a day, I am ready to talk, but till then, good-bye."

Bill has gone, but his experience lingers with me yet, and I can't help thinking how nice it would be if all the boys could find a hole that they fitted into as well as Bill has.

A. P. Press.

THREE-PIECE ELLIPSOGRAPH.

Editor Machinery:

To test the principle of an elliptical chuck we made the model shown herewith by means of which it was possible to trace with a stationary pencil, an ellipse of any size or proportion, on the revolving platen.

Fig. 1 is the base or stationary part, and it consists of a piece of 1¼-inch pine about 16 inches square, having a slot

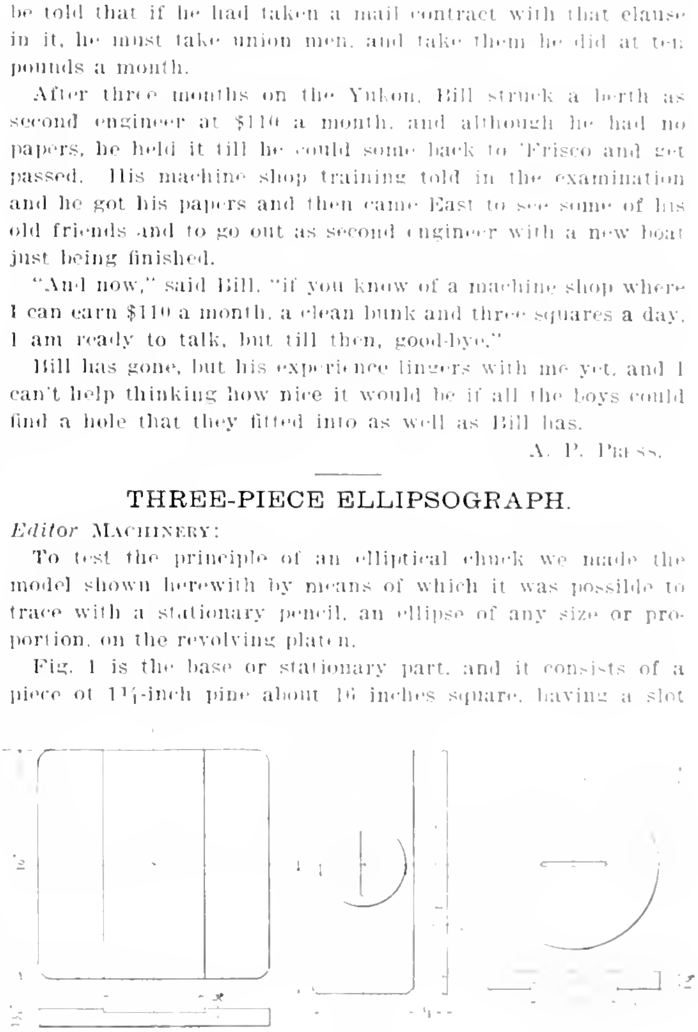


Fig. 1. Fig. 2. Fig. 3.

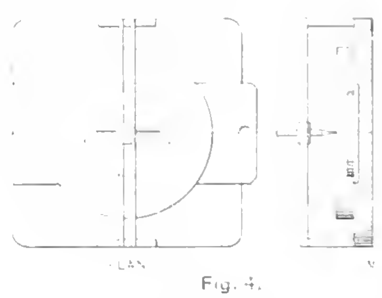

Fig. 4.

Three-piece Ellipsograph.

about 7 inches wide and ¼ inch deep across the center of the upper side. Into this slot is placed the piece for adjusting the eccentricity of the ellipse. This part is shown in Fig. 2 and consists of a piece of ¼-inch pine with a disk 6 inches diameter and ½ inch thick attached to its upper side. Fig. 3 shows the platen, which is 12 inches diameter, with a groove 6

inches wide and ½ inch deep across its under side. This groove fits over the 6-inch disk, shown in Fig. 2. The whole apparatus is held together by a large wood screw passing through Fig. 2 and Fig. 3 into the center of Fig. 1. Two small strips are supported from the base and run diametrically across and about 2 inches above the platen. A small block supporting a lead pencil, slides between these strips, as shown in the assembled drawing.

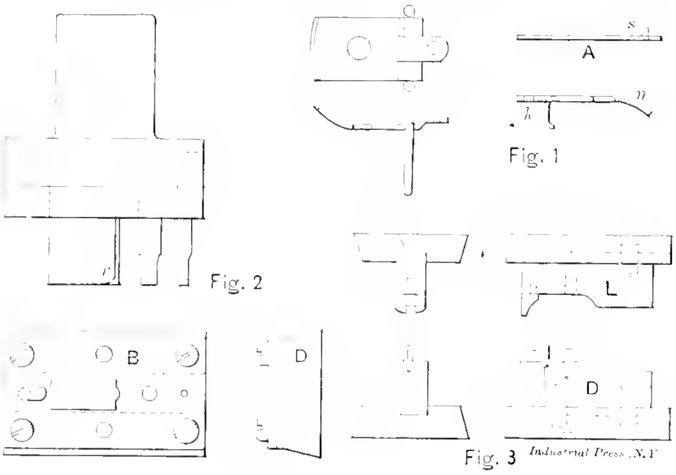
To operate a paper is tacked on the platen. The piece shown in Fig. 2 is drawn to the right according to the eccentricity desired and the pencil pushed away from the center, according to the minor axis desired. Upon rotating the platen by hand an ellipse will be traced. As any proportion between the minor and major axes can be obtained the apparatus was later used with a cutter instead of a lead pencil, which gave good results in cutting photographs, etc. J. D. Adams.

Phoenix, Ariz.

MAKING A SPRING LATCH.

Editor Machinery:

I send you herewith descriptions and drawings of dies for making the spring latch shown in Fig. 1. Fig. 2 shows the blanking punch and die, which is of the ordinary follow type, the only special feature being that the punch is rounded at *r* to start the two wings for curling. *D* is a cross view of die,



Making a Spring Latch.

while *B* is a plan view. *A*, Fig. 1, is the blank as it comes out from this operation. Fig. 3 is the splitting die for turning up the two ends as shown at *k*, Fig. 1. The blank *A* is laid on the die *D* with the bent ends *s* pointing down over the bending forms *I*. The punch *L* descends, bending the ends down as shown at *k* in the lower view of Fig. 1, and curving the back of the latch as shown at *n*.

We will next consider the staple die, Fig. 4. The wire being laid in the die as shown, the punch descends and the knife cuts the wire off at *C*. The punch, which is ⅛ inch shorter than the knife, pushes the wire, which is left lying in the groove against the stop pin *G*, down into the forming grooves *O O*. Then the punch rises and with it the spring stripper *R*, thus ejecting the staple when the wire is inserted in the die again and the operation repeated. This die is used in an inclined press, which causes the staples to fall by gravity after being formed. End views of the punch and die are shown at the right.

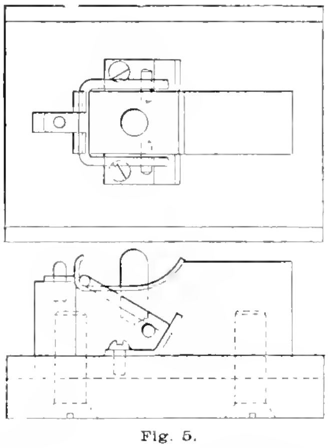


Fig. 5.

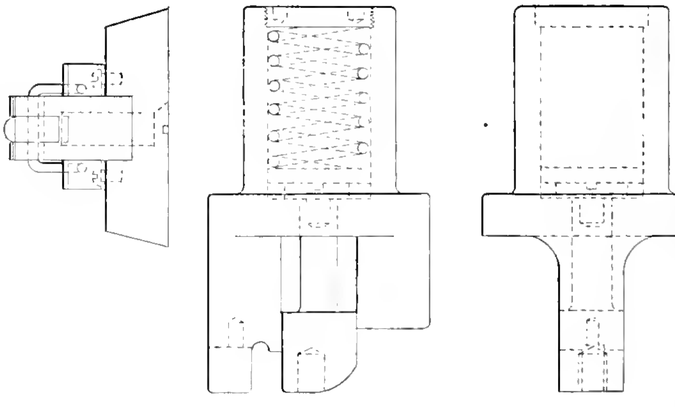

Fig. 6.

We are now ready to curl the two wings *k*, Fig. 1, over the staple, and for this purpose the punch and die, Figs. 5 and 6, were made. The punching *A*, Fig. 1, is laid on the die as shown with the ends resting on the holders on either side of the die. The punch in descending strikes the blank with the spring foot, which holds it in position while the curling punch coming on down forms over the ends *k*, Fig. 1, around the staple. At the end of the stroke, the tongue is formed over

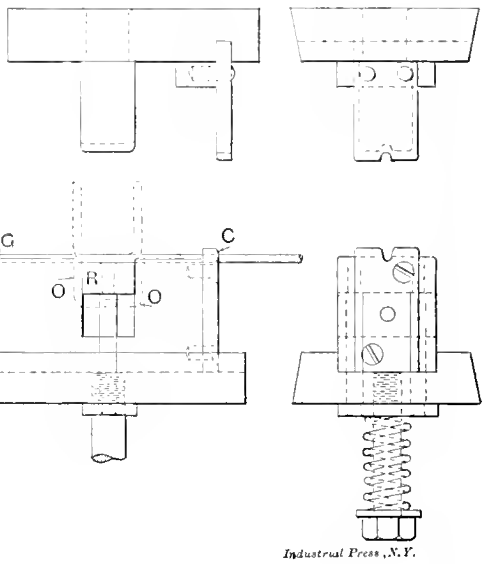

Fig. 4. Staple Die.

the raised die by the punch, thus completing the latch. I have not thought it necessary to explain the construction of the tools as it is made quite plain by the drawings.

H. R. H.

CATCHING THREADS AND GAGING THE DEPTH.

Editor Machinery:

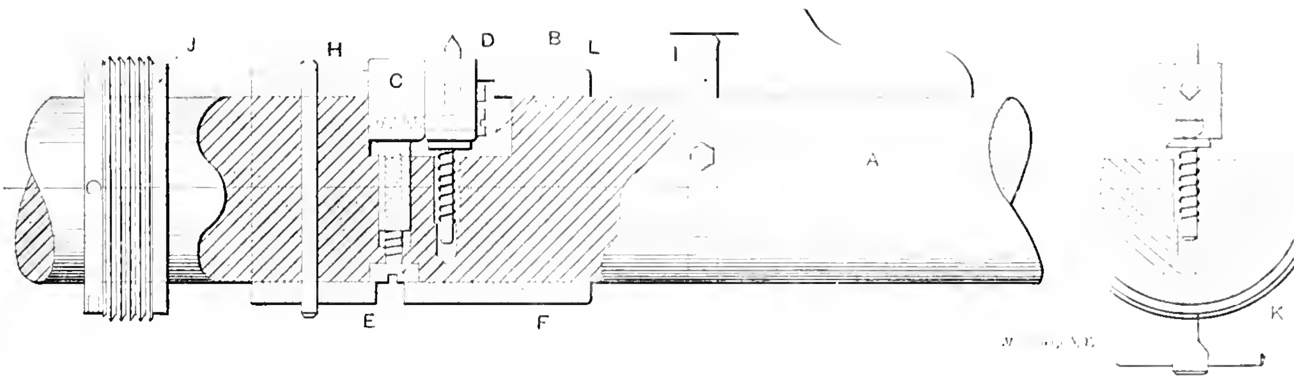
I noticed the remarks by John A. Burgess in the June issue and it carried my thoughts back to the days when I was an apprentice. As regards the knot holes in the wall, they were about the same, and I also had to take a broom in the winter and sweep the snow off the lathe after a storm that leaked through these same knot holes or some other aperture that was more convenient for the sparrows than the men.

Now, in this same shop I learned a method of cutting threads that may be interesting to your readers, and it was this: I used to carry the carriage back without stopping the lathe at all. I don't mean on a thread that was the same pitch as the lead screw, but I mean any thread, and I also mean long ones where the carrying back of the carriage was a great saving of time, and I very seldom made a mistake. It may seem a difficult operation, but it is simple when the idea is understood. All it requires is to regulate the speed at which the carriage is run back, by the length of the screw and the pitch. Now I used to put a chalk mark on the faceplate and another on the lathe bed at the end and beginning of the thread and far enough away to give me a chance to feed in the tool to the depth required. It is just the same as suggested by Mr. Burgess, only there are points that require a little explanation, for there are a great number of men still

going around that know of no other way than pulling back by hand or power, both of which are a lot of lost time. For example, if I am cutting 8 threads per inch and the tool has reached the end of the thread and my mark on the faceplate has come into view I disconnect the split nut, and with the lathe still running I carry back the carriage at the same time, counting in my mind 1, 2, 3, 4, etc., every time the mark on the faceplate comes in to my view. If I reach the starting of my thread in time to catch the fourth revolution of the faceplate I connect nut again and start afresh; if not I count up to 8, do the starting again from that point.

Now this brings me to another point, and that was the plan I employed to set the tool to the required depth in cutting. When I took the first cut I would notice in what position the handle stood, and we will say that it stands straight up. I would say to myself that it was at 12 (or you could call it anything you liked, but I used to say 12). Now the next cut I would call 5 past 12, and the next would be 10 past, and when it was 15 past the handle would just be one-fourth the way around. You see the handle I treated like the hands of a clock, and with a little practice it is surprising how accurate one can be, and when he gets familiar with the spacing he can finish the thread by counting single minutes. Now this may seem crude to some of your readers, and to some it may be new, but judging by the number of readers of MACHINERY about here you must have both kinds. To those who try this method they will be surprised at the rapidity at which they can cut threads compared to what they did before.

BARNEY.



Figs 1 and 2. Boring Bar for Chasing Threads.

BORING BAR FOR CHASING THREADS.

Editor MACHINERY:

Herewith is a sketch of a combined boring and thread-cutting bar, which was designed for boring and threading the large crossheads of the engines, which were built for the Brooklyn Rapid Transit Co., Brooklyn, N. Y., by the Allis-Chalmers Co., Scranton, Pa. The holes in these crossheads, when finished, were 8 inches in diameter by 12 inches long and threaded 6 per inch. The material used was Bessemer steel.

The bar *A*, in Fig. 1, is 8 feet long by 5½ inches in diameter, with a portion, marked *L*, cut away and two holes drilled to receive the feed slide, and the pawl which retains the tool block in position, as is shown in Fig. 4. The sleeve *B*, Fig. 3, is fitted to the bar and secured by the pin *H*. This sleeve is slotted to allow the feed slide *C* and the tool block *D*, Fig. 1, to move to the work and also to hold the tool block rigid, when cutting. The slot is cut sufficiently off the center to allow the tool block to be swung to one side when the cut is through, as shown by the dotted lines in Fig. 2. The workman, by disengaging the lead nut, can run back the lathe carriage to which the work is bolted, turn the tool block back into cutting position, feed the tool out, by means of the wrench *K*, Fig. 2, and take the next cut, repeating this until the hole is finished. The threaded collar *J*, Fig. 1, is a gage for sizing the thread without taking the bar out of the lathe, being made the exact size of the thread on the piston rod. *I* is the cutter (under the setting gage) for boring the hole before chasing the thread. The sleeve *B*, overlaps the head of the feed screw *E*, and takes the end thrust. The tool block *D*, swings on the pin *L*, and is held in the desired posi[illegible] the flat spring-pawl *F*. The merits of this tool may [illegible] at a glance, and I will say that it made a very good job of the crossheads.

D. L[illegible]SAY.

Plainfield, N. J.

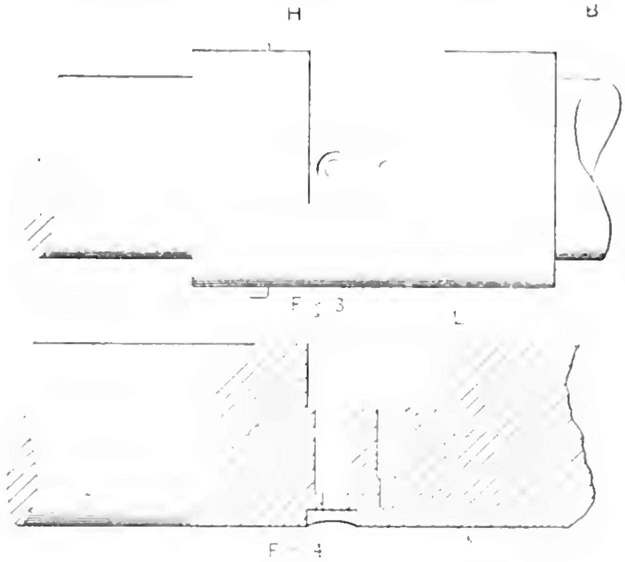
CHANGE GEARS FOR DIAMETRAL PITCH WORM TEETH—CUTTING MULTIPLE THREADED SCREWS.

Editor MACHINERY:

While it is customary to design worm gears by the circular pitch system, for convenience in finding the proper change gears for threading the worm in a lathe, yet occasionally the workman may have the problem of calculating the change gears required for a worm of the diametral pitch system. In such cases it may conveniently be done as follows. Multiply the ratio of the pitch (in threads per inch) of the lead screw of lathe, to the diametral pitch of wormwheel, by 3.1416 or (to avoid decimals), by 3 1-7. This will give the ratio of the stud gear of lathe to the screw gear. For example: Required the change gears to thread a worm of 6 D. P. the lead screw of lathe having 4 threads per inch.

$$\frac{1}{6} \times \frac{22}{7} = \frac{88}{42} \quad \begin{array}{l}\text{gear on stud.}\\ \text{gear on screw.}\end{array}$$

The above gears will give the required lead, with an error of not quite 0.0002 inch in the thread of worm, and is caused



Section of Boring Bar for Chasing Threads

by multiplying by 3 1-7 instead of 3.1416, which would give a fraction of a tooth or $\frac{87.9648}{42}$. Perhaps a better way to remember the rule would be: Multiply the threads per inch in lead screw of lathe by 22 and the diametral pitch of worm-

JOHN T. GIDDINGS was born in St. Johns, New Brunswick, June 18, 1865. He has a commercial education and is a graduate of the International Correspondence School. He served an apprenticeship with the Providence Machine Co. and the Rhode Island Locomotive Works. Besides these concerns he has worked for the Builders' Iron Foundry, the Brown & Sharpe Manufacturing Co., the Corliss Steam Engine Company, the American Screw Company, the American Ship Windlass Co., and others. His specialty as a machinist is lathe work; and as a draftsman, hoisting machines and windlasses.

wheel by 7. This will give the ratio of stud gear to screw gear. The above rule assumes that the stud of lathe makes the same number of revolutions as the lathe spindle. If it does not, then the equivalent pitch of lead screw should be used as explained by Mr. Fred H. Colvin in the November, 1903, issue of MACHINERY.

When a multiple threaded screw is to be cut in a lathe, if the faceplate is not divided into the required number of slots for shifting the driver (or dog) the usual method is to disconnect the change gears and either move the spindle through the required part of a revolution, or the gear on the lead screw may be moved enough to cause the required amount of tool travel for the next groove to be cut. For some cases this may be more conveniently done as follows: Calculate the amount of travel required for the tool to cut the next groove, then (the lathe being stopped) disconnect the lead screw half nuts, and move the carriage by hand the required amount, provided, of course, that the lead screw is of such a pitch as will admit of this method. For example: Required to thread a triple-threaded screw of $\frac{3}{4}$ inch lead. The lead screw of lathe has 4 threads per inch or $\frac{1}{4}$ inch lead. After cutting each groove, disconnect, and move the lathe carriage one thread of the lead screw, this will bring the tool in the proper position for the next grooves. For some cases this is not quite so easy, as for example: Required to cut 6 threads per inch, double; the lead screw same as before, $\frac{1}{4}$-inch lead. Then the lead of screw to be cut is 1-3-inch and the pitch of thread or the distance to move the carriage is 1-6-inch. We cannot move the carriage 1-6-inch and catch the thread with a $\frac{1}{4}$-inch pitch lead screw, but it may be moved 3-6 or $\frac{1}{2}$-inch, which will bring the tool in the proper position for cutting the second groove. For still other cases the pitch of the lead screw may be such as not to allow the above method to be used at all, but the principle having been explained the reader will have no difficulty in determining whether such is the case.

East Providence, R. I.

FORMULAS FOR DIFFERENTIAL INDEXING.

Editor MACHINERY:

In differential indexing the index circle is geared to the spindle so that, as the crank moves, the index circle also moves either clockwise or counter-clockwise, depending on whether we use one or two idlers. This motion of crank and index circle at different rates, and in the same or different directions, allows us to cut any number of divisions, exactly, without compound indexing. This method is called differential indexing.

To obtain a formula for determining the gears necessary to cut a given number of divisions we proceed as follows: If N divisions are to be cut, the spindle will rotate $\frac{1}{N}$ turn between each division; also the distance traversed by a hole of the index circle $\pm$ the distance traversed by the crank equals the number of turns, or part of turn, of the index circle.

If, then, we let $x:y$ be the ratio of the teeth of gear on spindle to the teeth of gear on worm, and if the crank turns 40 revolutions to one of the spindle, we can then obtain the following:

$$\frac{40x + y}{N\,x} = \text{the number of turns of index} \ldots\ldots\ldots\ldots (1)$$

The approximate fraction $\frac{40}{N}$ ....(2) shows the number of turns of index to use. For $\frac{40}{N}$ we should use a fraction whose denominator is a factor of some index plate at hand. By placing the proper values in formula (1) we may readily obtain the proper gears. I will illustrate by showing how to obtain the necessary gears to cut 113 divisions.

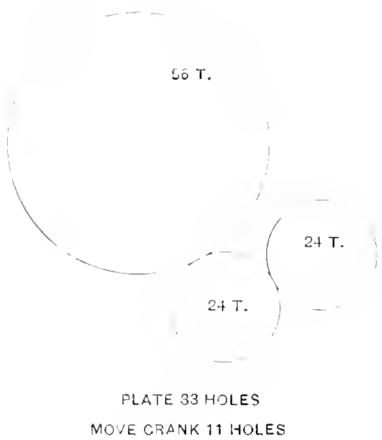

Fig. 1.

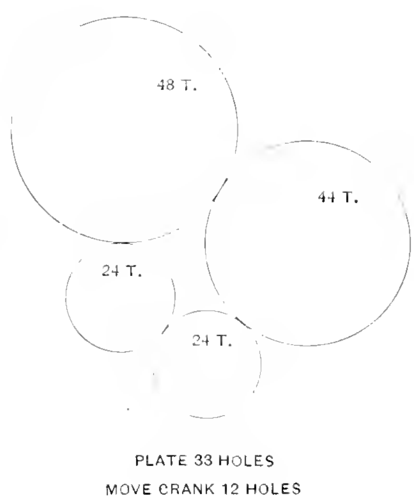

Fig. 2.

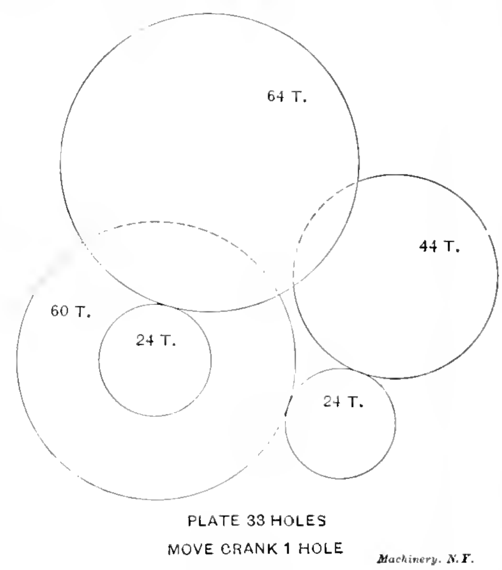

Fig. 3.

$$\text{Using formula (2)} \quad \frac{40}{113} = \frac{1}{3} \text{ nearly.}$$

$$\text{Using formula (1)} \quad \frac{40\,x + y}{113\,x} = \frac{1}{3}$$

$$\text{Solving, } 3\,y = -\,7\,x$$

Note that the sign of x is negative. This shows that only one idler is to be used, while if x is positive two must be used.

The ratio of the teeth on the worm gear to the teeth on spindle gear is 3:7

$$\begin{array}{cc} 3\,y = & -\,7\,x \\ & 8 \\ \hline 24 & 56 \end{array}$$

Use 24 gear on worm, 56 gear on spindle and one idler. Index on 33-hole circle spacing 11 holes or $\frac{11}{33}$ turns. See Fig. 1.

Often two or more sets of gears will cut the same number of divisions, depending on the number of turns of index taken. For example:

$$\frac{40\,x + y}{113\,x} = \frac{4}{11} \quad \ldots\ldots\ldots\ldots\ldots\ldots (1)$$

$$\text{Solving, } 11\,y = 12\,x$$

The sign of x is positive, therefore use two idlers.

$$\begin{array}{cc} 11\,y = & 12\,x \\ & 4 \\ \hline 44 & 48 \end{array}$$

J. O. Villars was born in Clarksville, Ohio, in 1873. His collegiate education was gained in Wilmington College, Ohio, and Haverford College, Pa. Since that time he has followed the profession of a teacher, having been assistant principal of Wilmington High School, Wilmington, Ohio, for three years, and now fills the position of instructor of physics and applied mechanics at the Williamson Free School of Mechanical Trades, Pa., in which position he has been for the past four and one-half years. In this school about 200 boys are receiving an education to fit them for the various trades of machinist, patternmaker, carpenter, bricklayer, steam or electrical engineer. The work of this school is very practical, the boys being apprentices and doing the work as they would in any well regulated shop. All the graduates are in demand at good wages.

Use 44 worm gear, 48 spindle, two idlers and index plate 33, using $\frac{12}{33}$ turns. See Fig. 2.

Suppose we wish to index 120 divisions, then

$$\frac{40x + y}{120x} = \frac{1}{3} \qquad \ldots\ldots\ldots\ldots (1)$$

$$3y = 0$$

This shows that with any index circle on which we may get 1-3 turn, we get 120 divisions, by using simple indexing.

Suppose we wish to space ¼ degree or 1,440 divisions,

$$\frac{40}{1440} = \frac{1}{36}$$

but we have no 36 plate. Therefore, use

$$\frac{40x + y}{1440x} = \frac{1}{33}$$

$$11y = 40x$$

Use two idlers compounding on one, with drivers 64 and 60, driven 24 and 44, index plate 33 and 1-33 turn. See Fig. 3.

Suppose we wish to space a vernier to read 5 minutes. By dividing 11 degree spaces into 12 parts we accomplish this. This would give $\frac{4320}{11}$ spaces in the circumference.

$$\frac{40x + y}{\frac{4320}{11}x} = \frac{1}{10} \qquad \ldots\ldots\ldots\ldots (1)$$

Solving:

$$11y = -8x$$

$$\frac{4}{44 \qquad 32}$$

Use 44 worm, 32 spindle, one idler and any index plate upon which 1-10 turn may be obtained. In this case use index plate 20, and 2-20 turn.

I believe this method should commend itself, especially where fractional indexing is needed, and where no table is given for the required number of divisions.

Williamson School, Pa.

MAKING PISTON RINGS.

Editor Machinery:

Referring to the article in the October, 1903, issue on tools for turning and boring piston rings, written by H. H. Eshenshade, it occurs to me that in his engine he used the one

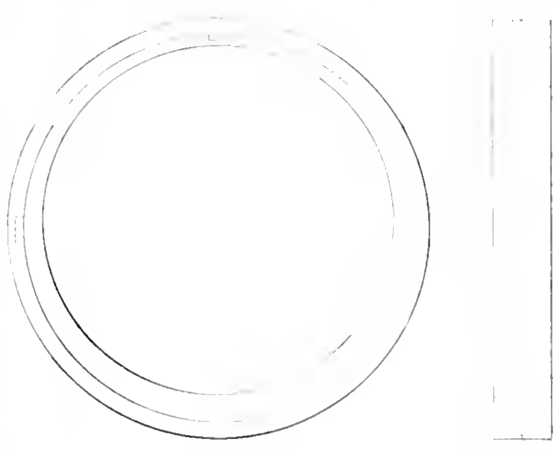

Fig 1. Making Piston Rings.

thickness of ring only, which, of course, is all right for a short-lived engine, but for fear that some one may think it the correct thing, I beg you to give me a hearing. Take for example the experience of the manufacturers of one high-grade engine covering a period of nearly forty-seven years. The conclusion at which they have arrived is that it is strictly right and proper to put in three rings, arranged in the manner shown in Fig 1. The inner one is called the bull-ring and is about 2 inches wide by ⅜ inch thick at the open side and ⅝ inch or ¾ inch thick at the other. Outside of this ring are the other two lying side by side. These are 1 inch wide by ⅝ inch thick all around. The inside of the bull-ring is not machined, the scale being left on for additional strength but the outside is turned and finished to diameter size. The outer rings are finished inside and out and must be parallel both in thickness and in width. Here comes in Mr. Eshenshade's bell chuck and it is certainly first class. The castings from which the rings are to be made should be bolted into it, and while the tool in the toolpost is turning the outside, they are bored out by an ordinary boring head with follower strung on the mandrel.

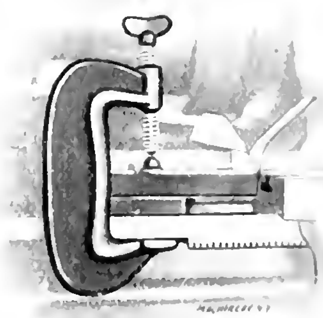

Fig. 2. Iron Clamped on Ways of Lathe to make a Position Stop for Carriage.

When this is all done and we have the exact size both inside and out, the front edge is faced off and we are ready to cut off the first ring. Now as every machine man knows that he cannot depend on a cutting-off tool to do its work exact and straight; it is, therefore, necessary to cut the ring about 1-64 inch wider than the desired finished width. After the first ring has been cut off we then face the front edge again and cut off another, and so continue until the entire blank is used up. After making one hundred or two hundred rings, we are ready to face the rough edge parallel with that already finished. This had always been a very slow operation, it being very diffcult to get them correct and interchangeable for width and at the same time keep the two sides perfectly parallel until the following plan was adopted.

The outer rings were bored and turned and cut rough to length before the bull-ring was made. Then when the bull-ring blank was on the face plate and it had been turned on the outside to fit the bore of the outer rings, and cut into sections up to the butt end of the casting, a section of this butt about ⅞ inch long was turned to a driving fit for the outer rings and the shoulder thus formed faced off perfectly square with a little clearance in the corner. One of the outer rings is then driven on with the finished side snugly against the shoulder, and an ordinary diamond point tool set for a facing cut. When the finishing cut has been taken on the first ring, and before the lathe carriage is moved, a block of iron is clamped on the ways of the lathe "bang up" against the end of the carriage as shown in Fig. 2, thus providing a position stop for the carriage. The carriage may then be run back out of the way, and the finished ring driven off, and another put on in its place. The lathe man then drops two thicknesses of ordinary paper in between the carriage and the stop piece, as shown in Fig. 2, and then takes a cut off the end of the ring. The slips of paper are then removed and with the carriage run close up against the stop, the finishing cut is taken.

Harry E. Wood was born in Fulton, N. Y., June 16, 1870. He served an apprenticeship with Frank Dilts, Fulton, N. Y., and has since acquired an extensive experience, having worked for F. W. Wheeler, Bay City, Mich., Industrial Works, Bay City, Mich., Russell & Co., Massillon, Ohio; Oswego Machine Works, Oswego, N. Y.; Ames Iron Works, Oswego, N. Y.; Dexter Folder Co., Pearl River, N. Y.; and others. Mr. Wood is an all-around machinist, tool-maker and designer, and has held the positions of gang boss and foreman. His specialties are steam engine work and paper working machinery. He spent some weeks at the Louisiana Purchase Exposition this summer in charge of an exhibit for the Dexter Folder Co.

Following this method I have faced off sixty-two 14-inch rings in 2¼ hours' time, and at the inspection every one passed O. K.

STEEL.

ACCURATE JIG MAKING.

Editor MACHINERY:

The subject of accurate measurements is one that appeals directly to every machinist and toolmaker and upon which two much light cannot be shed. In a large majority of the shops of this country the micrometer and the vernier are the only instruments used in determining whether work is made to the desired dimension, and thus these tools become the arbiters as to the accuracy of any measurements no matter how obtained, whether by screw or gage. Measurements of length and diameter within the limits of these tools are directly attained, but measurements of distance on a plane surface are not so readily found or proved until after the work is done. A method of measuring spaces on a plane surface was described by the writer in the October, 1902, issue of MACHINERY, and it was with the object of calling the attention of your readers to this method and with no desire to criticise the method described by Mr. Frank E. Shailor, in the July issue of MACHINERY that I wrote the letter that appeared in the August issue. I believe I stated that his method is a good one, but that I wished to call attention to mine, which I believe to be better—better because more generally applicable to the average shop. No method, however carefully devised, is of value unless care is taken in using it, and I venture to say ignorance or incompetence will cause errors as gross by one method as by another.

Mr. Shailor has written a letter in which he shows some ten chances for errors that I took in making jigs by the gage method of spacing the distance for bushings. I venture to say he has not read the original article carefully, for if he had he would not have advanced some of the arguments he did.

The first chance for error, according to his letter, was in placing the hole in the bracket central with the drill spindle. This does not appear to me to be a very difficult job, and is one that any good machinist or toolmaker can do without calling very heavily upon his skill. Since Mr. Shailor seems to think it difficult of accomplishment I will briefly state how it may be done: We will suppose all the play of the sleeve in the drill press is taken up and the bracket fastened to the frame of the drill press, then a short, fine-pointed centering drill is put in the chuck, and a center is very slowly and carefully made for the drill; next a short drill is used to drill the hole, which must be somewhat smaller than the bushing to be used. A boring tool is then put in the spindle of the drill press and the hole is bored central with the spindle. If Mr. Shailor will turn to the October, 1902, issue of MACHINERY he will find in my article on jig-making the description of a boring tool that is suitable for the purpose. The hole being bored, a chucking reamer is next run through it, to size it, and it is ready for the bushing.

A second chance for error, he thinks, is in not having the hole in the bushing concentric with the outside. Well, this would apply to the bushings used in any jig, and to me this appears as a trivial objection since Mr. Shailor in his July article gives minute directions for making the bushings for jigs.

The third chance for error is in the fit of the drill and the hole in the bushing; that is, they should fit each other perfectly. There is no doubt about that and it is another mechanical job not very difficult to perform. This is also a condition that must prevail when making any jigs for interchangeable work. It would not seem difficult to make a single bushing to do this when some jigs contain dozens of bushings, each one of which must have its exact size.

The fourth chance is in the fit of the outside diameter of the bushing and the hole in the bracket. This, again, it seems to me, to be trivial since it is a matter that only requires the skill sufficient to find the size of the hole and make the bushing size accordingly; a toolmaker who cannot do this much is not worthy the name.

Fifth, the spindle of the drill press must be at right angles with the table of press in every direction. This is also true of any method of making holes whether upon the drill press or against an angle-plate. No good toolmaker will take anything for granted in the machine line, since he has chips and dirt to look out for in any work he is doing. Any inaccuracy that may exist in this respect is readily found by using a piece of wire as a sweep, and is readily corrected.

The sixth chance for error is put in the form of a question which Mr. Shailor answers to his own satisfaction at least. It is: "What assurance have I that the drill continues straight through the plate?" Answer: "None whatever." Oh! yes I have, I have the assurance that comes from long practice and of doing it repeatedly. Twist drills sometimes run out, as it is called, for several reasons, the first and most common cause being that they are not properly centered and started, the second that they are crowded through the work and caused to deflect by a pressure that buckles them, especially if they are of small diameter. If it were a serious or difficult matter to drill a hole true, even to considerable depths, then I am afraid it would not be of much use to make drill jigs, since they are used solely to guide drills in the work. That it is not so is evidenced by the fact that holes of small diameter and great depth are quite common, such as, for instance, the holes that are drilled in drills having oil feed, gun barrels, etc. A drill that has been started into a piece of work true and to a depth equal to its diameter will continue to run true if it is not crowded and it encounters no variation in density of metal; that is, no holes in the work. Should it do so, however, it gives instant warning of the same by the vibration it causes in the work or the drill itself. Mr. Shailor thinks that sensitive drill presses are more sensitive to spring than any other machine, and for that reason a drill will not continue straight through a piece of work. This is undoubtedly true if sufficient pressure is put upon the drill; it is for that very reason that a small drill is first put through the work which will not require sufficient pressure to spring even a more delicate machine. The greater portion of the pressure comes upon the point of the drill and when the larger drill is used the pressure is thereby eliminated.

The seventh chance for error, he says, is when the holes are opened up with a half-round center reamer having but one cutting point, since cast iron is full of grit and that it requires but a small particle of grit to cause the center reamer to change its location. The statement that cast iron is full of grit is an astonishing one to me. Grit, as I understand the word, is a product of the rocks and stones, and if it were present in any quantity in cast iron but few if any tools could be used upon it. Cast iron, when it comes from the mold, is covered on its surface more or less with the sand from the mold, but this is usually removed by the tumbling barrel or by pickling; in any case such tools as jigs are made of finished castings, and it is only with the interior part of the casting we have to deal. Brown & Sharpe Mfg. Co. in their catalogue give an illustration of a gear tooth cutter that has cut a number of teeth of 4-pitch that is equivalent to cutting a length of 7,472 feet in cast iron. I believe that this particular cutter must have encountered very little grit to have done this amount of work. The object of using a half-round center reamer is that it tends to keep true to the hole it is opening out and it requires not a little effort to cause it to deflect.

The eighth and greatest chance is in opening the holes with a larger drill, the danger coming from having one lip of the drill the least bit longer than the other. This is provided for by the half-round center reamer which opens the mouth of the hole to a diameter equal to the reamer size and therefore larger than the drill. When the drill is entered into the hole it can cut only on the outer edges of the lips since the angle of the center reamer is 60 degrees, while the angle of the lips of the drill (to a transverse plane) is about 30 degrees or less; the drill is therefore entered a considerable distance into the work before the full size chip is taken.

It is my experience that a drill having one lip a little longer than the other will cut somewhat larger than its size, but that it should cause it to run in any direction other than that

of the least resistance is to say the least doubtful. But since this chance seems so objectionable to Mr. Shailor, I call his attention to the fact that the hole can be opened by a counterbore, and as he has said nothing against this way of opening the holes I take it for granted that it is at least feasible in his opinion.

The ninth error is in sizing the hole with a reamer. If the holes were sized with a hand reamer there would be some weight to this objection, as a hand reamer cuts only on the face of the tooth, but the holes should be opened with a machine reamer which, having it start in the hole given it by the center reamer, will follow true, as these reamers cut only on the end and not at all on the sides.

The tenth chance is the personal error in calipering the gages. Personal error, I take it, means the inability to measure twice alike and also the inability of two individuals to attain the same degree of pressure on the measuring instruments. If this condition existed there would be no such a thing as making interchangeable work, since an inch at one time would to the same man be more or less than an inch at some other time, and the product of one workman would not agree

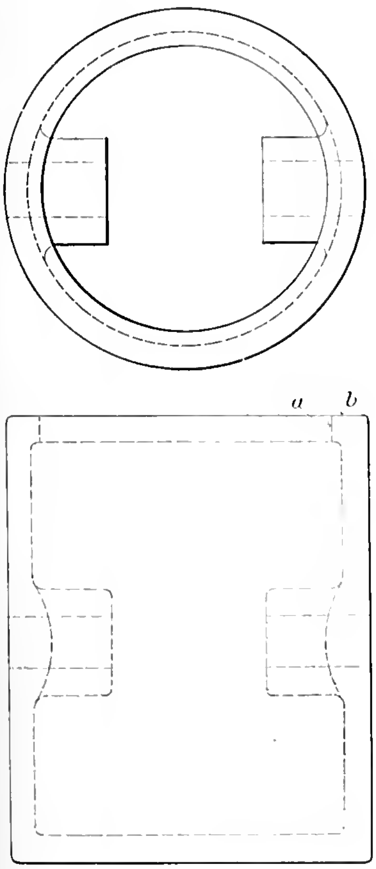

Fig. 1.

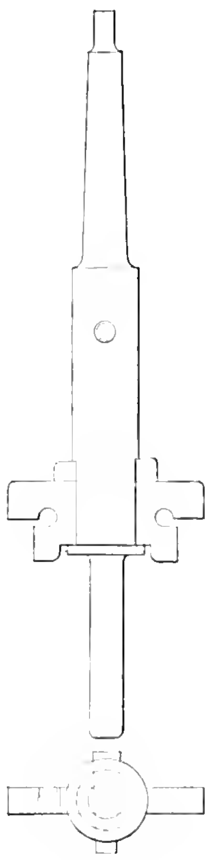

Industrial Press, N.Y.

Fig. 5.

with that of another. The facts are that men who have been accustomed to close measurements agree so perfectly with each other that when a question of this kind arises it generally leads to a test of the instruments. It is true that the pressure given the instrument may vary from one man to another slightly, but they in that case vary the initial pressure on their instruments and thus attain the same results. Mr. Shailor seems to think I add one gage on top of another in spacing the distances, but such is not the case. If I wish to move the plate one inch, then the gage would have the length to give the inch of distance required; if I next wished to move the plate one half inch further, then a gage one-half inch longer than the other is used. Errors are not then multiplied, as he seems to think.

His doubts as to whether jigs made by the method I have described could be duplicated amount to nothing, and I will state that they can be exactly duplicated if the same gages are used in both jigs and, moreover, they can be duplicated the same day or ten years hence, which is more than can be said of any milling machine screw that receives anything like the usual service given in most machine shops. J. R. GORDON.

Brooklyn, N. Y.

JIGS AND TOOLS FOR MACHINING SMALL PISTONS.

Editor MACHINERY:

I send herewith drawings of a jig and tools for machining a small piston to prepare it for the turning and grinding. The work is done by a boy on a drill press and by this method he is able to finish three in the same time that it formerly took a man to do one on a lathe. The machining consists of boring and facing one end of the piston approximately true with the inside as shown at *a* and *b*, Fig. 1.

The casting which is shown in Fig. 1 is placed in the jig, Fig. 7, but not at once clamped in place. The jig has been

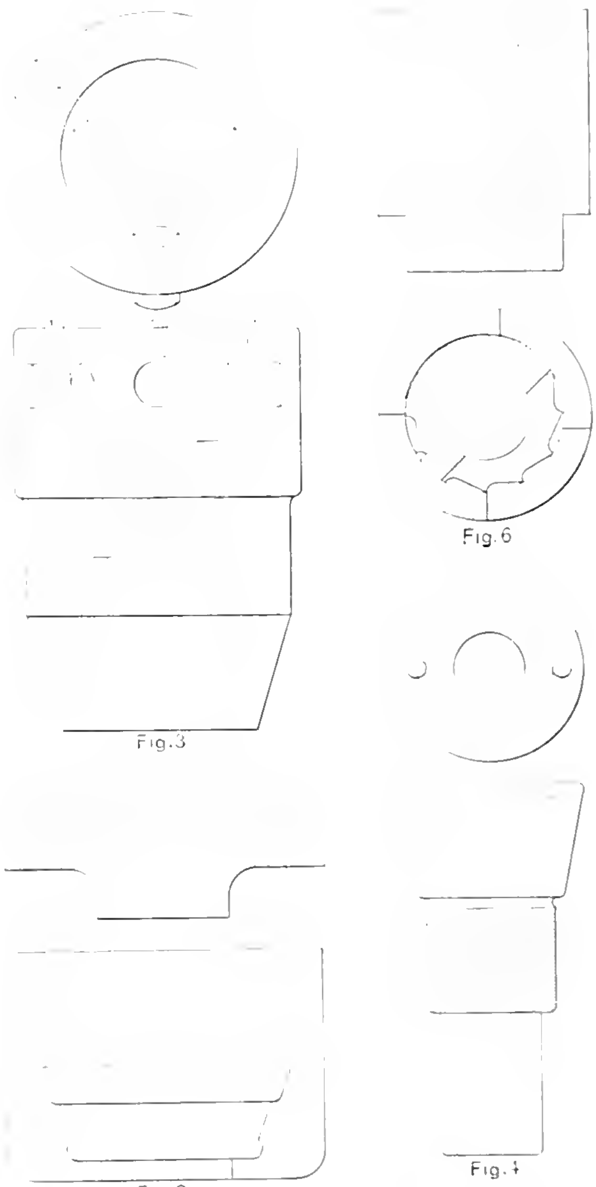

Fig. 6

Fig. 3

Fig. 2

Fig. 4

secured in place on the drill press, in spindle of which are held the boring and facing tools shown in Figs. 5 and 6. Two similar pieces, one of which is shown in Fig. 2, are then dropped to the bottom of the casting and followed by the part, Fig. 3, which, as it goes down, pushes the first two hard against the sides. The part shown in Fig. 4 is then screwed into place, the taper thereon forcing the sliding pins or dogs hard against the sides of the casting. The spindle of the drill press is now lowered until the pilot enters the lower bearing of the bushing, Fig. 4, after which the four setscrews in the sides of the jig, Fig. 7, are brought against the sides of the casting, and the clamp put in place and drawn up tight.

Before the roughing tool, Fig. 5, is placed in the drill press spindle, the finishing tool, Fig. 6, is slipped over its shank, with the lower end of the reamer resting on the roughing

cutters. After the roughing is done, Fig. 6 is turned around until the two slots come over the roughing cutters, when it will drop down until the finishing cutters are below. The taper pin is then put in place to hold it down when the finishing cut is taken.

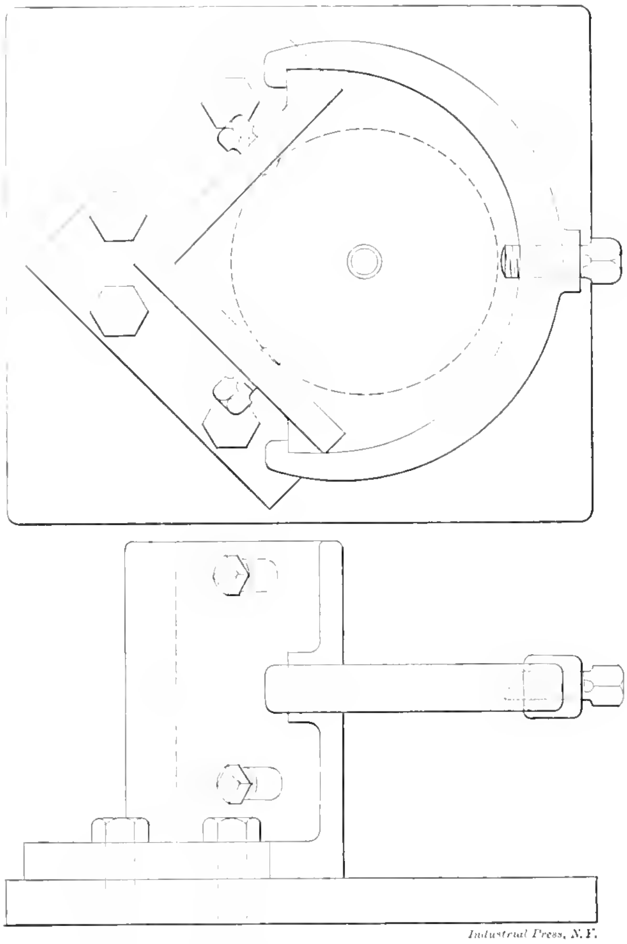

Fig. 7. Jig for Holding Cylinder.

After this operation the wrist pin hole is drilled in a jig, after which it goes to the lathe where it is drawn against a face plate by means of an eye bolt and pin, and is turned and ground in one setting. WILLIAM N. TAYLOR.

MAKING A CORE BOX FROM THE PATTERN.

Editor MACHINERY:

The following method of making a core box for a pattern, after the original core box had been destroyed, was used by

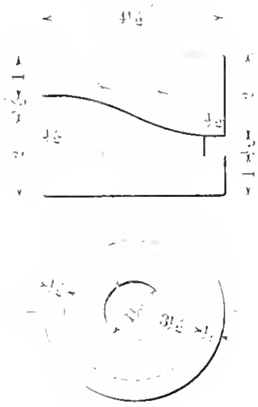

Fig. 1
Finished Casting

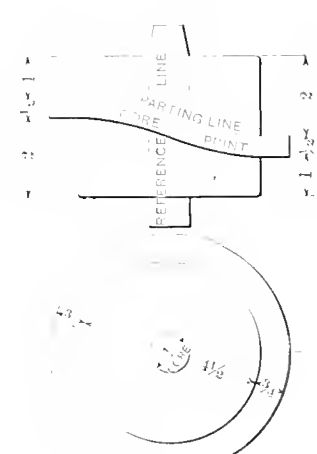

Fig. 2
Pattern with Core Prints

Making a Core-box from the Pattern.

us and may be of interest to some readers of MACHINERY. Fig. 1 shows the finished casting and Fig. 2 the pattern as sent to us. The pattern was parted, along the top of the core print, as shown in Fig. 2.

Three cylinders were turned up as follows: No. 1, Fig. 3, was made $2\frac{1}{2}$ inches long, hollow, with inside diameter of 6 inches, which was the outside diameter of the core print on pattern.

No. 2, Fig. 4, was made 2 inches long, hollow, with inside diameter of $3\frac{1}{2}$ inches, and outside diameter of 6 inches, which were, respectively, the inside and outside diameters of the core to be made:

No. 3, Fig. 5, was made solid, $2\frac{1}{2}$ inches long, with outside diameter of $3\frac{1}{2}$ inches. Reference lines were drawn on the pattern, parallel with axis, as shown in Fig. 2; on the inside of cylinder No. 1; on the outside of cylinder No. 3; and on both sides of cylinder No. 2.

The top of the pattern was taken off and the bottom part put inside cylinder No. 1, with reference line of pattern coinciding with reference line on inside of cylinder and highest part of pattern flush with top of cylinder. A line was then scribed along the inclined surface of pattern on the inside of cylinder, and the pattern was pushed back ½ inch (the thickness of core print) and with reference lines again coinciding, another line was drawn parallel to the first, and ½ inch below. The cylinder was now cut off along the first line drawn. Cylinder No. 2 was then put inside cylinder No. 1, with bottom of No. 2 ½ inch above bottom of No. 1, and with reference lines coinciding. A line was scribed along

Fig. 3 Cylinder No. 1.

Fig. 5 Cylinder No. 3.

Fig. 4 Cylinder No. 2.

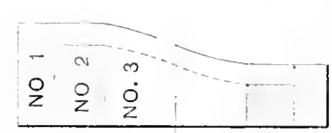

Fig. 6 Cylinder No's 1-2-3
Complete Core Box.
Machinery, N.Y.

Parts of the Core-box.

the inclined surface of cylinder No. 1, on outside surface of No. 2, and cylinder No. 2 was cut off to line scribed. Cylinder No. 3 was put inside No. 2, with bottom of No. 2 ½ inch above bottom of No. 3, and with reference lines coinciding. A line was scribed along inclined surface of cylinder No. 2 on outside surface of No. 3, and cylinder was cut off to this line.

Then cylinder No. 2 was fastened inside No. 1, and cylinder No. 3 was fastened inside of No. 2, with the bottom surfaces all flush, and all reference lines coinciding, this making the complete core box as shown in Fig. 6. Cylinder No. 3 should come flush on top with cylinder No. 1, and cylinder No. 2 should be ½ inch below, and should come even with the second line scribed on cylinder No. 1.

This method does away with making paper templets and obviates mistakes caused by discrepancy in transferring from paper to wood. If the curve is irregular it is just as easy to lay off with this method as if it were a regular curve. We get the exact curve because we scribe our first working line from the pattern itself. JULIAN D. PAGE.

Youngstown, Ohio.

"CAST IRON SINKS."

A good joke, like the Wandering Jew, can never die. Although it be as ancient and hoary-headed as the everlasting hills, still will it periodically come forth from some unknown hiding place, and gambol before the multitude as nimbly as when the world was young. Who in his youth has not heard of the rustic glaring at the sign: "Cast Iron Sinks" and his scornful comment: "Of course it does, who thought 'twould float," but, like Banquo's ghost, it again walks, and the printed page of a contemporary blazons it forth as a fine sample of original Maine humor to tickle the risibilities of the simple-minded.

SHOP KINKS.

A DEPARTMENT OF PRACTICAL IDEAS FOR THE SHOP.

Contributions of kinks, devices and methods of doing work are solicited for this column. Write on one side of the paper only and send sketches when necessary.

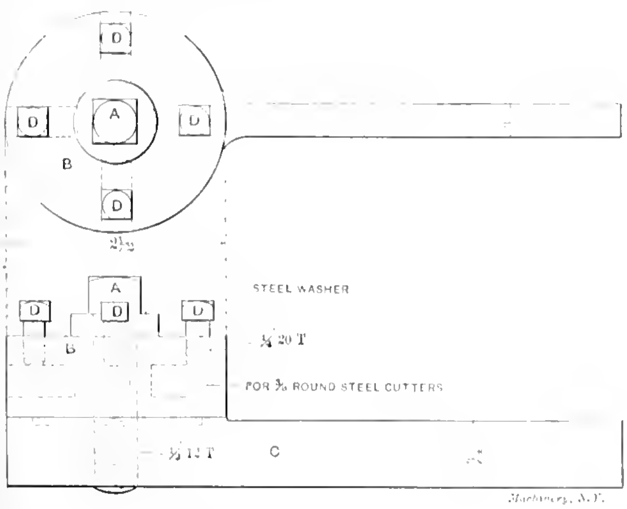
SCREW CUTTING KINK.

When cutting screws of very quick pitch, or cutting the teeth of spiral gears in a lathe, I place a pulley on the lead screw and lengthen the cone belt so as to drive the lead screw directly from the countershaft, and drive the spindle back through the change gear. By doing this, I am enabled to drive the carriage back and fouth much quicker and with less strain on the lathe. When cutting a quick pitch, more power is generally required to operate the carriage than to drive the spindle. EUGENE WORALETZKY.

Trenton, N. J.

TURRET TOOL HOLDER.

The sketch shows a turret toolholder that I use in the toolpost of an engine lathe, and which I find to be a great timesaver on many jobs. The lower or shank part of the tool *C* is a forging with an enlarged end, which is faced, recessed and tapped for the ½-inch clamping screw, *A*. The turret head *B* is turned with a shoulder to fit the recess in the shank *C*, and has four holes drilled in its periphery for the ⅝-inch Jessop steel cutters. The cutters are held with ¼-inch setscrews. On most work the turret head is set so that two tools are used without loosening the clamping screw, *A*, and in some cases three tools may be so used. For instance, suppose we have a facing and turning job on a ring that can



be caught on the outside of the chuck jaws. The right-hand tool is used for facing the side of the ring next the chuck; the front tool for turning the outside; and the left-hand tool for facing the side toward the tailstock. In close quarters, of course, this cannot be done, but where it is necessary to shift the turret it can be done much quicker and with a fraction of the effort required to change a tool held in the toolpost. While the turret has only four holes a mechanic with some ingenuity will often be able to perform five or six operations with them. A gear blank, for example, can be centered, drilled, bored and reamed (a shell reamer being fitted over the boring tool), faced and turned with it. In fact it makes a pretty fair substitute for a turret lathe on many jobs.

New York. L. S. ROSENTHAL.

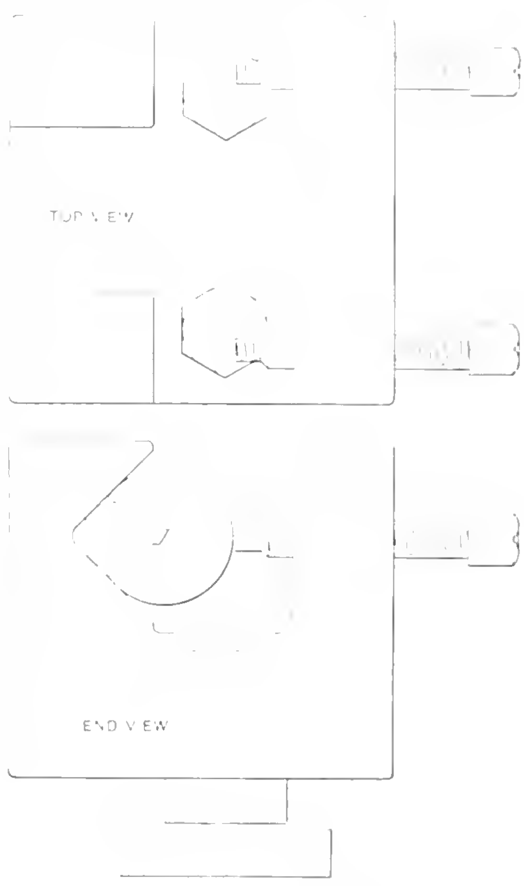
SHRINKING NUTS OR RINGS FOR PERMANENT SET.

If you should have a nut that requires a snug fit and the tap has cut it too large by three to five thousandths or more, put the nut in the fire, heat it to a bright cherry red, then hold it on a rod and let a stream of water strike it on the outside, keep it turning all the while, cooling off from the outside entirely. Another good way is to heat the nut, the same as before, then hang it on a hook of light wire and immerse one-half of it in the water until cool, then place it back in the fire, heat it as before and cool the other half in the same manner. Be sure to turn the nut half around. Often the nuts fit a little too tight after shrinking, but it is an easy matter to reduce the bolt a few thousandths. In shrinking a ring of about 8 inches diameter made of ⅜ x 1¼-inch flat stock, the diameter can be permanently reduced about ⅛ inch by heating to a glowing red and dipping in the water edgewise to just half the width until cool, then place in the fire, heat, as before, and cool the other half in the same manner. The idea is to shrink one edge and the other will be compressed as long as there is enough heat in it, and so takes a permanent set. C. D.

Hanover, Pa.

BORING BAR HOLDER.

The accompanying sketches illustrate a boring bar holder in use on a 24-inch lathe. It is made of soft steel, and was casehardened to keep the V-groove from getting bruised. It was made large enough to take in a 3-inch bar. In this holder the boring bars are always at the proper height regardless of their size. No extra bushings are required for smaller bars. A socket for a large size taper shank drill and the necessary reducers are part of the outfit.

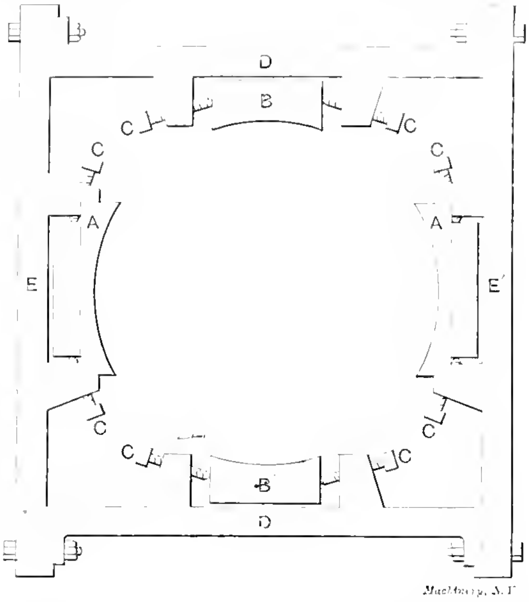


In making this holder the outside was finished, and also the inside, excepting the V. It was then put on the lathe and a light cut taken on both sides of the V, using a bar held in the chuck. Then the V was planed true with the cut, this insuring that the bar would always be held in line with the centers. H. G.

FIXTURE FOR BORING BRASSES.

The cut shows an efficient and cheaply made jig or fixture for holding the main brasses and quarter brasses of large bearings, for boring. The frame of the jig is composed of four parts, *D D'* and *E E'*, held together at the corners by through bolts. The height of the jig or fixture depends of course upon the length of the brasses to be bored. The reason for making the jig or fixture in four parts, as indicated, was first that the pattern work and molding was cheaper, and second that the jaws for the brasses could be easily planed out, which would not have been the case in this shop if cast solid, since we have no slotter. The plan of the jig is

shown in the cut, and it will be noted that the holding screws *C* are set in an inclined position, thus tending to force the brasses solidly against the outside of the fixture. It was

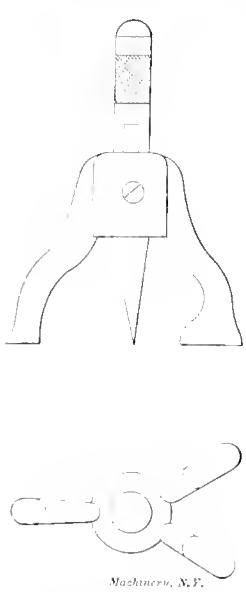


made so that it would take in a variety of sizes, distance pieces being provided to go between the brasses and the frame. It is used on a boring mill and works very well.

PHILADELPHIA.

PRICK PUNCH HOLDER.

The accompanying cut (which is full size) of a prick punch and holder was designed for prick-punching the center mark when laying out work that is afterward to be trued up by this center mark in the lathe by an indicator.



The punch is made an easy but close fit in the holder and is flattened slightly on one side as shown, so that the small setscrew will keep it from coming out of the holder. The point of the punch must be ground true after hardening, otherwise it might draw to one side when struck with the hammer. As the holder rests on three legs there is no tendency to rock, and when the point of the punch rests on the work and is given a light blow, it is sure to go straight down, leaving the center and sides of the hole true. When a center is required that comes close to the edge of the work the two legs with the largest feet may be pressed firmly down to the work and the third leg allowed to overhang while the blow is struck.

Watervliet, N. Y. M. H. BALL.

TOOLS FOR FACING WORK IN THE LATHE.

We all know what a useful tool the half center shown in Fig. 1 is, and we also know that it is a tool rarely found on the various lathes in machine shops, although it is a very annoying proposition to properly face off the ends of shafts, etc., without the proper tools. For this purpose I devised a little contrivance which is a "crackerjack." My first plan was to use the combination drill and countersink (60 degrees) for centering in the usual manner and then re-countersink slightly with a blunter countersink about 90 degrees. Fig. 2 shows how this second countersinking operation made it easy to face down the center. Fig. 3, however, shows my improved method of obtaining the desired result, the small shell end mill *A* being made of drill rod to fit the combination drill and countersink. The teeth are simply filed and headless screw is pointed and small notches are ground in the body of the countersink which completes the outfit. It will be found extremely useful, and especially desirable is the feature of using this new combination tool for the ends of mandrels, as it sets the center back from the end, thereby protecting same from the hammer blows. Various sizes of shell mills

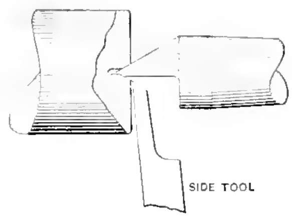


Fig. 1.

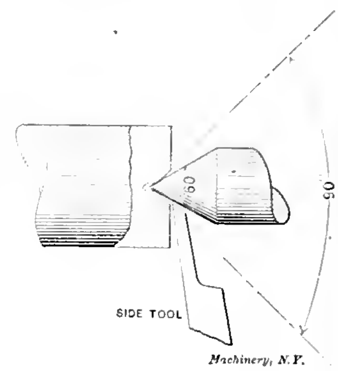

Fig. 2.

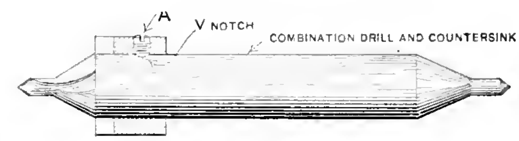

Fig. 3

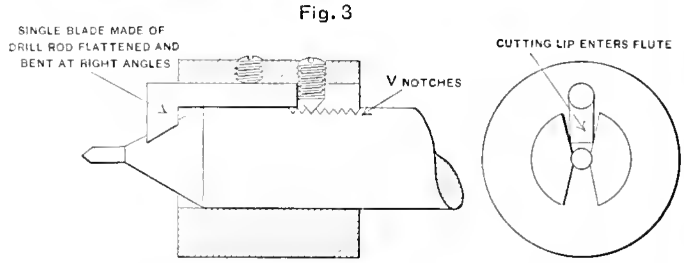

Fig. 4

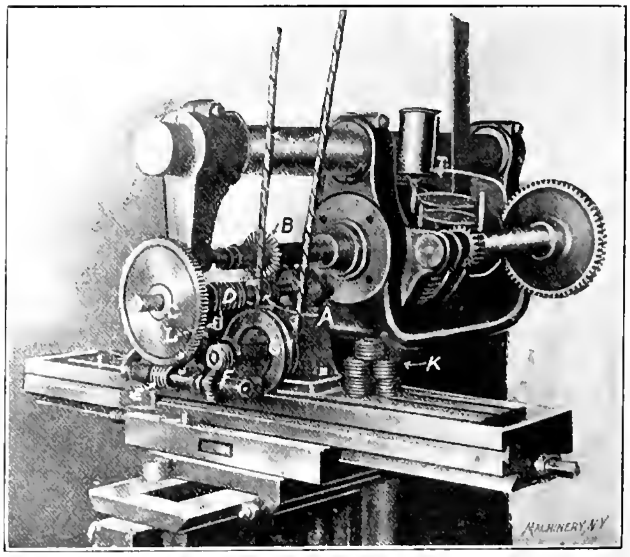
can be kept on hand should same be found necessary. Fig. 4 shows a single blade arrangement adjustable so small centers can be drilled.

ROBERT A. LACHMANN.

Chicago, Ill.

MILLING MACHINE ATTACHMENT FOR THREADING WORM WHEELS.

The half-tone shows a milling machine attachment used in our shop for several years for cutting the threads of cast iron worms. It includes a base which is bolted to the milling machine platen and provided with bearings for the work arbor and the cone pulley shaft. The worm to be cut is mounted on the arbor and is rotated and moved longitudinally at the same time so as to mill the thread. *A* is the work; *B*, the milling cutter; *C*, a worm wheel; *D*, the lead screw; *L*, a pin having a thin end, which engages the thread of lead screw and acts as a half-nut; *E*, a worm driving wormwheel *C*. It in turn receives its motion from the worm and wormwheel shown at *F*. Power is transmitted to the cone pulley *G*, by the leather belt *H*. The work arbor is splined and is free to



move longitudinally in its bearings, so that as it rotates the lead screw can move it longitudinally as is required to generate the thread. A number of the finished worms are shown on the platen at *K*. PHILADELPHIA.

USING A TAP AS A REAMER.

Having drilled a hole which I was intending to ream out with a 1¼ inch reamer, I found that there was not one of the reamers of that size could be used. So an old tap of the same size was fitted with an extension holder (so it could be held in the drill chuck) and put it in the drill press chuck. Putting on the feed I got as good a hole as I could have gotten with a regulation reamer. Of course the tap could go no faster than the feed was set and consequently the thread cut by one tooth was cut off by the next. ROBERT B. OTIS.

Orange, Mass.

PLANING A CROSS GROOVE.

On one occasion I had to plane a groove in a very large table square across the face. To drive the tool back and forth by hand with the cross-feed is a very tiresome job, so I rigged up means for doing it by power. We had two planers in the shop standing parallel to each other. From planer No. 1 I took out the cross-feed screw, and placed in the end bearing a roller over which a chain was run to a roller in the toolpost of No. 2, then connected to a heavy stud in the platen of planer No. 2. The other end of the chain was secued to the cross slide of planer No. 1 by one of the swiveling screws. Another chain was connected to the opposite side of the cross-slide and run over the roller held in the toolpost in planer No. 2, and thence to the heavy stud. One chain was used to pull the cross-slide back, and the other to pull it ahead. The stroke of the platen of planer No. 2 was set at just the right length, and a helper stopped it at the end of each stroke and exchanged the chains, while I operated the feed on planer No. 1. It was necessary to lift the tool up on every back stroke, as the clapper-box, of course, could not lift to relieve the tool. EUGENE WOPALETZKY.

Trenton, N. J.

* * *

HOW AND WHY.

A DEPARTMENT INTENDED TO CONTAIN CORRECT ANSWERS TO PRACTICAL QUESTIONS OF GENERAL INTEREST.

Give all details and name and address. The latter are for our own convenience and will not be published.

12. C. W. M.—In the directions for turning tapers in the September, 1904, issue, where does "J. T." get the figure 8 which he uses as a multiplier of the distance between the centers; also of the distance to throw the tailstock?

A.—The use of the number 8 as a multiplier is optional, any number could be used instead—or none. The idea is merely to increase the length and amount of taper for convenience in measurement. But both the length and the taper must be multiplied by the same number in order to keep the correct proportion. With the larger dimensions, it is, of course, much easier to get accurate measurements, and that is the only reason for multiplying the given dimensions by *any* number.

13. H. T. S.—I made the lathe roller according to the instructions given by Mr. R. F. Kiefer in the August issue, but find that it works unsatisfactorily. When forced against the work under sufficient pressure to smooth it, the roller ceases revolving and stops. What is the trouble?

A.—The reason the roller refuses to revolve when forced against the work with considerable pressure is undoubtedly because of excessive friction in the bearing. It may be that you did not get the hole through the fork bored square with the sides, in which case the roller may bear hard against one side. In any case the roller should be made with narrow collars projecting above its sides immediately around the bearing. These collars take the side thrust against the sides of the fork and thus reduce the friction from what it would be if the whole side of the roller bore against the fork. To further reduce friction the bolt or pin upon which the roller revolves should be hardened; this also prevents cutting. In general it is best to make lathe rollers for finishing work with a wider bearing than that indicated in Mr. Kiefer's sketch. The best practice is to make the bearing from two to three times the width of the face, thus with a ½-inch face the bearing should be, say 1½ inches long. In some cases the roll is made of brass or bronze, thus reducing the frictional resistance.

14. Y. E. B.—Will you please explain the method of determining the compression space in a gas engine cylinder so as to obtain any desired amount of compression?

A.—There are two parts to the inside of a gas engine cylinder, one being the compression space and the other the portion traversed by the piston. The latter is equal to the stroke in length, so we will designate it by the term "stroke," while the former we will call the "compression." The sum of these two portions is equal to cylinder volume. See Fig. 1.

Now, if we desire to make our calculations in atmospheres, then the number of atmospheres which we wish the compression to be will represent the total cylinder volume, and one atmosphere will represent the compression space, so we have: Total cylinder volume — 1 = stroke. See Fig. 2.

If we wish to build an engine having a stroke of 12 inches with a compression equal to 4 atmospheres, we would have: Cylinder volume, 4 — 1 (compression) = 3 = stroke. The stroke is 12 inches, so if 3 equals 12 inches, then 1 equals 1-3 of 12, which is 4 inches. Therefore, the compression space should be 4 inches in length.

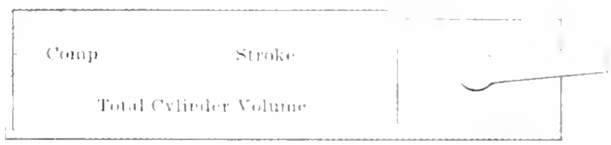


Fig. 1

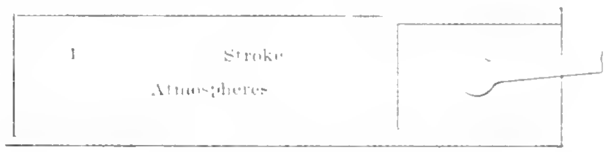

Fig. 2

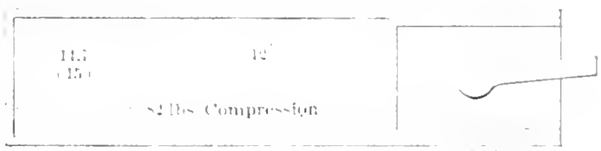

Fig. 3

Had we desired to obtain a compression of 4⅛ atmospheres, then 4⅛ = 33-8, so that 33 = cylinder volume and 8 = compression. Then 33 — 8 = 25 = stroke. If the stroke is 12 inches, 8-25 of 12 = 3.81 = compression space. This relation may be expressed by the formula:

$$\frac{\text{stroke}}{\text{atmospheres} - 1} = \text{compression space.}$$

If it is desired to express the compression in pounds rather than atmospheres, then the compression space will be represented by the value of 1 atmosphere in pounds, or 14.7 pounds. The total cylinder volume or length will be represented by the total number of pounds compression to be obtained. In this case we have:

$$\frac{\text{stroke} \times 14.7}{\text{compression} - 14.7} = \text{compression space. See Fig. 3.}$$

For general purposes, it is sufficiently accurate to consider the value of 1 atmosphere as 15 pounds.

Example: In an engine of 12 inches stroke, it is desired to have a compression of 82 pounds, what will be the length of the compression space?

$$\frac{\text{(stroke) 12-inch} \times 15}{\text{(comp.) 82 lbs.} - 15} = 2.68 \text{ inches} = \text{compression space.}$$

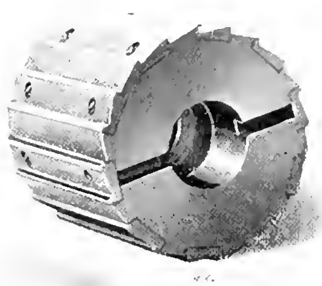
In the foregoing examples, no consideration has been taken of the increase of temperature.

NEW TOOLS OF THE MONTH.

A RECORD OF NEW TOOLS AND APPLIANCES FOR MACHINE SHOP USE.

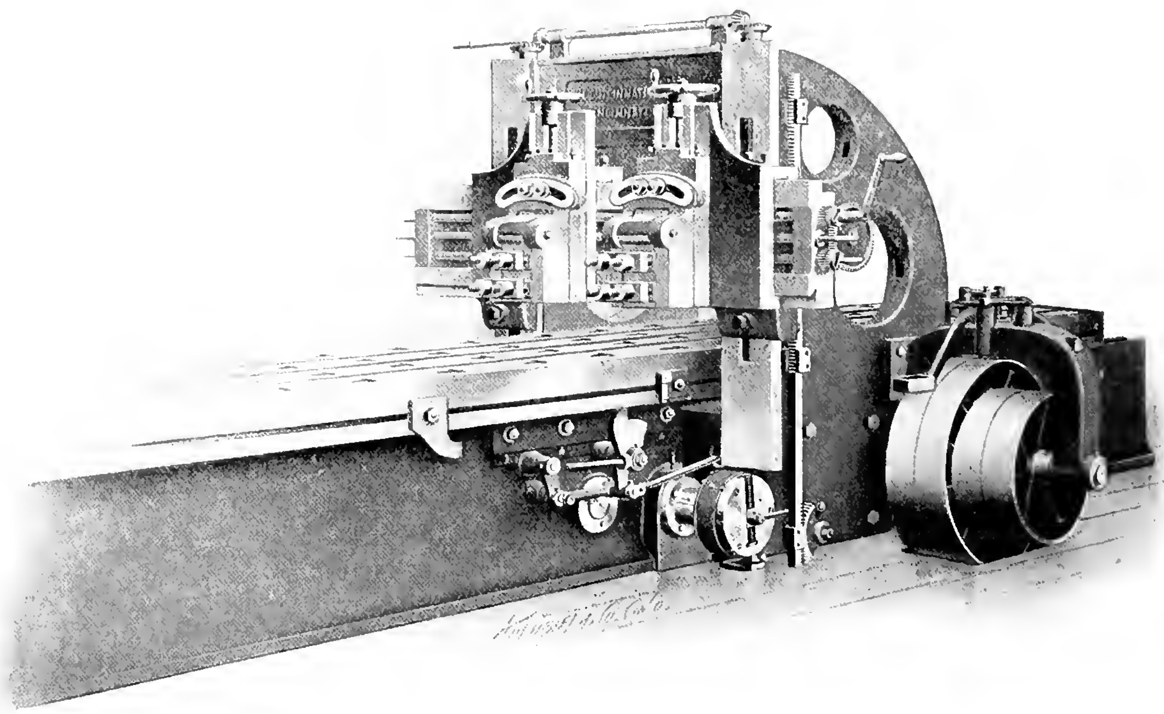
A "SOLID" ADJUSTABLE REAMER.

One of the late additions to the ever-increasing list of improved tools, and one that has the advantage of having been designed to meet the want which was felt for it in the shop



Gisholt Adjustable Reamer.

of its builders, the Gisholt Machine Co., is shown in the accompanying illustration. It is an adjustable shell reamer, the principal feature being the extra heavy blades, each having two cutting edges. This gives a simple and strong construction and is a close approach to the solidity of a one-piece tool. The body is made of crucible cast steel, bored and slotted to fit the standard shell reamer arbors. These reamers are manufactured in all standard sizes, both for hand and machine use.



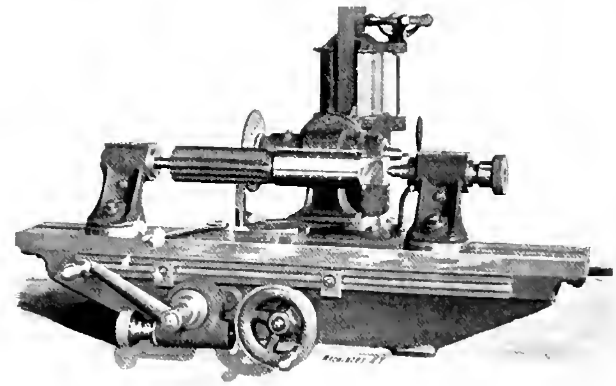
Planer for Frog and Switch Work, Cincinnati Planer Company.

THIRTY-SIX INCH FROG AND SWITCH PLANER.

The half-tone above illustrates a 36-inch planer for frog and switch work. In this tool the bed is deep and braced by box girders and four walls have been built between the housings, where there is the greatest strain. Extra wide vees are also provided, which are well lubricated. The table is massive and has an inside bearing on the bed its entire length, overcoming the pressure of heavy side cuts; and to prevent lifting there are adjustable steel gibs on each side. The housings are of box form 10 inches face and extend to the floor. The cross rail is 18 inches wide and strongly braced, making a very rigid construction. The heads have automatic cross and vertical feeds, and are made right and left to bring them close together. There is a safety locking device on the shifting mechanism, and the levers are so arranged that the machine can be operated from either side. The driving shafts are unusually large and run in long bearings fitted solidly into the bed. The rack and gearing are made from solid crucible steel and have been designed to withstand the enormous strain incident to frog and switch work. The countershaft gives two cutting speeds, with a constant return, and is equipped with adjustable ring-oiling hangers. This tool is manufactured by the Cincinnati Planer Co., Cincinnati, O.

WALKER TOOL GRINDER.

We recently illustrated a new cutter and reamer grinder made by the Walker Grinder Co., Worcester, Mass., which has a number of novel features. Among these is the swiveling head attached to an upright column at the rear of the machine, the construction being made possible by the method of belt connection in the Walker type of grinder. The swiveling head construction and belt connection are employed also in the grinder shown herewith. The machine, however, is smaller and less expensive than the one previously illustrated. It is made either as a bench grinder or is mounted on a base, as preferred. The spindle can be used at any angle from horizontal to vertical without altering the belt tension, adapting it to grinding angular mills, backing off reamers, grinding shoulders, the edges of flat pieces, etc. The machine is pro-



Walker Tool Grinder.

vided with an adjustable stop for lever cross feed, the bed is supported on a three-point bearing, the platen is of the T-slot pattern and the center heads are clamped against one side of the T-slot insuring perfect and permanent alignment. All swiveling parts are graduated. An overhanging guard on the rear protects the cross slide. A graduated swivel socket holder, which can also be used as a center, and a tail center block, are provided and, if desired, a vise and other accessories can be supplied.

NEW SENSITIVE DRILL PRESSES.

There has recently been perfected a sensitive drill press for which many advantages are claimed. The inventor of this machine is Mr. Charles D. Rice, superintendent of the

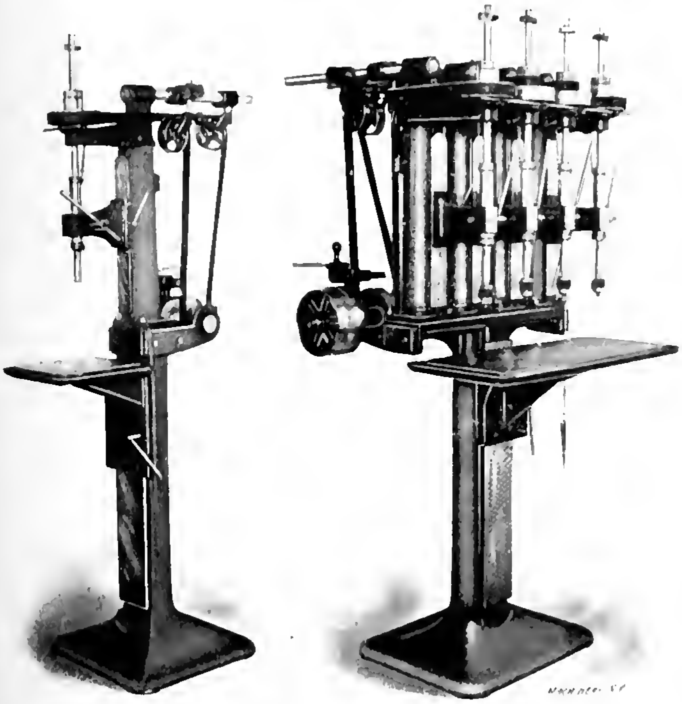


Fig. 1. Drill Presses made by the Henry & Wright Mfg. Co.

Underwood Typewriter Co., Hartford, Conn. Mr. Rice's extended experience in the manufacture of small parts led him to believe that marked improvements were possible with light drilling machines, particularly as regards the high spindle speeds for small drills and the driving efficiency for large ones. This new press is manufactured by the Henry & Wright Mfg. Co., of Hartford, Conn., which company has had designed and constructed a complete outfit of special tools and fixtures for its manufacture in quantity lots and on a strictly interchangeable basis, they having acquired the exclusive right to manufacture for the American trade.

In this drill press the friction is very largely reduced by the use of ball bearings throughout. The spindle is driven by a continuous cemented belt, with means for taking up any slackness and for giving the belt sufficient tension. A new balanced roller key for the spindle drive reduces the friction required in feeding the drill spindle under heavy orsional strains; and the frame is heavier than usual, to secure rigidity. There is also an arrangement whereby four spindle speeds are obtained without adding to the weight of the pulleys. These features have resulted in a greater increase in the amount of work turned out.

Recent tests have shown the following results: A 5-16 drill driven at 1,740 revolutions per minute, drilled through cast iron 1¼ inches thick in 5 seconds, which in one minute would drill through cast iron 15 inches thick. A 7-16 inch drill driven at 780 revolutions per minute, drilled through cast iron 1¼ inches thick in 7 seconds, which in one minute at this speed would drill through cast iron 10 inches thick. A ¾-inch drill at 780 revolutions per minute, drilled through cast iron 1¼ inches thick in 15 seconds, which in one minute at this speed would drill through cast iron 5 inches thick.

These are so unusual that they would seem to a mechanic to be exaggerated, but we are assured that they are actual results that can easily be attained by one of these machines.

It will be observed that the adaptability of the press to drills of from ⅜- to ¾-inch diameter, which heretofore sensitive drill presses have not been able to handle with the economy of heavier machines, makes it available for much of the drilling that has heretofore been done on slower upright geared drill presses.

As stated, the drill presses are equipped throughout with ball bearings, even to the loose pulley used for its driving belt; and the machines run so freely that the same width of belt and size of main driving pulley are used for any number of spindles, from 1 to 6. The same width of belt is used for the main drive as on each drill spindle. The rated power of the driving belt, as given by the makers, for a 6-spindle machine, is but 30 per cent. of that commonly used, yet they state that the drill spindles have fully twice the driving capacity of a machine without the ball bearings, and other features for increasing the efficiency.

Fig. 2 shows details of the driving shaft at the rear of the drill press and indicates the character of the ball bearings on both pulleys and also the method of adjusting the driving pulley on its shaft to enable it to track properly when the belt is changed from one step of the pulley to the other.

A novel idler system has been introduced to make the single endless belt feature feasible. The innermost idler can be adjusted vertically to deliver the belt to either step of the drill spindle cone, while the rear idler has a horizontal adjustment for giving the belt any desired tension.

An interesting feature is the method employed for obtaining four different speeds for the drill spindles and with but two steps to each cone pulley. The plan is to procure the two slowest speeds by allowing the belt to remain on the largest drill spindle pulley step and to shift the rear driving cone pulley lengthwise, introducing either step of the rear driving pulley for action. The two higher speeds are had by dealing with the small step of the drill spindle pulley in a similar manner. It will be noted that when the larger drills are in use only the major diameter of the spindle pulley is used, thereby giving marked driving advantages; also when dealing with smaller drills and which offer less resistance, a very much smaller pulley diameter is used, thereby maintaining a low belt travel as compared with the drill spindle speed, so that

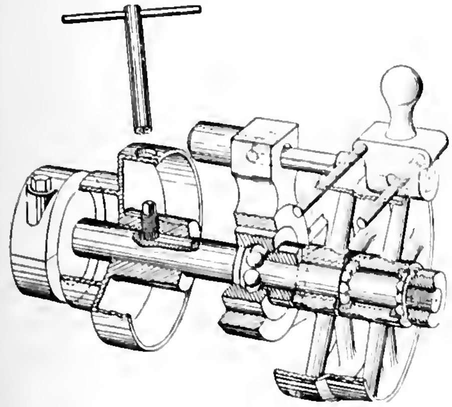

Fig. 2.

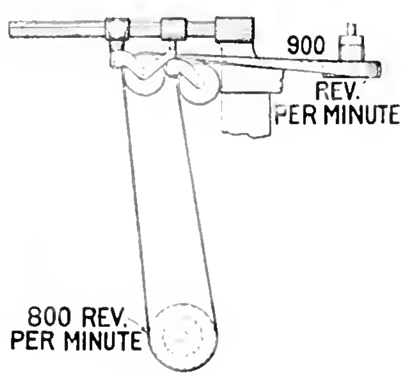

Fig. 3.

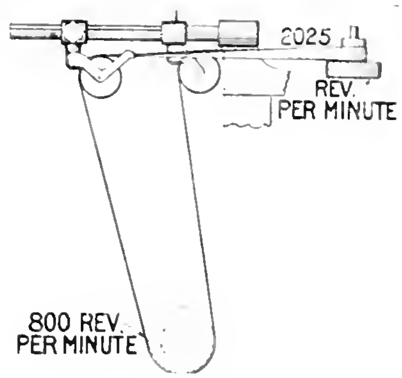

Fig. 4.

with the belt travel advantage, and frictionless journals, very high speeds are possible in every-day practice, which particularly qualifies the tool for the using of drills made of high-speed steel.

In Figs. 3 and 4 the belt is shown in two different positions, for giving spindle speeds respectively of 900 and 2,025 revolutions per minute, with a constant speed of the driving shaft of 800 revolutions per minute. In Fig. 3 the belt is on the large step of the driving pulley and the large step of the spindle pulley, with the idlers arranged accordingly; while in Fig. 4 the belt is still on the large step of the driving pulley but on the small step of the spindle pulley. Similarly by changing to the small step of the driving pulley, two more speeds of 900 and 1,350 revolutions per minute are obtained without changing the speed of the driving shaft. In the large sketch Fig. 5 is a rear view of the machine indicating the method

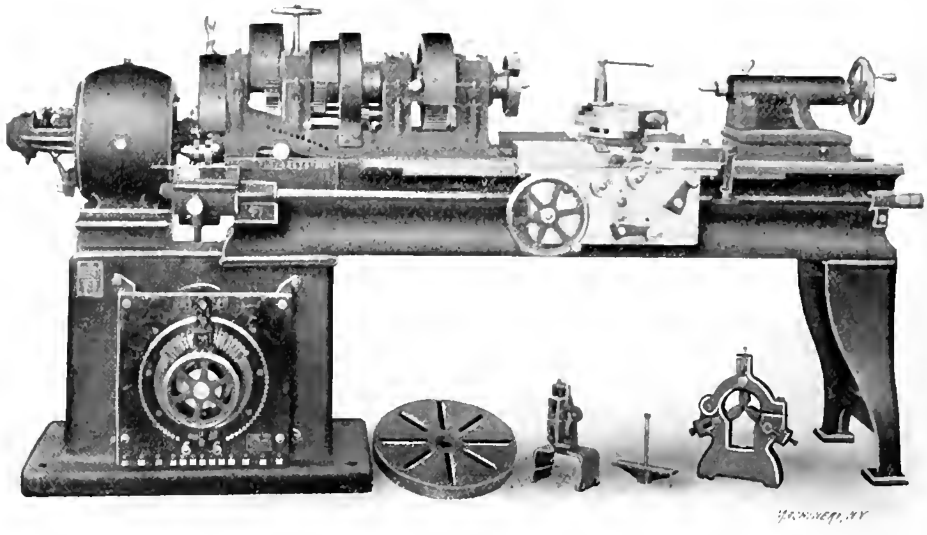

Fig. 1. Lathe Designed especially for Motor Driving.

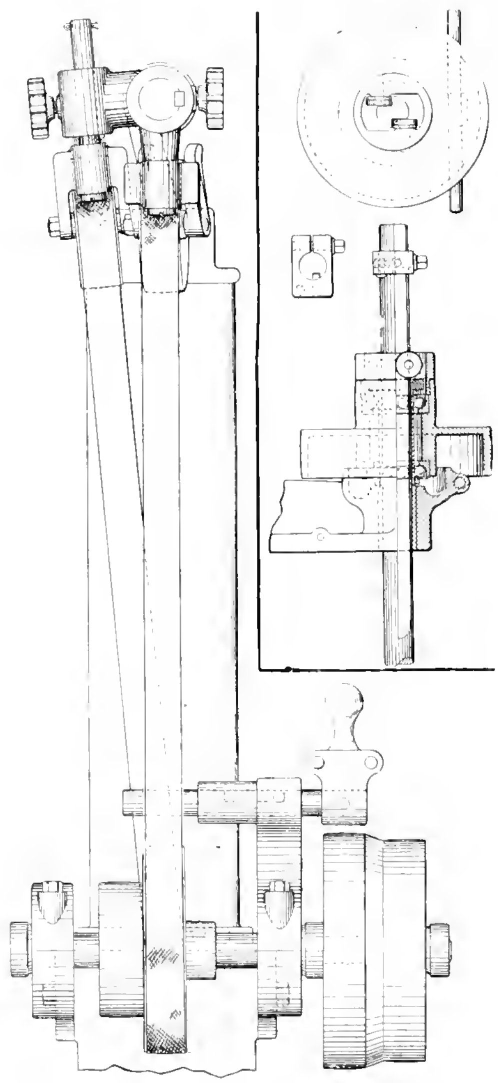

Fig. 5.

of adjusting the idler pulleys to allow the belt to track properly and to take up the slack in the belt.

Another original feature is the use of balanced roller keys, placed diametrally opposite on the drill spindle, for transmitting power between the pulley and the spindle. The object is to overcome the drag due to a plain sliding feather. By using the two balanced keys the spindle is relieved of side thrust in the bearing which supports it within the pulley and by using keys of the roller type, which Mr. Rice has introduced, friction is further eliminated. The small view in Fig. 5 illustrates the balanced roller keys, to take up friction at this point, and also shows the detail of the two-step pulley which drives the spindle. This pulley runs on ball bearings on a sleeve attached to the frame of the drill press, which relieves the spindle entirely from strain due to belt pull.

These drill presses can be used with high-speed steel drills up to the full capacity of the drills, without injury to the press.

LODGE & SHIPLEY LATHE, WITH MOTOR.

The two illustrations herewith are of a motor-driven lathe as now built and equipped by the Lodge & Shipley Machine Tool Co., Cincinnati, O. The motor will give a speed variation of two to one, and the lathe head gives three speed changes which, with the two mechanical changes on the driving shaft, makes six changes obtained in the lathe itself. This

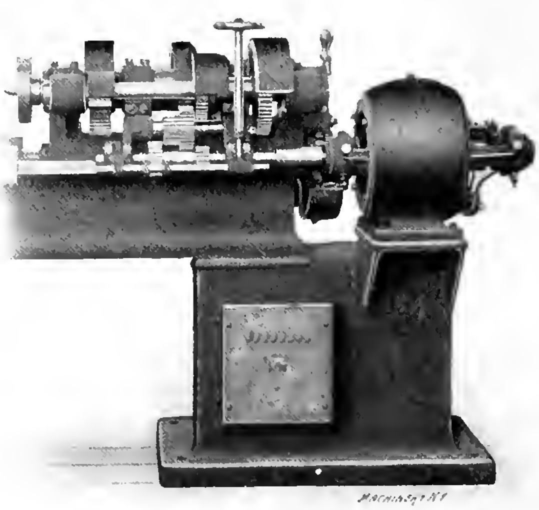

Fig. 2. Rear View of Headstock End.

with the speed variation of the motor, gives a very wide range. The whole arrangement is extremely simple and convenient for the operator. As regularly made, the controller is operated from the carriage and not as shown in the engraving. If desired the lathe can be furnished with a pulley suitably supported in place of the motor, so that the lathe may be operated directly from the line shaft with six changes of spindle speed. The special features to which the builders call attention are the mechanical simplicity of the design and its neatness of appearance. The headstock has all the advantages of the lathe head recently patented by this company, by which high speeds and heavy cuts are easily obtained throughout the whole range of diameters that the lathe can turn without introducing excessive strains or speeds in the bearings or other parts of the headstock mechanism. The illustrations shown in this connection are self-explanatory and need no further description.

NEW AUTOMATIC DRILLING MACHINE.

A year ago we illustrated a rotary-pattern multiple-spindle drill made by the National Automatic Tool Co., Dayton, O., for drilling the small parts of machinery to be manufactured in large quantities. This machine was designed with two groups of spindles, the idea being that if one set of drills was able to handle the drilling, the other set could be used for reaming or tapping; or if the holes were so near together, or there were so many of them that one cluster of spindles could not drill them all, the other group could be called into requisition. Another machine has now been brought out by this company in which this idea is extended so as to include a greater number of combinations, and perform a greater variety of work. The machine has a platen that revolves and carries the jigs with it. The pieces of work are put into and taken out of the jigs by the operator as the table rotates, and one complete rotation of the table completes all the operations to be performed upon a given piece.

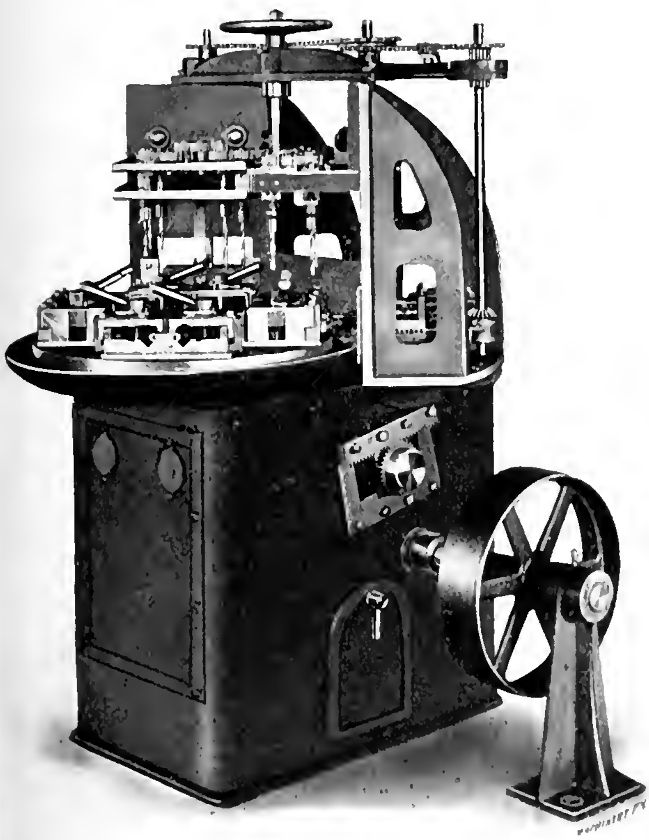

Fig. 1. Automatic Manufacturing Drilling Machine.

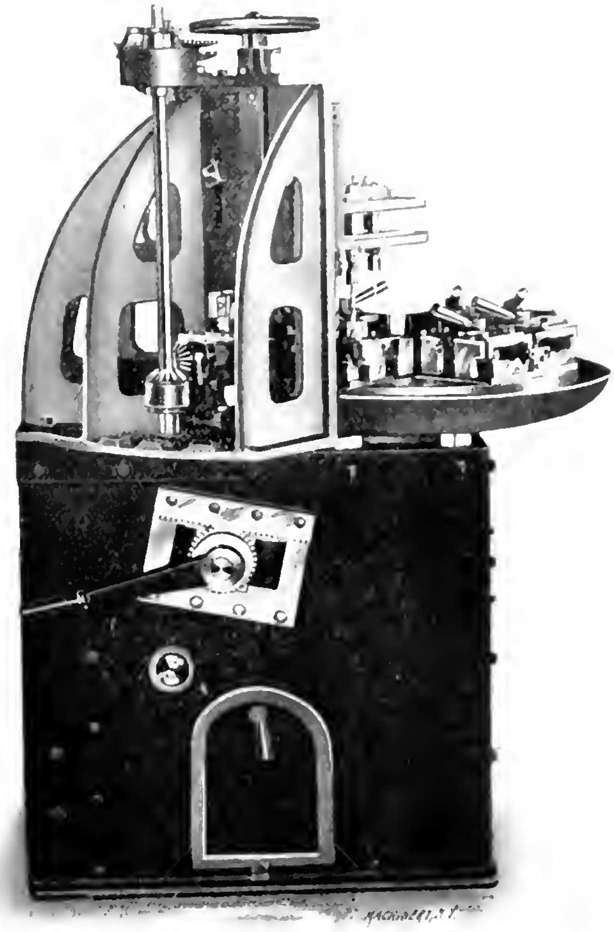

Fig. 2. Automatic Drilling Machine.

The machine has two vertical heads that are adjustable to give variation of depth in the hole drilled. The jigs are attached to the table with a key and dowel so that they can be easily removed and others substituted. The table can be indexed as many times per revolution as the character of the work requires. Among recent orders for this machine were two from a typewriter manufacturer who wished to use it in drilling small drop forgings. Each forging has two drilled holes—one to be reamed and one countersunk. The machine finishes 2,000 of these holes per hour. The jigs furnished for this particular job automatically open and close so that the only duty of the operator is to place the pieces to be drilled in position and remove them.

INTERESTING WORK OF A CIRCULAR SAW.

The universal saw table built by the Colburn Machine Tool Co., Franklin, Pa., of which we have already published a description, apparently has unusual capabilities in the hands of a competent workman, as shown by the samples of work illustrated herewith. This saw bench has all the adjustments of the table and guides that can be applied to such a machine, which enables angular and even circular work to be done to great advantage.

In Figs. 1 and 2 herewith are shown four sample boards of pieces all made on the Colburn saw, and are selected from a lot of six similar boards gotten out for the benefit of the agents of this company.

These samples show in a practical manner the great variety of work which can be done on this machine. No attempt has

Fig 1 Samples of Work done on Circular Saw

been made to put a fine finish on the samples, and they are shown just as the saws left them, and in most cases the saw marks are plainly visible. The object in leaving the samples in this manner is to prove beyond any question that they were

actually made with the circular saws, notwithstanding the seeming impossibility of such a performance. While it is true that some of the samples may be curiosities, still nearly all of them represent practical operations and to an ingenious mind suggest innumerable other cuts, all of which can be made on the machine.

Panels Nos. 1 and 2 show a variety of novel and fancy ornaments executed by the saw, which will suggest innumerable possible operations to the ingenious mechanic. Panel 3

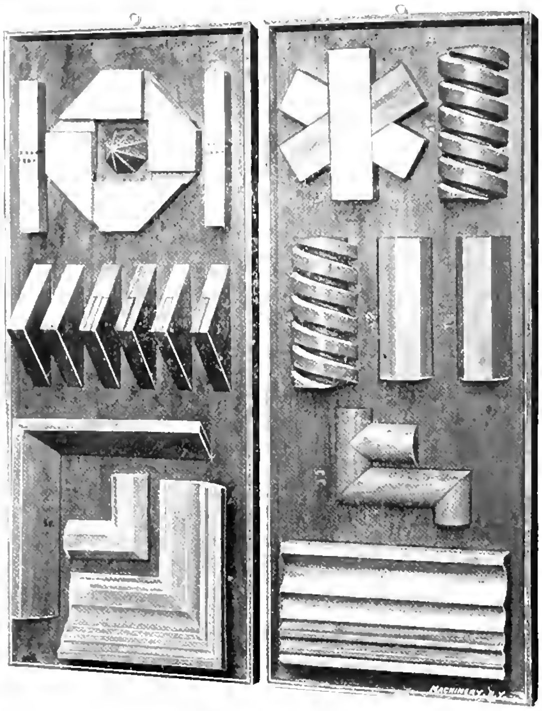

Fig. 2. Samples of Work done by Circular Saw.

shows samples of moldings having a variety of peculiar cuts, and in the center are six different samples of corner joints. Panel 4 shows, at the bottom, hollow cuts for such work as core boxes, etc., which may be made in sizes up to 4 and 5 inches in diameter. The next piece above illustrates special angular cuts made with the cross-cut saw. Above this are samples of polygonal shapes and samples of jointings; also a wooden screw made for a pattern. A larger illustration of this

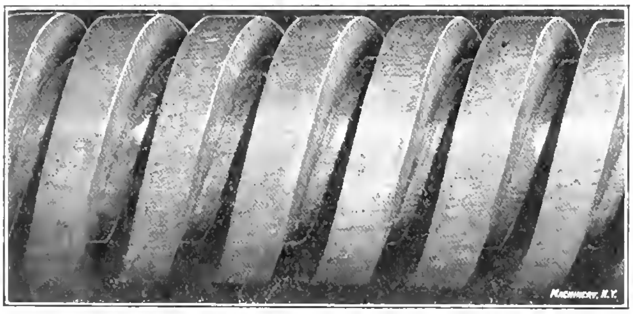

Fig. 3. Pattern for Screw Cut by Circular Saw.

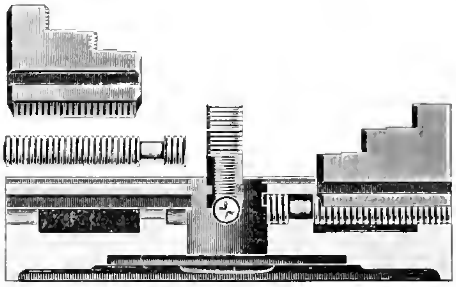
screw appears in Fig. 3. This is made by first marking the lead of thread on a round cylinder. The table of the machine is tilted to the proper angle on the thread, and the saw adjusted to cut the depth of thread. The block is then revolved by hand and a little pointer assists the operator in following the markings on the outside. Screws of any diameter and pitch can be cut in this manner.

NEW SKINNER CHUCK.

A new 1904 pattern independent lathe chuck has been brought out by the Skinner Chuck Co., New Britain, Conn., which has several features of interest. The adjusting screws of the jaws are threaded to the periphery of the chuck body so as to permit the holding with safety of larger pieces in a chuck of the corresponding size than in others where the screw is only threaded part of the length and the thrust of the screw taken on the shoulder near the outside of the chuck. The screw has a square hole in the end for receiving a square headed wrench instead of having a square headed screw with the usual style of socket wrench; the advantage of this construction is that the operator can see just how to hold the wrench to enter the socket in the screw, while with the old style socket wrench the nut of the screw is covered and it is always a matter of guess work just how to turn the wrench to have it fit the nut. By taking the thrust on the screw near the inner end of the screw, this strain is brought directly under the face plate to which the screw is attached and is in the

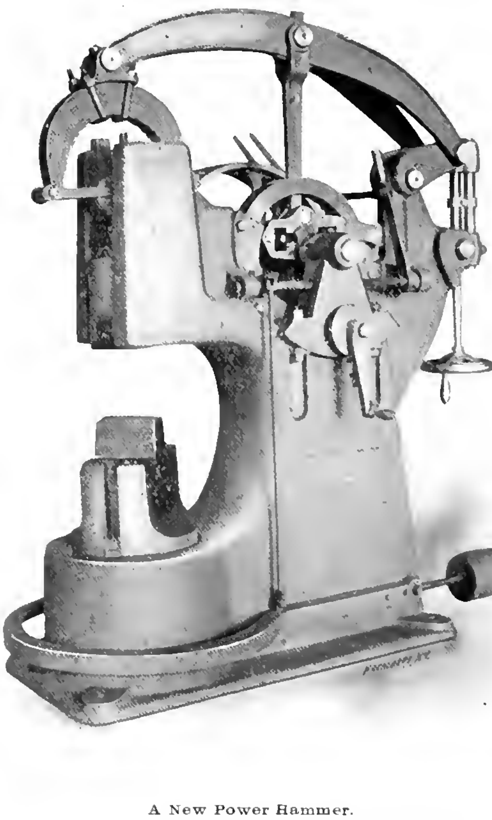


Details of Skinner Chuck.

strongest part of the chuck body. The jaws, which are made of drop forged steel and case hardened in this chuck, are ground on the steps after hardening, insuring the steps being parallel with the face of the chuck. It has been the ordinary practice to grind universal and combination lathe chuck jaws for a long time, but it is a new practice to grind the steps of the jaws on an independent jaw chuck.

THE "THOR" POWER HAMMER.

This hammer is composed as usual of a frame, an anvil, a hammer head, a lever, to which the hammer head is attached by means of the spring, and a crankshaft, acting on the lever. In the plane of the lever, there is supported in the frame, a ring of comparatively large diameter, through which the



A New Power Hammer.

crankshaft passes. To the ring is jointed an arm, which is connected to the crank of the shaft by being provided with a slot, in which it reciprocates during the rotation of the crank. There is a journal or sliding block on the crank. The arm is oscillated by this movement and is connected to the lever by means of links.

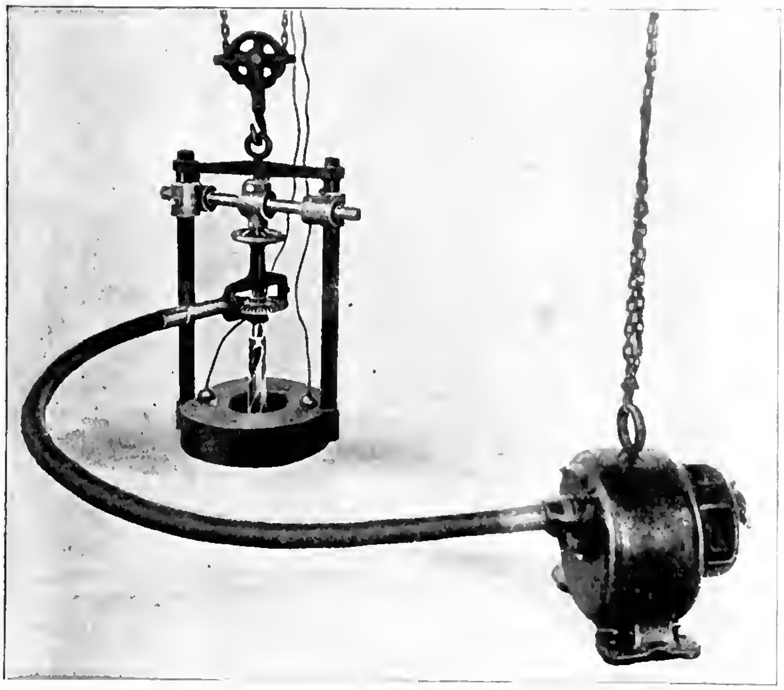
The length of the stroke is adjusted by revolving the ring. If the ring be rotated toward the right, the angle formed between the arm and the perpendicular through the shaft will be decreased. The stroke of the arm and consequently that of the lever and the hammer head, will thus be smaller. When rotating the ring toward the left, the angle mentioned will increase and the stroke of the arm and hammer head will be greater. The ring is rotated by means of the handwheel and screw at the rear.

The advantage of this construction is that the hammer ascends slowly and descends quickly, as the crank at the rotation of the shaft acts on the outer part of the arm when the hammer head ascends, but on the inner part of the arm when the hammer head descends.

It will be evident from the description that this construction gives a means for varying the strength of the blow, and also for adjusting the hammer for different sizes of forgings, while the hammer is running at full power; and these adjustments can be made without danger to the workman. The hammer is therefore applicable for large as well as for small work, and may also be used for drop forging. It is compact and easy to handle. The hammer is made in two sizes, one of which has a weight of drop of 170 pounds and one of 95 pounds. The former will operate successfully upon forgings 6 inches square, and the latter 4 inches square if occasion requires, but for general work the large hammer is recommended for forgings up to 4 inches square and the smaller one up to 3 inches square. The horse power required for the two hammers respectively is 4 and 1.5. The hammer has recently been brought out by the American Machine & Mfg. Co., Cleveland, O.

NOVEL PORTABLE EQUIPMENT.

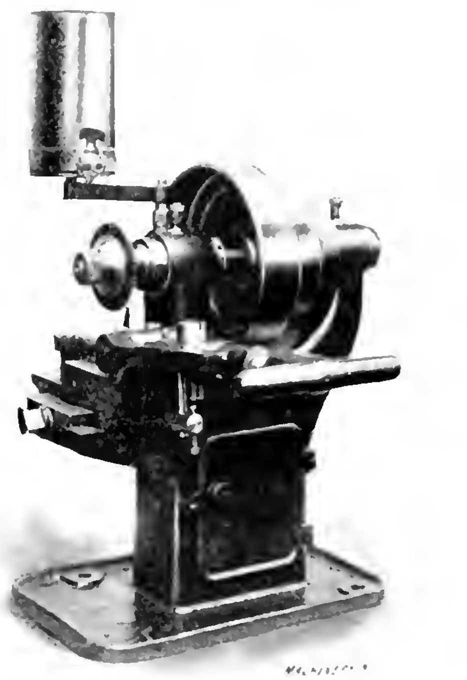
A neat portable drilling equipment has been brought out by the Coates Clipper Mfg. Co., Worcester, Mass. In this the drill is operated by electric motor through the flexible shaft manufactured by this company, but in addition to the general convenience of a portable drilling device of this description, this tool has the additional one of a magnetic hold-on arrangement which avoids clamping the "old man" to the material to be drilled. This hold-on is built strong enough for drilling a 2-inch hole, and is of especial value to steel plate and armor plate manufacturers. Formerly it was necessary to drill through a hole in the plate in order to fasten the bracket that holds the drill press, or else have the drill press backed up by a sufficient weight to take the thrust of the drill. The magnets used can be quickly attached or detached from the steel plate or casting by simply turning on or off the electric current, and in many classes of work the hole would be drilled while preparations were being made to attach the drilling device.



Drilling Device with Magnetic Hold-on.

BENCH SCREW SLOTTER.

The bench screw slotter illustrated herewith has been brought out by the Grant Mfg. & Machine Co., Bridgeport, Conn. In its design the manufacturers have aimed to meet the requirements of the shop having numerous small quantities of special screws, etc., to slot, and its capacity covers a range of screw sizes from the smallest to ½ inch filister head. The smaller ones can be slotted at the rate of 500 per hour. The spindle runs in two tapered self-oiling bronze bearings with adjustments on each to compensate for wear. The carrier slide has a transverse adjustment of ⅞ inch, making it possible to place two cutters on the spindle for milling two sides of a piece at once. The cone pulley has three steps for one-inch belt, and gives ample range of speed for both brass and iron screws. The jaws for holding the work are of one-inch round cold-drawn steel, and are simple and inexpensive to make. Jaws for irregular shapes that may be included in a ½- x ¾-inch space may be used in the machine to advantage. The fulcrum pin on which the carrier holding the jaws swings has large adjustable bearings, and the handle on the jaw clamping screw can be placed in such a position that when the jaws are closed this handle will be parallel with the spindle, the most favorable position for the operator. A stop screw is provided to regulate the depth of slots in screws. The method of operation is simple and rapid. The gripping, slotting, and releasing of the screws are all done with the right hand. The screw to be slotted is inserted between the carrier jaw with the thumb and finger of the right hand and is clamped with the screw shown at the top of the hinged carrier in front of the saw. After slotting the screw, the operator swings the carrier away from the saw, and at the same time releases it by a slight turn of the clamping screw

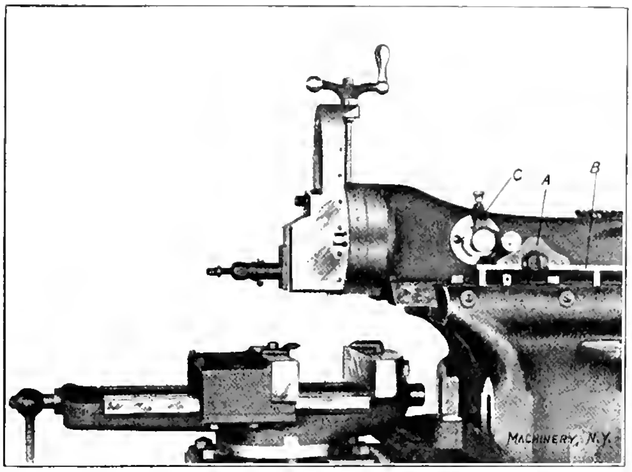


Bench Screw Slotter.

SHAPER ATTACHMENT.

Gould & Eberhardt, Newark, N. J., have recently fitted to their shapers a vertical feed attachment of unusually neat design, which adds materially to the usefulness of this tool as well as to the convenience of the workman. The accompanying half-tone, which shows a shaper equipped with the device, will give a clear idea of the construction of the feed motion. A rail *B* is attached to the top of the frame, alongside of the shaper ram, and a cam-shaped piece, *A*, may be clamped to this rail at any point desired, according to the length and position of the stroke of the shaper. A roll at-

tached to one arm of the bell-crank rides up on this cam at each stroke of the ram, and the other arm of the bell-crank carries a pawl which operates a ratchet wheel attached to the feed mechanism. The distance that the roll rides up on the cam, therefore, determines the number of teeth fed by the pawl at each stroke. It will be seen, therefore, that the cam *A* is the only part that ever needs adjustment, either for varying the amount of feed or to accommodate any change in the stroke of the shaper. A supplemental screw adjustment to the cam is in contemplation, for conveniently varying the feed from 1 to 10 teeth, after the cam is once set.

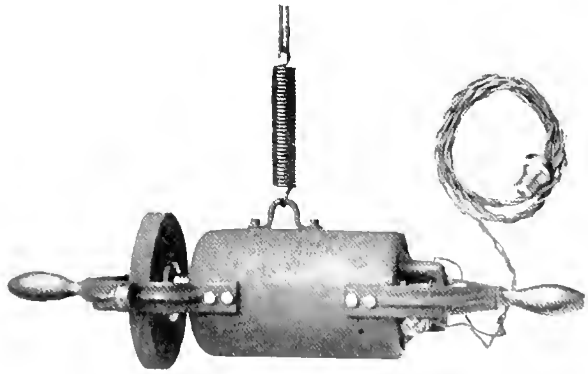


Vertical Feed Attachment.

PORTABLE "AERIAL GRINDER."

A very handy tool has recently been designed and placed on the market by the Hisey-Wolf Machine Co., Cincinnati, O. It is a "portable aerial surface grinder," electrically driven, and is illustrated herewith.

This grinder was particularly designed for irregular surface grinding, and the cleaning of castings of any kind or shape. It can be suspended anywhere, or counterbalanced from the ceiling or a traveler. The motor is enclosed, and especially built for the work for which it is intended. It has adjustable cone bearings, and detachable handles. The driving power is obtained from the ordinary incandescent lamp socket —direct current only. This machine can be carried to work in any part of the shop, which does away with the handling of heavy castings that require grinding, saving the loss of time and money for re-handling.



Hisey-Wolf Suspended Grinder.

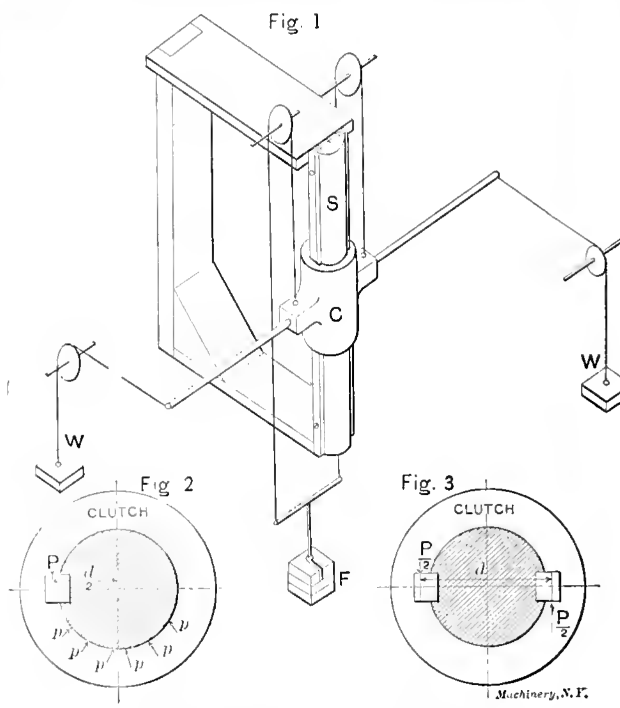
These machines are made in two sizes: ½ and 1 horse power, weighing 40 and 65 pounds, respectively. They are sent out complete, ready for work, as illustrated, with cord, socket and wheel.

* * *

FRICTION OF SLIDING KEYWAYS.

It is generally appreciated that a splined shaft used to transmit motion to a rotary part through which it slides meets with much resistance to sliding motion if the power transmitted is considerable. When the pressure is heavy the frictional resistance may become so great as to break some part taking the longitudinal stress, although apparently amply strong to meet the pressure of ordinary work. Even if breakdowns do not occur the keys or feathers wear out quickly and tend to make the splined shaft, which is an indispensable feature of machine tools and many other machines, a troublesome part. It is not, however, generally known, we believe, that two keyways, on opposite sides of a shaft which is to slide through and transmit rotary motion to a gear or wheel, greatly reduce the frictional resistance to longitudinal motion. A knowledge of this fact would often enable the designer to avoid serious troubles arising from the use of this class of transmitting mechanism.

A British civil engineer, having been called on to investigate and discover the cause for the failure of some large penstock sluice-valves of a dock which were worked by power through large clutches of the claw-tooth type, publishes the result of his investigation in *Engineering*. The clutch which caused the shaft to rotate was provided with only one key and it was suggested that the frictional resistance to longitudinal motion would be reduced by the use of two keys. The suggestion was followed with very successful results. After making the suggestion the engineer rigged up an experimental model, shown diagrammatically herewith, which demonstrated conclusively that where power is transmitted by a splined shaft the resistance to sliding motion is fully two times as great with one key as it is with two keys placed diametrically opposite.



Model Illustrating Friction of Sliding Keyways.

In the model the shaft *S*, Fig. 1, was 1½ inches in diameter, with keys in proportion, and was held in a vertical position in a frame, as indicated. One key was fixed in position and the other was movable, but capable of being fixed in place when required by means of countersunk screws. The clutch represented by the cylinder *C* was provided with the necessary keyways, and was capable of sliding along the shaft while subjected to a twisting couple, supplied by means of two equal weights acting upon the ends of the lever arms, through the medium of two pulleys. The weight of *C* was first balanced by means of the strings led vertically up from it and then down over the pulleys to weight *F*. Torsion was then applied to the clutch *C* by the means before described, and the two keys being fixed in position, it was found that a force represented by the weight of 3 pounds was required to just cause *C* to slide up the shaft. One key was then removed, and the force required to just cause *C* to slide was found to be 5 pounds. The result of this experiment showed that the frictional resistance of the clutch to sliding along shaft while transmitting power by means of two keys is only 60 per cent. of that met with when one key only is used. Further experiments confirmed this.

MACHINERY.

AN EXPERIMENTAL GAS TURBINE.

DR. ALFRED GRADENWITZ.

It is a natural outcome of modern gas engine construction on one side, and the development of steam turbine building on the other, that endeavors should be made to combine the advantages inherent in both these rivals of the reciprocating steam engine.

The principle of a hot air turbine was enunciated as far back as 1853 by F. Redtenbacher in his book on the "Caloric Engine," where attention is drawn to the fact that a turbine would be an ideal motor to be propelled by hot air, as any difficulty resulting from unequal expansion of the parts would be done away with. The enormous speed of revolution necessary in a gas turbine, however, led him to think that a constructive realization of his idea would be impossible. Meantime, methods of gas engine construction have been immensely improved upon, while in designing steam turbines means of reducing the speed to suitable limits by dividing the pressure into steps have been found out, so that obstacles that were formerly insurmountable do not now present serious difficulties. The moment seems to have come for a successful gas turbine to be designed, and some solutions of the problem are now being attempted.

An interesting type of gas turbine, the so-called "fire turbine," due to Dr. F. Stolze of Berlin Charlottenburg, is attracting much attention at the present day, and it is fair to state that the inventor of this engine enunciated the principle of dividing the pressure into steps with a view to diminishing the speed in his first description of this turbine more than thirty years ago, at which time, however, patents were refused him by the Prussian Patent Office on account of the special conditions then attached to patenting. The matter was again taken up later on, when patents were readily granted both for the original invention and subsequent additions to the same. Although the realization of the idea might have been difficult to carry out at the time of its being first conceived, there are no such difficulties in the way now and the experimental plant of 200 horse power, illustrated in Fig. 2, is nearing completion.

The underlying principle consists in compressing the atmospheric air to a moderate tension—say $1\frac{1}{2}$ atmospheres above atmospheric pressure—and in afterward heating this compressed air so that it will assume a volume 2 or $2\frac{1}{2}$ times as great at the same tension. After this the air is allowed to expand again to atmospheric pressure, while passing through the passages of the turbine. The energy available for doing work upon the vanes of the turbine, is due to the increase in volume resulting from the heating of the air. The process is carried out as follows: By means of a compression system consisting of ten turbine wheels or runners arranged one behind another on a conical drum, atmospheric air at a temperature of, say, 15 degrees C. is compressed adiabatically until a point is reached where its pressure is equivalent to that of $2\frac{1}{2}$ atmospheres. During this process, its temperature rises by 103 degrees C., leaving 282 degrees C. to be provided for by the heat of the furnace in order to bring the air up to the

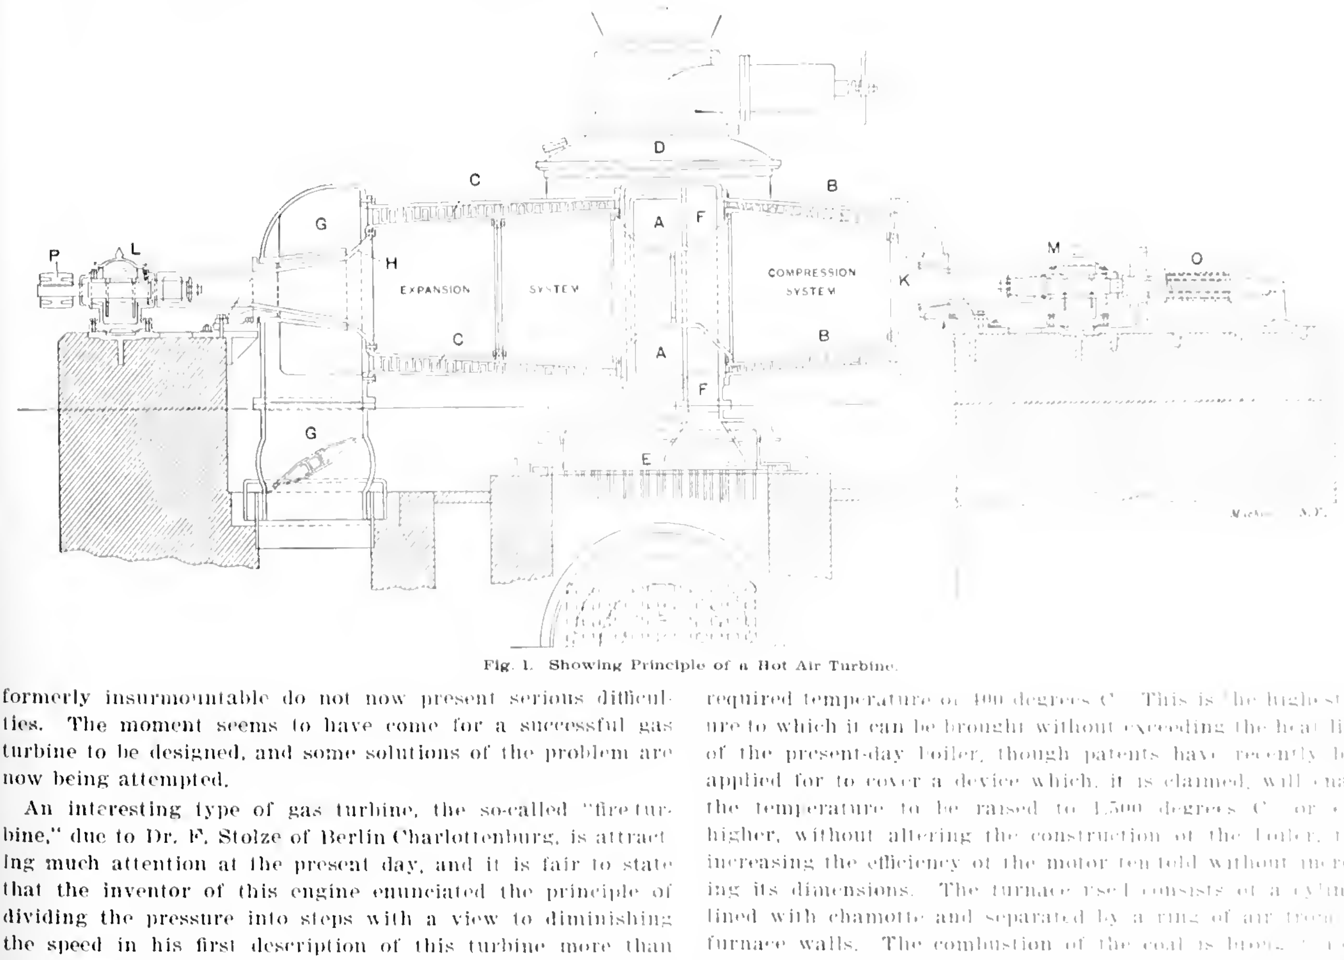

Fig. 1. Showing Principle of a Hot Air Turbine.

required temperature of 400 degrees C. This is the highest figure to which it can be brought without exceeding the heat limit of the present-day boiler, though patents have recently been applied for to cover a device which, it is claimed, will enable the temperature to be raised to 1,500 degrees C. or even higher, without altering the construction of the boiler, thus increasing the efficiency of the motor ten fold without increasing its dimensions. The furnace itself consists of a cylinder lined with chamotte and separated by a ring of air from the furnace walls. The combustion of the coal is brought about by means of a part of the compressed air passing through the grate, and the carbon monoxide thus formed is converted into carbon dioxide on issuing into the surrounding ring-shaped space, which contains the remainder of the compressed air as yet only partially heated. By a special regulation device, the supply of compressed air is so controlled as to maintain a constant temperature of 400 degrees C. The compressed air, having been mixed with the heated gases now streams toward the expansion system, which comprises the turbine, and is mounted on the same axle as the compression system. In passing through the expansion system the compressed air is expanded down to one atmosphere, during which process it cools to 243 degrees C. In order to avoid wasting the heat contained in the exhausted gases at this high temperature, they are now conducted through a tubular heater which is

A great deal of attention is now being given to the question of the gas turbine, both in this country and in Europe. Although much experimental work has been carried on, the apparatus of Dr. Stolze, described in this article, is the first to be so far perfected as to attract the attention of engineers generally. While his work has not progressed so far as to enable one to predict whether he will achieve success in his endeavors, his apparatus is of unusual interest because it is a pioneer in what is destined to be an important field.

located between the compression system and the furnace. The exhausted gases therefore raise the temperature of the compressed air during its passage from the compression system to the furnace. As stated above, the air when leaving the compressor has a temperature of 118 degrees C., which is raised to about 180 degrees C. in the heater before it reaches the furnace. It therefore remains for the furnace to raise the temperature of the air by only 220 degrees in order to reach the initial temperature of 400 degrees, at which the air and gases pass to the turbine.

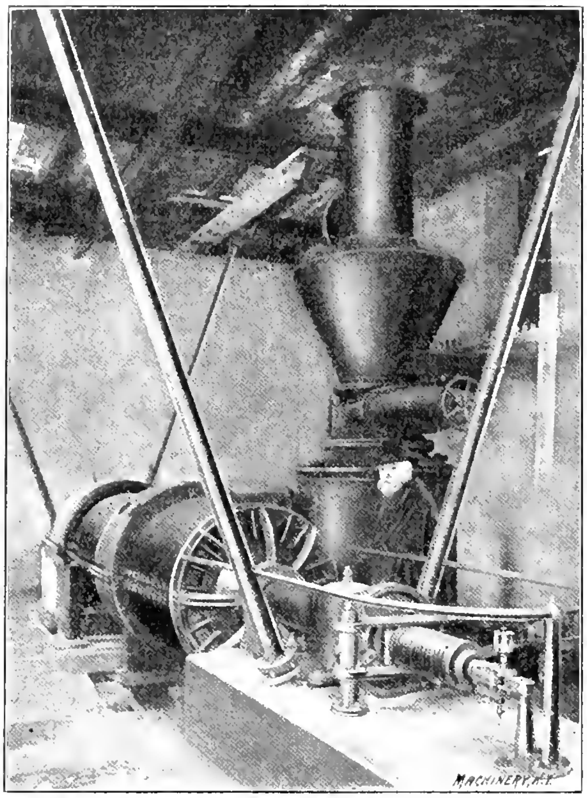

Fig. 2. Two-hundred H. P. Experimental Plant.

In Fig. 3 is a diagrammatic sketch of Dr. Stolze's invention, showing in outline the arrangement of the compression and expansion systems comprising respectively the air compressor and the turbine motor. In casing *A* on shaft *I* is seen a set of "fire-turbines." The outlet of *A* is at *C*, and the inlet (not shown in the sketch) at the opposite end of the turbine set. On the same shaft is placed a larger set of turbines in casing *B*, which has an inlet at *E* and an outlet at the opposite end. The two pipes *C* and *E* communicate with the heating device,

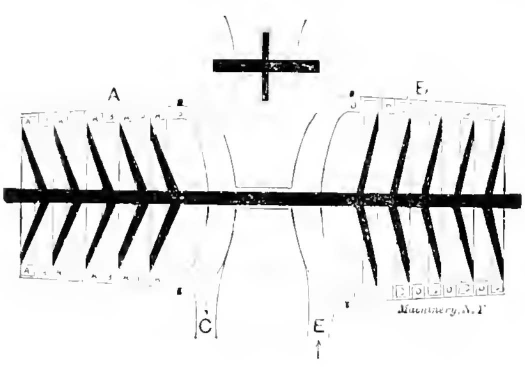

Fig. 3.

whereby the temperature of the motor fluid can be raised. The apparatus is operated as follows: Shaft *I* is made to rotate in the direction of the outer ends of the turbine blades in *A*. The set of turbines in casing *A* will then draw in the air, compress it, and finally deliver it in the compressed state through *C* to the gas producer or any other calorific medium provided. The gases generated in the producer pass in the heated state through *E* into *B*, where their motive force is utilized by the turbines. The energy developed in the larger casing, *B*, will obviously exceed the energy required to draw the cold air into *A*, so that the apparatus becomes self-driving, developing energy for motive power. *aa*, etc., are the vanes of the rotating elements of the compressor, and *bb* the stationary guide vanes; *cc*, etc., are the moving vanes of the turbine motor, and *dd*, etc., are the guide vanes. If desired, the expansion and compression systems may be duplicated, which will be found useful to avoid end thrust on the shaft. To prevent the direct passage of air from *A* to *B*, the device shown diagrammatically in the upper part of Fig. 3 may be made use of. This consists of an annular casing on the hollow tube through which the shaft passes, fitting close to a disk on the shaft. The disk may be grooved or scored to prevent the flow of air over its surface. It is interesting to note the similarity of this device, designed thirty years ago, to the device of the labyrinth used by Parsons in the construction of his turbine.

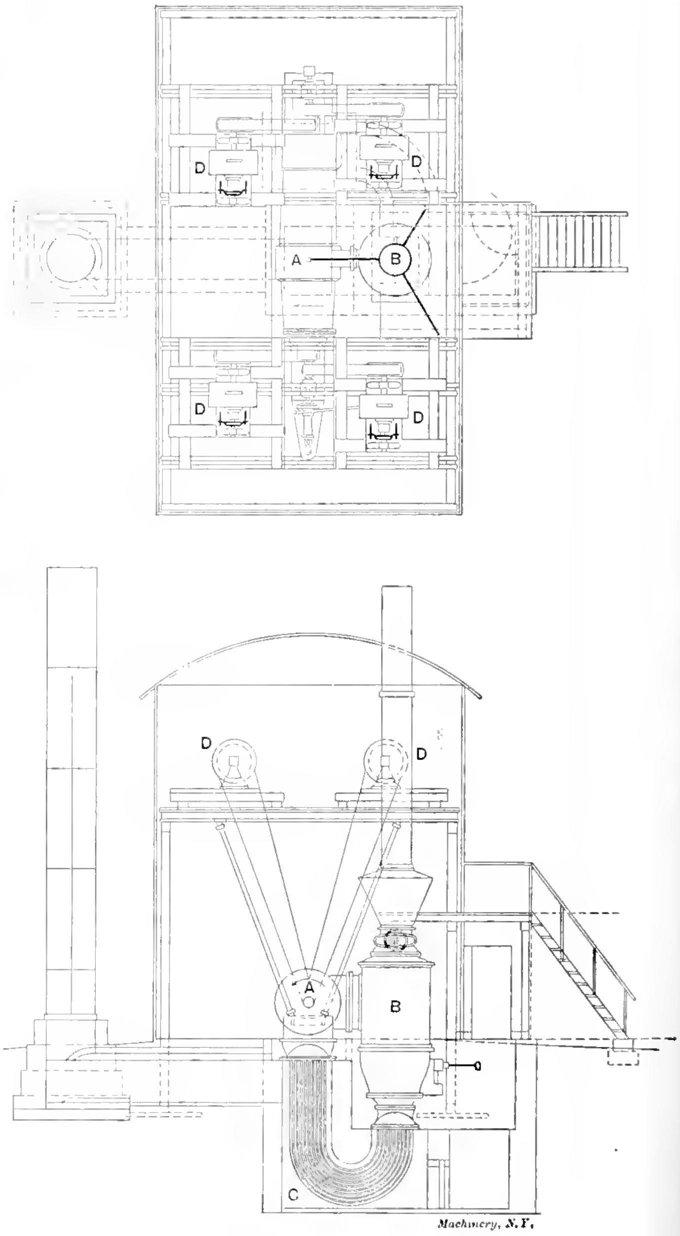

Fig. 4. Sectional Elevation and Plan of Plant.

In consequence of friction between the fuel particles, it might happen that considerable reaction or back pressure would be produced, retarding the motion of the heating gases and air, and to some extent preventing perfect combustion. This possibility is eliminated by either of the two devices shown in Figs. 5 and 6, whereby the supply of combustible gases and compressed air is so arranged that they flow into the mixing chamber in the same direction, and each of the two currents has a tendency to draw the other along with itself. Back pressure is thus avoided. In these cuts *A* is the furnace, *B* the mixing chamber for the combustible gases and compressed air, *N* the place where the combustion of the carbonic oxide gas occurs, *M* a funnel through which fuel is supplied, *V*

the grate, C the passage for the compressed air from the compression turbine, D the passage for the compressed air into the mixing chamber, E the passage for the supply of air to the furnace, while F and G show the method of introducing gases and air in parallel directions.

Figs. 1 and 4 show more completely the arrangement of the hot air turbine, and of the plant containing it. In Fig. 1 the apparatus is seen, consisting of a large shell in the form of a double cone, one end of which is the expansion or motor end and the other end, K, comprises the compression part. On the compression end is a series of rings of vanes attached to the drum and alternating with stationary rings of vanes. On the other end are similar vanes, comprising the expansion system. The air is drawn in through the passage between the vanes indicated at BB, and is delivered to the chamber FF from which it passes through the tubular heater E to the furnace D. It then enters the annular space, AA, and passes through the passage between the vanes CC to the exhaust chamber, GG, and thence to the tubes of the heater, E. LM are the bearings at the two ends, O is the governor, and P the pulley from which power is taken off the belt.

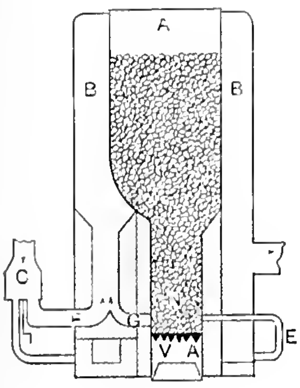

Fig. 5.

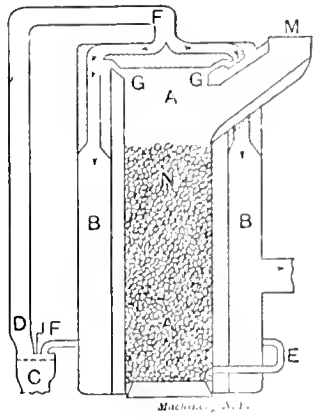

Fig. 6.

In Fig. 4 appears a sectional elevation and a plan of the whole plant. A is the turbine and compressor, B the furnace, C the heater, and DD the electric generator driven by the turbine.

One of the principal advantages of hot air turbines over steam turbines is their relatively low speed of revolution, at most 2,000 revolutions per minute with a maximum diameter of 1 meter. The main advantages, however, are that every bit of fuel consumed is utilized for power generated, no heat of escaping exhaust gases being lost, and that the air does not require previous vaporization as does water, an important item when we consider that to produce 1 kilogram of steam at atmospheric pressure consumes over 600 calories, while yet further heat is needed to induce working energy in the steam. It is claimed that the 200 horse power motor now in course of construction will insure a saving in the fuel consumed as high as 33 1-3 per cent. of that used in a steam engine plant.

* * *

We recently published a note in regard to the use of compressed air for maintaining water pressure where there was no available head of water. Our attention has since been drawn to an installation of the Acme Water Storage & Construction Company at the St. Louis Fair, which operates on this principle and is intended to make possible a constant supply of water under high pressure, thus displacing water towers and elevated tanks. The apparatus consists of two tanks, an air compressor, and a pump. One tank is kept constantly charged with air at a high pressure, while the second contains both air and water, the water being forced in by a pump, and the air being admitted from the first tank by a pressure reducing valve set to give constant pressure. As the water is pumped into the water tank, the air is removed by the compressor and returned to the air tank, so the pressure is always uniform. It is only necessary to run the compressor and pump when charging the system, for the apparatus is so arranged that the entire contents of the water tank may be used under a constant pressure before charging again. The Deane vertical pump was used with the apparatus exhibited.

VARIABLE SPEED MOTORS.—8.

THE STOW MULTI-SPEED MOTORS.

WM. BAXTER, JR.

In previous articles we have explained several methods for varying the speed of motors by varying the strength of the magnetic field in which the armature rotates. In all these arrangements the field strength is varied by electrical means, that is, by varying the strength of the magnetizing current that passes through the shunt field coils. It is possible, however, to vary the strength of the motor field by mechanical means, and this is the method employed in the Stow multi-speed motors.

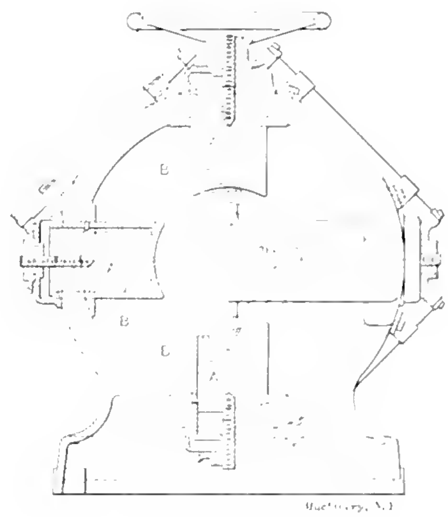

Fig. 1

The mechanical method of varying the strength of the motor field complicates the construction somewhat, but on the other hand it increases the range of speed variation obtainable with a motor of a given size; that is, this result is obtained if the construction is such as is used in the Stow motors. A brief explanation of the principles involved in obtaining speed variation by means of changes in the field strength will serve to make the matter clear.

Principles of Commutation.

For a motor to run without injurious sparking at the commutator it is necessary that the strength of the motor field be sufficient to counteract the effect of the armature reaction. In a two pole motor the current flows through the armature

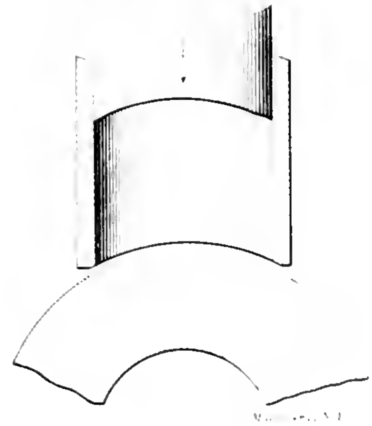

Fig. 2

coils in one direction while they are passing through one half of the revolution, and in the opposite direction while passing through the other half. At the instant when a commutator segment passes under the brush, the current flowing in the coil connected with this segment and the one back of it, must reverse its direction. To accomplish this result the field magnetism at this point must be in the right direction to induce a reverse current, and of proper strength to develop a current equal to that flowing in the other coils. If this is done there will be no sparking at the brushes. If a motor runs with a uniform load, and at a uniform speed, there is no difficulty in

accomplishing this result, but if the load varies the reaction of the armature will vary and if the speed varies it must be produced by a variation in the field strength, and both these actions will result in disturbing what we might call the commutation balance, so that sparkless operation cannot be obtained. In practice, a considerable variation in the field strength can be obtained without producing a noticeable increase in the sparking, but with the standard designs of stationary motors this variation is seldom more than 20 or 30 per cent. To obtain a speed variation of say two to one by means of field strength variation obtained by varying the strength of the field magnetizing current, it is necessary to make the motor considerably larger than for constant speed work, so that the armature may be reduced and the field increased. This change reduces the relative effect of the armature reaction, so that when the field strength is varied, its direction is not materially changed, and as a consequence the sparking at the brushes is not increased.

Perfect commutation does not depend upon maintaining the strength of the magnetic field within proper limits over the entire surface of the poles, but only over that portion that the armature coils pass through while the act of commutation is

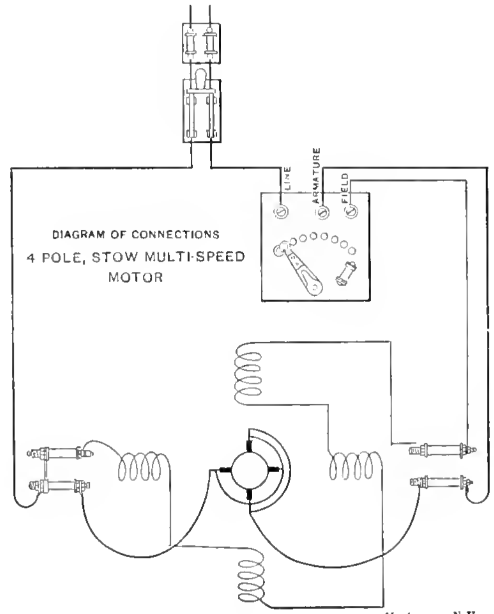

Fig. 3.

taking place; in other words, over the portion through which the coils pass as they are short-circuited by the commutator brushes. This portion of the magnetic field is developed by the edges of the pole pieces, so that if at these points the magnetism can be kept practically constant it matters little how much it may vary over the balance of the pole surface.

When the field is varied by varying the strength of the magnetizing current, the strength of the magnetic field varies alike over the whole of the polar surface, hence, only a comparatively small change can be effected in the magnetic density before the commutator brushes begin to spark badly.

Mechanical Method of Varying the Field Strength.

The strength of the field of a motor is varied mechanically by varying the distance between the surface of the poles and the surface of the armature core. This variation in the distance between the surfaces of the two parts varies the field strength, owing to the fact that iron does not resist being magnetized as much as air, or as it is commonly stated, the magnetic reluctance of iron is much lower than that of air. If the poles are drawn away from the armature the strength of the magnetic field is reduced. The reduction, however, will be uniform over the whole polar surface. This method of varying the field strength was embodied in several designs of motors made in the early days of electrical development, but it did not survive, owing to the fact that it produces precisely the same result as is obtained by varying the strength of the magnetizing current and has no advantage to offer to offset the increased cost of making the motor.

Principle of the Stow Multi-speed Motor.

The Stow multi-speed motor is constructed upon a modification of this principle which, while apparently small, produces decidedly different results.

A clear understanding of the construction of this motor can be obtained from Fig. 1, which is a sectional vertical elevation at right angles to the shaft. The poles of the motor are

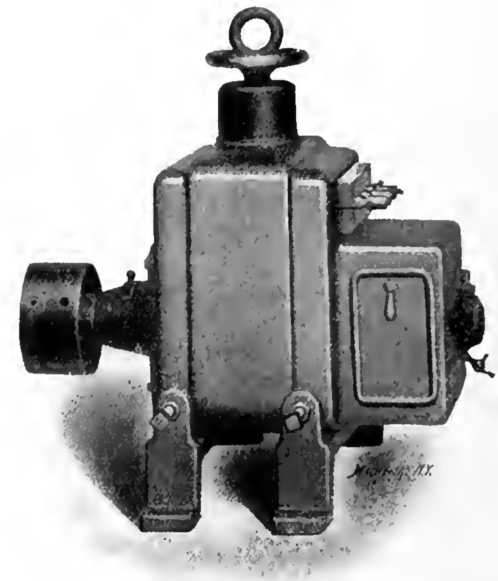

Fig. 5.

made up of a stationary shell, *B*, and a movable core, *A*, both parts being made of iron. The cores *A* of the several poles are moved in a radial direction by means of the handwheel seen at the top, and the miter gear connections, so that all the cores move equally. When the cores are in the closest position to the armature, the air space is reduced to the minimum point, and as a consequence the field strength is the greatest.

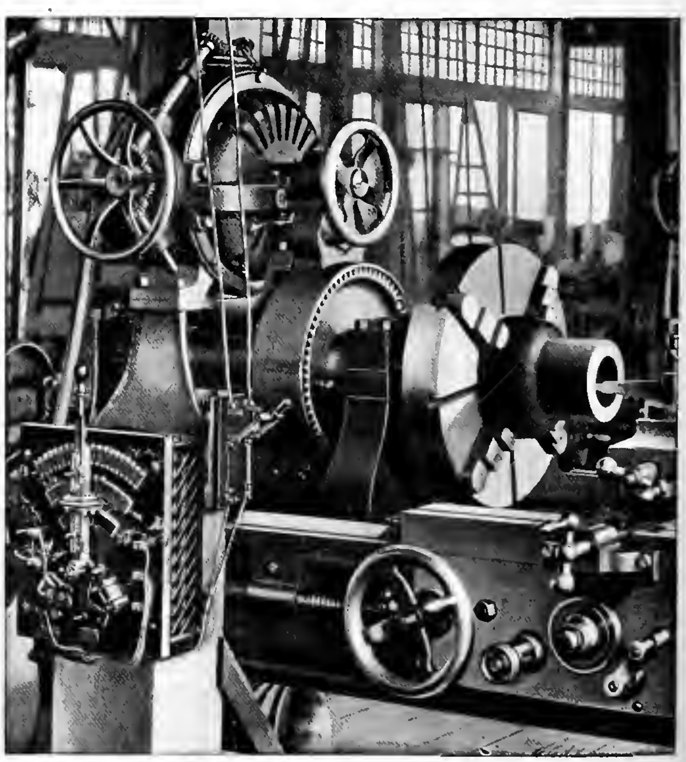

Fig. 4.

As the cores *A* are withdrawn from the armature, the length of air interposed in the magnetic path is increased, and as a result the strength of the magnetism is reduced. When the cores are withdrawn as far as they will go, the magnetic field is reduced to the lowest point. From this it will be seen that by varying the position of the cores *A*, the strength of the field is varied, and thereby the speed of the motor is changed.

It will be noticed in Fig. 1 that at all times the distance between the end of the outer casing, *B*, and the armature remains the same; hence, the resistance to the flow of magnetism along this path remains unchanged, and as the magnetizing current also remains unchanged, the magnetic strength of the field between the armature and the end of casing *B* does not vary to any appreciable extent. It is this magnetism that acts upon the armature coils when they are passing under the brushes, and are undergoing commutation;

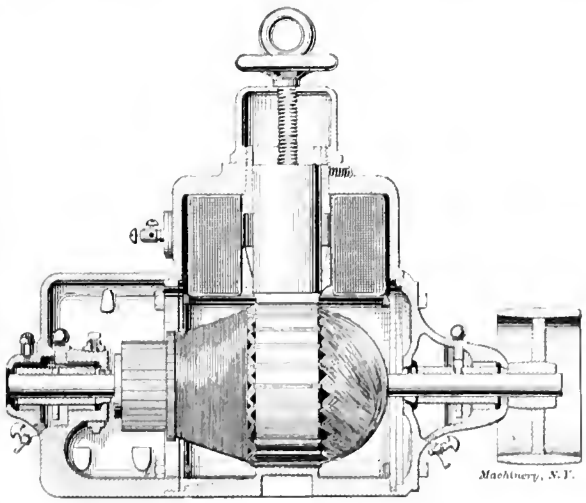

Fig. 6.

therefore, the act of commutation is as perfectly performed when the cores *A* are far removed from the armature, as when they are near by. In fact, the changing of the position of these cores only changes the strength of the magnetism flowing from the central portion of the pole surface, and thus varies the total amount of magnetism acting on the armature, and thereby the speed of the latter, but without interfering with the sparkless operation of the brushes. The practical result of this action is that a motor of a given design can be made to vary its velocity through a much wider range than if the variation were obtained by changing the strength of the field magnetizing current.

Speed Variation of Motors.

The average stationary motor, not intended for variable speed work, will not run well at the brushes if the speed is varied much above 30 per cent.; but a machine of the same size and electrical proportions, if provided with the movable cores *A* can vary its velocity in the ratio of 2½ to 1 without injurious sparking at the commutator. To obtain this same range of speed variation by varying the strength of the field

110 VOLT 6 H.P. STOW MOTOR

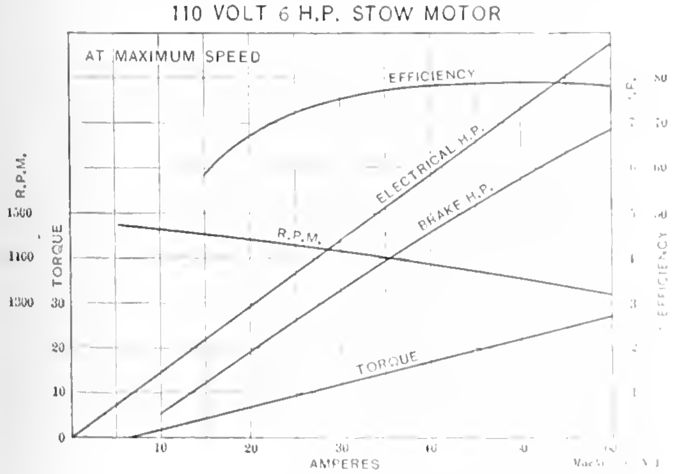

Fig. 7

current it would be necessary to make the motor much larger.

Thus it will be seen that the effect of the Stow construction is to increase the range of speed variation without increasing the size of the motor.

Modifications in the Construction of the Movable Cores.

In Fig. 1 the cores *A*, when in the position nearest to the armature, are some distance away from the pole surface, the casings *B* being constructed with a thin bottom which forms the actual polar face. In some of these motors, however, the cores *A* project through the end of the casings *B* so as to come flush with their inner ends, as shown in Fig. 2.

Motor Starter.

As already explained, the Stow multi-speed motor owes its speed variation to changes in the reluctance of the magnetic circuit. The electrical circuits remain unchanged under all conditions and hence no electrical controller, rheostat or circuit-changing device is required to vary the speed. A simple motor starter, such as is used with constant-speed stationary motors, is all that is required; the connection with the starter, the line wires and the motor for a four-pole motor, being as shown in Fig. 3. For operation with machines that have to be driven in opposite directions, a reversing motor starter is required, as shown in Fig. 4, which shows a Stow motor mounted upon a lathe, and provided with a reversing motor starter.

Bi polar Stow Multi-speed Motors.

Multi-speed motors are made of the bi-polar, as well as the multi-polar type. Fig. 5 shows the external appearance of a bi-polar machine. With this type of motor no miter wheel gearing is used for connecting the movable pole cores. The gearing is dispensed with by constructing the motor so that there is only one movable core. The construction is clearly shown in Fig. 6, which is a vertical sectional view of Fig. 5 taken parallel with the shaft.

Efficiency of the Stow Motor.

There is nothing in the construction of these motors that can prevent them from being just as efficient as those in which

110 VOLT 6 H.P. STOW MOTOR.

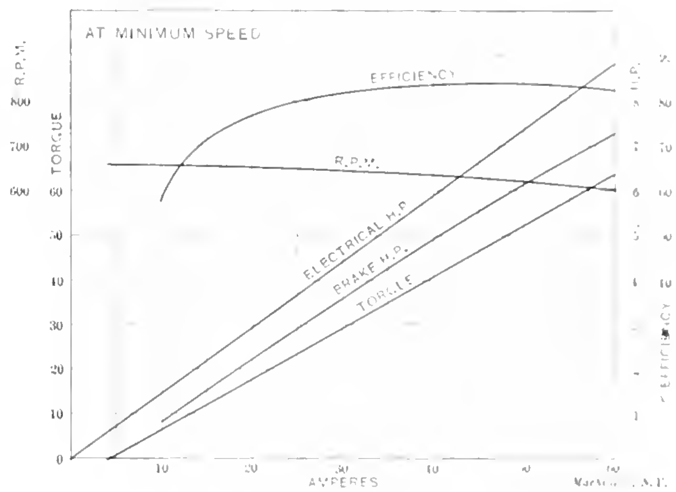

Fig. 8

speed variation is obtained by changing the strength of the field magnetizing current. The latter type may be able to show a slightly higher efficiency at high velocities, owing to the fact that then the field current is reduced, and thus a slight saving is made. But the total amount of energy required to magnetize the field is so small, from 2 to 3 per cent. of the whole, that the difference amounts to nothing, practically considered.

The efficiency of Stow motors when running at the maximum and minimum velocities with variable load is shown in the two diagrams, Figs. 7 and 8, which show the performance of a 6-horse-power motor of the four-pole type.

The advantages claimed for the Stow multi-speed motor are: That it gives a speed variation of 2½ to 1 with a machine of a given size, which, if wound for the same horse-power, and arranged to vary the speed by varying the strength of the field magnetizing current, would not give a speed variation much more than half as great; that practically the same power is given at all speeds; that the same efficiency is obtained at all velocities; that the speed remains unchanged when the load changes (this result being accomplished owing to the fact that no armature resistance is used to vary the speed), and, finally, that an infinite number of speeds can be obtained between the highest and the lowest, this being due to the fact that the cores *A* can be moved to an infinite number of positions.

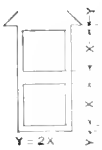
DIRECTIONS FOR DRAWING D. C. COILS.

OSCAR STEGEMAN.

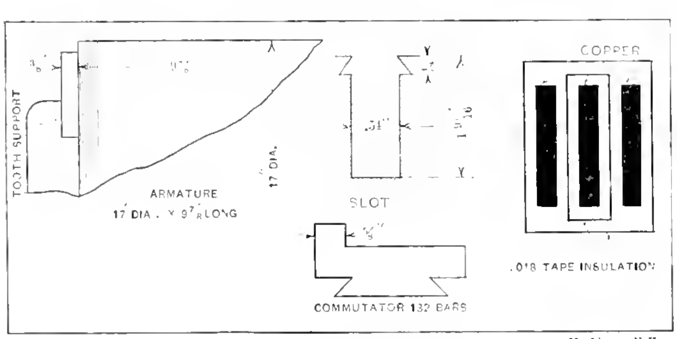
Example: Armature Connected Straight.

Given: 44 slots, 132 coils, each coil consisting of one turn ⅛ inch by ½ inch copper. Wind No. 1 to No. 12; connect No. 1 to No. 2. 1-32 inch clearance between insulated groups. Insulation per group equals 4 × .018 = .072 inch. This allows for shellac, etc.

Solution. Draw a semicircle with a radius equal to that of the armature. Divide this semi-circle into half as many parts as there are number of slots in armature. Let the distance from point *A* on center line to slots Nos. 1 and 12 be equal. Draw the bare groups of coils in slots as in sketch, $Y = 2X$. Then draw the rear view; the part *B-C* as an arc of a circle with the armature center as the center for the radius. Draw the part *D-E* straight to the right from *D* until its runs tangent to an arc of a circle with a radius whose center is on a line running through center of armature and center line of slot No. 12. The distance from *C* to *D* is equal to twice the radius R_1, plus width of copper strap.



Then on the plan view draw center line *a a'*, this being the center line for the bending pin for bending rear end of coil. This line also to run through center of R_2. For the pitch of the coils, set off from center line of R_2 "*n*" number of equal parts—the length of these parts equal to the distance between two slots projected on lower edge of respective groups. In this case set off $b\ c = 4$ (*F-G*); *F-G* equal to projection of 2 slots projected on lower edges of *B-C*. $b'\ c' = 4$ (*H-I*) *H-I* equal to projection of two slots projected on lower edge of *D-E*. Take *c* and *c'* as centers for arcs of circles with radii (R_3) = *n* (thickness of group + insulation + clearance between insulated groups) + R_2. In this case 4 (.375 + .072 + .03125) + .25 = 2.165". The tangents of these arcs and of R_2 are the pitch of the group. From the center line develop the distances *C* to *B* and *D* to *E*. The developed length obtained from lowest edge of group. For center of R_4 for lower part of group, let coils project ⅜ beyond the tooth support (in this case ⅜ + ⅜ = ¾" beyond armature). For upper part of group this dimension must be scaled. Draw two lines a short distance apart, to denote the length of armature iron. As the developed distances from *E* to *D* and from *E* to *L* are not alike it is necessary, to obtain accuracy, to develop the front parts of coil separately. Draw center line *f-f'* and *g-g'* a slight distance to the right and left. Then place R_5 for both upper and lower parts of group the same distance beyond the tooth support as R_4 for the lower part of group. Then set off from *d* to *e* the same distance as from *b* to *c*. From *d'* to *e'* set off the same number of spaces as from *b'* to *c'* using the



Example of Armature Details.

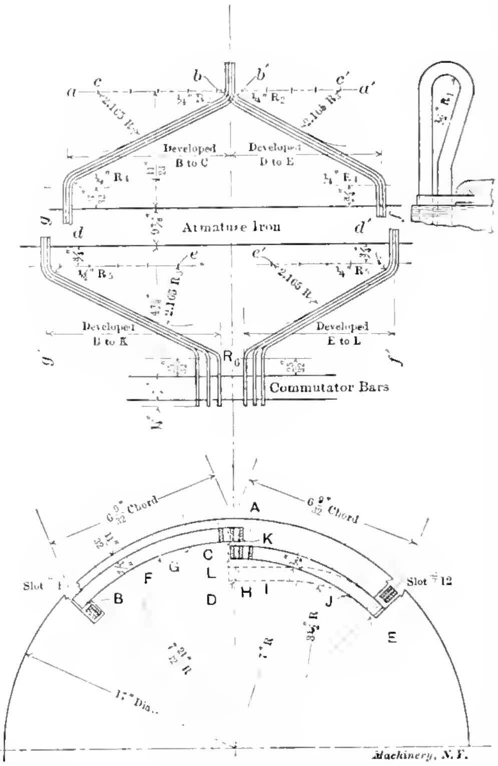
distance *E-J* instead of *H-I*. With *c* and *e'* as centers draw arcs of circles with R_3 as a radius. The tangents of these arcs and of R_5 are the pitch of the group for the front part of coil. To determine center of R_6 and also developed distance *B* to *K* and *E* to *L*, a few trials are necessary. Draw an arc of a circle from *B* to *K* with armature center as center for radius. Likewise from *E* to *L*. Center of R_6 should be ¾ inch from edge of commutator bars. This is obtained by moving the ends of coils to the right or left until the developed distance from *B* to *K* and from *E* to *L* are such as will bring

*This article may be properly considered a part of the data sheet contributed by Mr. Stegeman this month, and is published in the reading columns so that it may appear in the same number with the data sheet.

center of both R_6 on exactly the same line. Then draw the commutator bars ¾ inch further on and let the coils extend ¼ beyond. The distance from coil No. 1 to coil No. 2 is a space set off on the armature circumference equal to 1-3 of the distance from center line of one slot to center line of the next. After the plan view has been finished the end view is to be completed. Draw in the ends of coils and give dimensions, except R_3, as shown in diagram. These dimensions are all to be scaled from the drawing, and are sufficient for making a former.

Example: Armature Connected Cross.

Given: 44 slots, 132 coils, each coil consisting of one turn ⅛ inch by ½ inch copper Wind No. 1 to No. 12. Connect No. 1 to No. 67. 1-32 inch clearance between insulated groups. Insulation per group = 4 × .018 = .072 inch. This allows for shellac, etc.



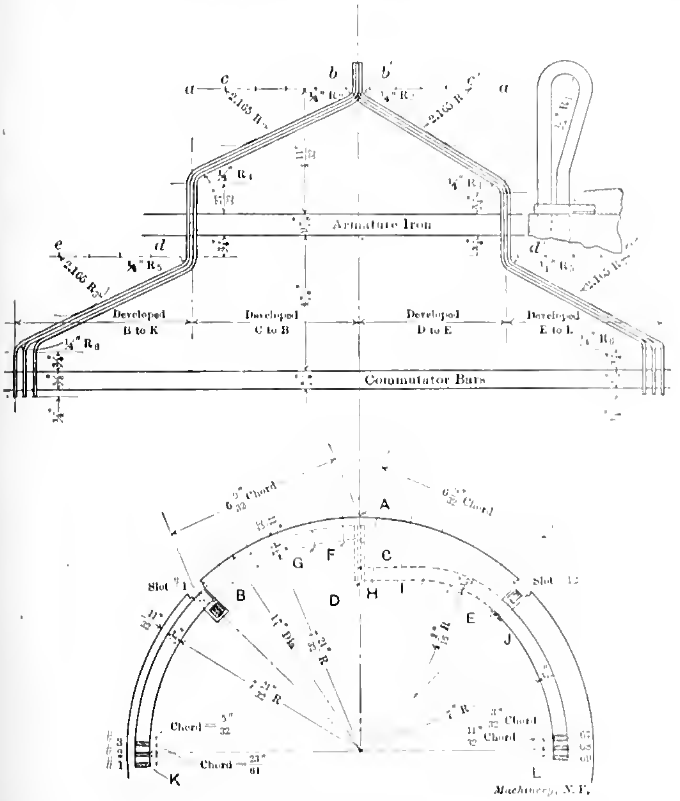
Method of Laying Out D. C. Coil Forms. Barrel Winding Armature Connected Straight.

Solution. Draw a semi-circle with a radius equal to that of the armature. Divide this semi-circle into half as many parts as there are number of slots in armature, and let the distance from point *A* on center line to slots Nos. 1 and 12 be equal. Draw bare groups of coils in slots as in small sketch. $X = 2Y$. Then draw the rear view, the part *B-C* as an arc of a circle with the armature center as the center for the radius. Draw the part *D-E* straight to the right from *D* until it runs tangent to an arc of a circle with a radius whose center is on a line running through center of armature and center line of slot No. 12. The distance from *C* to *D* is equal to twice the radius R_1 + width of copper strap.

Then on the plan view draw center line, *a-a'*, this being the center line for the bending pin for bending rear end of coil. This line also to run through center of R_2. For the pitch of the coils, set off from center of R_2 "*n*" number of equal parts, the length of these parts equal to the distance between two slots projected on lower edge of respective groups. (In this case set off $b\text{-}c = 4$ (*F-G*), *F-G* equal to a projection of two slots projected on lower edge of *B-C*. And $b'\text{-}c' = 4$ (*H-I*) *H* equal to a projection of two slots projected on lower edge of *D-E*. Take *c* and *c'* as centers for arcs of circles with radii (R_3) = *n* (thickness of group + insulation + clearance between insulated groups) + R_2. In this case 4 (.375 inch + .072 inch + .03125 inch + .25 inch = 2.165". The tangents of these arcs and of R_2 are the pitch of the group. From the center line develop the distances *C* to *B* and *D* to *E*. The developed length obtained from lowest edge of group. For center of R_4 for lower part of group, let coils project ⅜ beyond the tooth support (in this case ⅜ + ⅜ = ¾" beyond armature),

For upper part of group this dimension must then be scaled. Draw two lines a short distance apart, to denote the length of armature iron. Then place R_5, for both upper and lower part of group, the same distance beyond the tooth support as R_4 for the lower part of group. Then set off from d to e the same distance as from b to c. From d' to e' set off the same number of spaces as from b' to c', using the distance E-J instead of H-I.

With e and e' as centers, draw arcs of circles with R_3 as a radius. The tangents of these arcs and of R_5 are the pitch of the group for the front part of coil. To determine center of R_6 and also developed distance B to K and E to L, a few trials are necessary. Draw an arc of a circle from B to K, with armature center as center for radius. Likewise from E to L. Center of R_6 should be ¾ inch from edge



Method of Laying Out D. C. Coil Forms. Barrel Winding Armature Connected Cross.

of commutator bars. This is obtained by moving coils Nos. 1, 2 and 3, and 67, 68 and 69, up and down until the developed distances from B to K and from E to L are such as will bring center of both R_6 on exactly the same line. Then draw the commutator bars ¾ inch further on and let coils extend ¼ inch beyond. The distance from coils Nos. 1 to 67 is 66 equal spaces, set off on the armature circumference, each space equal to 1-3 of the distance from center line of one slot to the center line of the next. After the plan view has been finished, the end view is to be completed. Draw in the ends of the coils and give dimensions, except R_3, as shown in diagram. These dimensions are all to be scaled from the drawing and are sufficient for making a former.

* * *

"BEAMS AND PLANES ECCENTRICALLY LOADED."

Editor MACHINERY:

As Mr. Blake, in his letter in the October, 1904, issue of MACHINERY, asks why I assumed the origin of axes at B with direction OB, also for me to extend my method to a spider having five arms, I offer the following explanation: It is a well-known principle that when a system of parallel forces is in equilibrium, the algebraic sum of their moments about *any* set of rectangular axes in a plane perpendicular to the forces is zero. In other words, the location of the origin and the direction of the axes may be fixed to suit one's fancy. It is consequently correct to assume some convenient point for the origin and through that point draw the axes in a convenient direction. It is a practical convenience to locate the axes so that one force passes through the origin, thus eliminating its moments from the moment equations. Then by drawing the axes through as many of the other forces as possible (generally only one other is possible) more terms may be eliminated from the moment equations. It will be understood then that my reason for selecting the particular point B for the origin was because it is correct and convenient, not that it is a better location than any of the other four points, A, C, D, or O. Similar reasons determined OB as the direction for the X axis. It would have served the purpose just as well to have passed the X axis through any of the other points, A, C, or D; or the Y axis through any of the points, A, C, D, or O.

In the light of the foregoing Mr. Blake has a right to and is correct in assuming axes as he has done. Since the location of the axes is immaterial we may take moments of the forces, as I determined them, about the axes Mr. Blake has assumed and we will find that their algebraic sum is, within an allowable per cent of error, equal to zero. The error arises from using the dimensions within the nearest eighth of an inch to the scaled dimensions. If we take moments of the forces, as determined by Mr. Blake, about the same axes we find that their algebraic sum is not zero, consequently the system of forces is not in equilibrium. When a load is supported by a frame of any kind the reactions are so distributed that, when taken with the load, they form a system of forces which is in equilibrium, hence any method of determining reactions which does not give a system of forces in equilibrium is incorrect.

There should be no difficulty in extending the method I gave for a four-armed spider to the case of a five-armed spider. The method, simply stated, is to so proportion the reactions that the resulting system of forces is in equilibrium, as this is a fundamental requirement, and then design the arms in accordance with the assumptions made when proportioning the reactions. E. E. GRAHAM.

Cleveland, Ohio.

ANNUAL A. S. M. E. MEETING.

The annual meeting of the American Society of Mechanical Engineers will take place on December 6 at the headquarters of the Society, No. 12 West Thirty-first Street, New York City. The opening session will be on Tuesday evening, December 6, at 9 P. M., when President Ambrose Swasey will deliver the annual address. Following is a list of the papers to be read and discussed at the different sessions:

Wednesday morning, December 7, at the Hall Mendelssohn Union, 113 West Fortieth Street: "A New Hydraulic Experiment," by A. F. Nagle; "A Twist Drill Dynamometer," W. W. Bird and H. P. Fairfield; "Diamond Tools," Gus P. Henning.

Thursday morning, also at Mendelssohn Hall: "Centrifugal Fans," A. J. Bowie, Jr.; "Computation of Values of Water Powers and Damages caused by Diversion of Water used for Power," Charles T. Main; "An Indicating Steam Meter," Charles E. Sargent; "Staybolts, Braces and Flat Surfaces; Rules and Formulas," Robert S. Hale, and "Condensers for Steam Turbines," George I. Rockwood.

Thursday afternoon, Mendelssohn Hall: "Bursting of Four-foot Flywheels," Charles H. Benjamin; "Influence of the Connecting Rod upon Engine Forces," Sanford A. Moss; "Losses in Non-conducting Engines," James B. Stanwood; "Power Plant of Tall Office Buildings," Stirling H. Bunnell; "Pressures and Temperatures in Free Expansion," A. Borsody and R. C. Cairncross.

Friday morning, December 9, at 10 o'clock, at the Society House: "Fuel Consumption of Locomotives," George R. Henderson; "Road Tests of Brooks Passenger Locomotives," E. A. Hitchcock; "Discharge of Water with Steam from Water-tube Boilers," A. Bement; "More Exact Method for Determining the Efficiency of Steam-generating Apparatus," A. Bement; "Forcing Capacity of Fire-tube Boilers," Francis W. Dean.

The list of officers to be voted for, as presented by the Nominating Committee is: For president, John R. Freeman, Providence, R. I.; for treasurer, Wm. H. Wiley, New York; vice-presidents, S. M. Vauclain, Philadelphia; H. H. Westinghouse, Pittsburg, and Fred W. Taylor, Philadelphia; managers, George M. Brill, Chicago; Fred J. Miller, New York, and Richard H. Rice, Lynn, Mass.

STRENGTH OF BEAMS WITH RIBBED SECTIONS —A PARADOX.

WM. N BARNARD.

Is it possible for a beam which is broken part way through, to have greater strength than it had originally? Or, what is the same thing, Can a given beam be made stronger by reducing the area of its cross section?

These seem to be absurd questions and probably few people would hesitate to answer in the negative. For the usual cases, that answer would be correct, but it is a curious fact that there can be instances when it would not be.

We naturally, at first, think of the beam with a rectangular section. Any reduction in the area of this section will always decrease the strength of the beam. The same will be true of beams with circular and with polygonal sections, whether solid or hollow. It is also usually true of the ribbed section, such as the T, L and channel, but there may be exceptions. It is generally supposed that the addition of a rib will *always* increase the strength of a beam-member. If added properly the rib *will* be a source of strength, but if added improperly it may be a source of weakness, as we will endeavor to show.

Suppose, for instance, the beam has the section shown in Fig. 1, the rib being quite small and narrow compared with the main body of the section and the material being homogeneous. We would expect the rib to crack under only a slight deflection of the beam. If there was no rib, the beam with the rectangular section (2" x 5") would stand a greater deflection, under a greater load. The beam without the rib would be the stronger of the two.

Since the strength of a beam-member is proportional to the "modulus of its section" the question may be asked: Can the section be such that a reduction in its area will result in a section with a greater modulus?

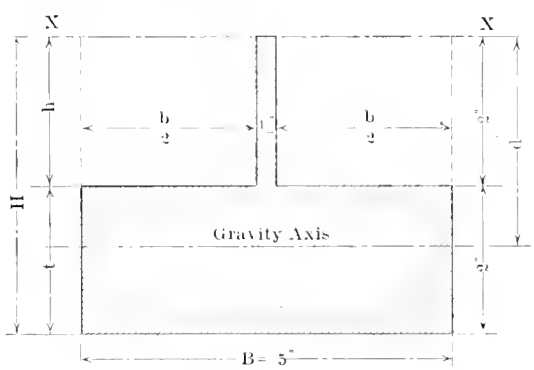

Fig. 1

We will compare the modulus of the 2 x 5 inch rectangular section, with that of the section shown in Fig. 1.

For the rectangular section the modulus is

$$Z = \tfrac{1}{6}\,B\,t^2 = \tfrac{1}{6} \times 5 \times (2)^2 = 3\tfrac{1}{3}.$$

In which B = breadth of section = 5 inches
t = thickness = 2 inches

To get the modulus of the ribbed section we will proceed as follows, referring to Fig. 1 for the letters and the dimensions used:

The moment of inertia about the axis XX, Fig. 1, is

$$I_x = \tfrac{1}{3}\,B\,H^3 - \tfrac{1}{3}\,b\,h^3.$$
$$= \tfrac{1}{3} \times 5 \times (4)^3 - \tfrac{1}{3} \times (4\tfrac{3}{4}) \times (2)^3 = 94\ 00.$$

The area of the section is

$$A = B\,H - b\,h = (5 \times 4) - (4\tfrac{3}{4} \times 2) = 10\tfrac{1}{2} \text{ sq, in.}$$

The distance of the gravity axis from the axis $X\,X$ is

$$d = \tfrac{1}{2}\,(B\,H^2 - b\,h^2) \div (B\,H - b\,h).$$
$$= \tfrac{1}{2}\,(5 \times 4^2 - 4\tfrac{3}{4} \times 2^2) \div (5 \times 4 - 4\tfrac{3}{4} \times 2) = 2.90.$$

The moment of inertia about the gravity axis is

$$I = I_x - A\,d^2.$$
$$= 94 - (10\tfrac{1}{2} \times 2.9^2) = 5\ 7.$$

The least modulus of the section is

$$Z = I / d = 5.7 / 2.9 = 1\ 96.$$

The ribbed section would therefore be only 1.96/3.33, or less than 6/10, as strong as the section without the rib. A crack through the rib would make the beam 10/6 stronger to resist further fracture.

From the foregoing it appears that there are two breaking strengths for a beam-member with a ribbed section, in which the rib is a source of weakness. At a certain load the rib will begin to crack. This may be called the "*initial*" breaking load. It will take a greater load to cause complete fracture. This may be called the "*final*," or "*ultimate*," breaking load.

In Fig. 2 is given a curve which shows the relation between the modulus of section and the depth of the rib, for the T-section which is shown in the same figure. It will be seen that the modulus of the T-section is less than that of the simple plate, 8 x 1½ inches, unless the 1-inch rib has a greater depth (h) than 1 8/10 inch. The data for the curve are given in the following table:

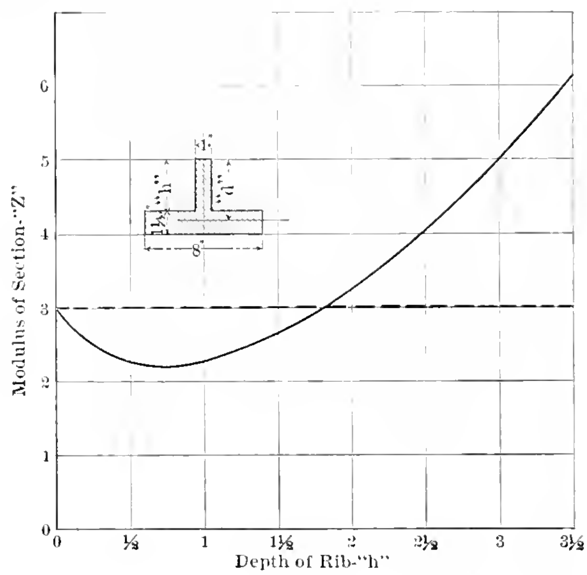

Fig. 2.

h	0	½	1	1½	2	2½	3	3½
I	2.25	2.75	3.77	5.52	8.16	11.78	16.65	22.75
d	.75	1.21	1.65	2.08	2.50	2.90	3.30	3.68
Z	3.00	2.27	2.29	2.65	3.26	4.06	5.05	6.17

In the foregoing we have spoken only of the strength of a beam as affected by the rib. There is also the consideration of the *stiffness*. This will always be increased by the addition of a rib. The stiffness is proportional to the moment of inertia of the section, which will always be made greater by increasing the area of the section in any way.

* * *

The trial electric locomotive built by the American Locomotive Co. in conjunction with the General Electric Co. of Schenectady, N. Y., has been tried on a trial track near Schenectady, and the results seem to indicate that the New York Central's terminal problem, so far as a motor is concerned, is solved. For years the New York Central and New York, New Haven and Hartford Railway has labored under great difficulties in handling the traffic at the New York terminal. The smoke and gases which accumulate in the Park Avenue tunnel make this section highly disagreeable to passengers and a menace to their safety, for there are periods when practically no other system of signals can be depended on but torpedoes. The terminal improvement plans require the use of electric motors and exclude the steam locomotive entirely in the New York City terminal proper. The specifications require electric locomotives capable of hauling trains weighing 435 tons, to make a run of 34 miles (Grand Central Station to Croton) in 44 minutes without stopping, and with only one hour lay over to be able to keep up this service continuously. The trials of the first locomotive built seem to indicate that its speed and acceleration are such as to easily accomplish the trip in the required time. With a 500-ton train, an acceleration of six-tenths of a mile per minute can be acquired from a dead stop, which means that one minute after the power is applied the train will be running at the rate of nearly 30 miles per hour. The trial track at Schenectady is only four miles long, so that it was not possible to make prolonged tests of speed acceleration, but speeds of 60 to 75 miles per hour were made while hauling a 500-ton train.

IMPROVEMENT ALL ALONG THE LINE.

THE MOST COMPREHENSIVE REPORT OF THE MACHINERY TRADE EVER PUBLISHED.

The machinery trade is unanimous in the opinion that business prospects are good for 1905, and that the improvement has already set in. To help manufacturers in forecasting the immediate future of the machinery trade a letter containing the following questions was sent to several hundred firms:

1. Has there been any improvement in your business lately?

2. Have we reached the bottom of the present business depression; if not, do you anticipate an early improvement in general business conditions?

3. What are the business prospects for 1905 in your line?

The substance of the replies received is given below in condensed form and almost without exception they express the belief in an upward trend in business conditions:

ACME MACHINERY CO.: Some improvement within 30 days, indications are for early improvement in business conditions. Inquiries are much more numerous than for some time past. Prospects encouraging.

AJAX MFG. CO.: Quite a little improvement lately, and business prospects seem very bright for 1905.

AKRON ELECTRICAL MFG. CO.: Radical change during the past six weeks. Booked more orders than previous four months combined. Have orders enough to keep factory running at fullest capacity for at least four months.

ALBRO-CLEM ELEVATOR CO.: Business improved wonderfully last two or three months; been very busy for that period. Think business prospects 1905 very bright.

T. R. ALMOND: Decided improvement in business latter part of September and October, which is continuing. Present volume of business equals that of same time one year ago. Have unquestionably passed the low point, and prospects for 1905 ought to be as good as any year that manufacturing industries of this kind have seen.

AMERICAN BALL CO.: Have had all the business in balls and ball bearings during past year that we could handle; sufficient orders on hand to keep us busy for the next two months or more. Outlook for 1905 very encouraging.

AMERICAN GAS FURNACE CO.: The business of this company has suffered no depression whatever. Facilities for turning out work have not increased as rapidly as demands for our product. Are therefore hardly in position to throw light upon the question. Overloaded with orders.

AMERICAN MCHE. & MFG. CO.: The present with us is not so busy as short time ago. Large amount of work in sight and we think we have reached the bottom and that from now on the tendency will be upward.

AMERICAN ROLLER BEARING CO.: Business exceedingly slack past summer and fall, but since election have noticed a remarkable change; have closed a number of deals, and prospects excellent.

AMERICAN TAP & DIE CO.: Our business has doubled during the past year. Have not noted any particular depression, possibly owing to increased energies made to secure larger business, which we have done. Anticipate a good business for 1905.

AMERICAN TOOL & MCHE. CO.: There has been practically no improvement in our business lately. Think we have reached the bottom of present business depression and anticipate early improvement in business conditions. Prospects for 1905 in our line we think are very good.

AMERICAN TOOL WORKS CO.: Business within last three months shown remarkable improvement. Are putting on additional men almost daily; also some additional equipment. Our opinion healthy and continued improvement has set in; anticipate enough business in 1905 to keep plant fully employed.

AMERICAN WATCH TOOL CO.: Our business gradually improving from year to year, and this year has been no exception. We have felt no business depression. Employed our usual complement of machinists all through the season, and our business compared favorably with that of 1903. No reason to expect anything less for 1905, but look for the same steady, conservative improvement.

ARGUTO OILLESS BEARING CO.: Business materially increased of late; not only due to healthier condition of trade in general, but also from effective advertising in MACHINERY. As "Arguto" is used in various industries we judge from increased orders and number of inquiries that business depression is now a thing of the past. Our prospects for 1905 are very bright.

ATLAS MCHE. CO.: Marked improvement in our business lately. Our foreign trade growing larger as well as our home trade. Can only conjecture as to whether we have reached bottom of present depression but confident that now the election is over every one can devote his time to business instead of to politics. Prospects much better for 1905 than for the present year.

AUBURN BALL BEARING CO.: The last month have had marked increase in our inquiries, and think next two months business will pick up very materially. Unable to fathom depression in metal trades which has continued since August, 1903, but from increased number of inquiries think that in next two or three months business in the metal trades will have big improvement.

AUTOMATIC MCHE. CO.: Have three distinct lines of business, i. e., marine work; original automatic wire-forming and experimental machinery, and automatic threading lathes. Marine trade has been good and is rapidly increasing; special work is and has been constant for past year; automatic threading lathe output depends upon the machine-tool trade, and this is steadily increasing. We notice foreign demand leads domestic, but home inquiries are more brisk and we confidently look for a uniform advance all along the three lines. We certainly believe we are at the ebb of the business depression.

HENRY CAREY BAIRD & CO.: We think decidedly we have reached bottom of depression; we believe prospects are very good.

BAIRD MCHY. CO.: Business has improved quite a little in past thirty days; inquiries very encouraging, and point, we think, to a lively business in the near future. Feel that late business depression was buried on Nov. 8th.

BAKER BROS.: Our machine tool business very quiet for last three months, but think there has been improvement since first of month and from present outlook are expecting good trade after first of year, believing that business conditions fully warrant such a hope.

BANTAM MFG. CO.: Improvement in business; prospect for coming year: our old time boom. The bottom was reached last August.

EDWIN E. BARTLETT: 1. Yes, decidedly. 2. We do. 3. Good.

WM. BARKER & CO.: Great improvement; expect to have a great deal more to do shortly; prospects for 1905 very favorable.

BAY STATE STAMPING CO.: Our business gradually improving since last January, and if there has been a depression in other lines it has not affected us in any way. Business prospects for 1905 seem to be very bright.

THE BAY STATE TAP & DIE CO.: Past two months decided improvement in our business.

BAYLDON MCHY. & TOOL CO.: There has been no increase in sales in our business lately, but inquiries vastly increased within last two weeks. Believe bottom of business depression was reached during the early summer months, and look for steady improvement.

H. G. BARR: Seems to be an improvement. Sales are on the increase. Think that machine tool business has reached bottom of present depression and that heavier tools will advance more noticeably than light tools for a little time. Expect twice the business for 1905 than in 1904.

BAUSH MCHE. TOOL CO.: 1. There has been an improvement in our business lately. 2. yes. 3. we would give a good box of cigars to know.

BEAMAN & SMITH CO.: Think indications are favorable for an improvement; think business prospects are better than they were a year ago.

BEAUDRY & CO.: Marked improvement in orders and tone of inquiries, bottom of depression we consider well past, and look for steady improvement in business conditions. Prospects for 1905 most promising.

BECKER BRAINARD MILLING MCHE. CO.: Quite a little improvement in conditions last two months. Believe bottom has been reached; are anticipating early improvement; do not look for much before new year. Believe prospects for 1905 good in machine tool business.

BELDEN MCHY. CO.: Improvement of late, and we feel very optimistic concerning outlook for coming year.

DAVID BELL ENG'G WORKS.: Decided improvement in orders; believe that the prospects for next year are fairly bright, although we do not look for a banner year until 1906.

BENSKIN MFG. CO.: Improvement in our business recently; certainly have reached bottom of present business depression. We have entire confidence in an early improvement in general business conditions, and the prospects for 1905 as they appear to us, are all that could be desired.

BERTSCH & CO.: Since election business steadily increased. Believe worst of business depression passed, and outlook for 1905 very good.

CHARLES H. BESLY & CO.: Marked improvement in our business lately. Our customers seem to be starting on a period of increasing activity. Business prospects for 1905 are good.

BETHLEHEM FDY. & MCHY. CO.: Our business has shown decided improvement lately, and believe depression is rapidly passing to buoyancy. Every indication of improvement in general business, and prospects for 1905 very encouraging.

H. BICKFORD & CO.: Outlook for better conditions in 1905 is excellent.

BICKFORD DRILL & TOOL CO.: Improvement last six weeks. Believe will continue, although do not anticipate marked increase until after first of year. Foreign trade also improving and 1905 should develop into a good year for us.

BIGNALL & KEELER MFG. CO.: Inquiries strong and their general tone gives the impression that people intend to buy in the near future. Think there is already an improvement in business conditions.

HUGO BILGRAM: My opinion is that recovery will be slow, as usual after depressions.

BILLINGS & SPENCER CO.: Believe we have reached bottom and indications are we are going to experience improvement in business from now on. Prospects very encouraging. Increased inquiries for products in our line.

BINSSE MCHE. CO.: Marked improvement in our business since September. Bottom of depression passed. Look for not merely an early improvement but for a demand for prompt delivery which will disappoint a great many. Foreign trade shows improvement.

BORDEN CO.: 1. consider [illegible] improvement lately. 2. we [illegible] best.

BOYNTON & P[illegible]: [illegible] early [illegible] increase. Look forward to 1905 as a good business year [illegible]

BRADFORD MCHE. TOOL CO.: Decided improvement [illegible] lately; now operating [illegible] steps [illegible] trade at home improving every day. Prospects [illegible] bright.

B. H. BROWN & CO.: Decided improvement [illegible] six weeks or two months. Think [illegible] reached [illegible] depression and anticipate [illegible] business [illegible] after middle of January.

BROWN & SHARPE MFG. CO.: [illegible] somewhat [illegible] tions will continue [illegible] Prospects [illegible] 1905 in our line are favorable.

BROWN HOISTING MCHY. CO.: [illegible] 2. and [illegible] look for big improvement immediately.

BROWN & ZEIGMAN MCHY. CO.: [illegible] in last forty days [illegible] business that has been hanging fire for six or eight months, and the business is from some of [illegible] corporations, indicating that the big people are once more going into the market. We feel bottom has been reached and are on a [illegible] starting [illegible]

recover from general depression felt more in Pittsburg territory than in any other part of country.

BUILDERS' IRON FOUNDRY: Slight improvement in our grinding and polishing machinery line. Orders larger and more frequent; more inquiries. Looking for early improvement, possibly not until first of year, but believe in 1905 there will be a decided improvement along all lines of manufacture.

BUTTERFIELD & CO.: Business improved very much since middle of year; believe bottom has been reached; prospects for 1905 are excellent.

ROYAL E. BURNHAM: Business was very good up to the first of September, when there was a marked falling off. Since settlement of political conditions, there are signs that business will return to its normal conditions.

JOHN T. BURR & SONS: Outlook for immediate future of our business very bright indeed. Our business for ten months this year more than equaled sales for whole of last year; numerous inquiries covering everything we manufacture.

BUTLER CHUCK CO.: Improvement in chuck demand recently and an undercurrent of inquiry which indicates that tide has already turned; strong grounds for expecting that future will not withhold its harvest from those who diligently plant.

CARBORUNDUM CO.: Some improvement in business lately, and from general outlook in this locality, look for steady improvement from now on.

CARPENTER TAP & DIE CO.: Fall trade shows great improvement, and indicates a good year for 1905.

CARR BROS: Our business has shown steady improvement the last four months, with good prospects for the future.

CARTER & HAKES MCHE. CO.: Business very even and steady during the whole of last year, and recently no marked change. Prospects of plenty of work for the next year.

CHAMBERSBURG ENG'G CO.: Decided improvement in our line of business lately.

CHANDLER PLANER CO.: Large amount of business in sight, but that may be due to the fact that we are offering something out of the usual course of machine tools. We are, however, in the market as purchasers, and the fact that business is reviving is evident from increased difficulty in getting promise of deliveries of certain tools that a few months ago were seeking purchasers.

CHATTANOOGA MCHY. CO.: 1. Yes. 2. We do. 3. Last six months our business improved materially; look for next year to be most prosperous we have had.

CINCINNATI MACHINE TOOL CO.: Much better feeling in machine tool market; some orders placed which have been hanging fire very long. Anticipate early improvement. Indications for next year are for good business.

CINCINNATI PLANER CO.: Considerable improvement during past sixty days. Believe are now starting on period of good healthy business. Anticipate increase of fully 50 per cent. for 1905. Believe people are gradually having their confidence restored.

CINCINNATI PUNCH & SHEAR CO.: Business was unusually quiet until about Oct. 1st, since which time decided improvement, not only in inquiries but in substantial orders. We are quoting as many probably now as during the last few rush years. Believe will be busy the rest of this year and busier next.

CINCINNATI SHAPER CO.: Very decided improvement in business conditions lately. No doubt bottom of the present business depression has been reached, and we anticipate the year 1905 to be a banner one.

JAS. CLARK, JR., & CO.: Marked improvement in our manufacturing business of late; in fact, we have as much as we can possibly do for several months to come with our present capacity. Believe business will gradually improve until in the very near future we believe that business will be on a boom.

CLEVELAND ATOMATIC MCHE. CO.: Last four months our business has been extremely good. Operating factory to fullest capacity, and hardly able to keep up with orders. Hardly think we have at the present time a business depression. True, in a number of branches, we are not as busy as one year ago, but nevertheless general business of country is in fairly good condition. Prospects in this country at present time exceedingly bright, and believe that after holidays business will improve rapidly.

CLEVELAND CAP SCREW CO.: Material improvement in trade last two or three months: look for a continuance, or even further improvement of this condition.

CLEVELAND CRANE & CAR CO.: Business has improved materially; that for last three months much better than for eight mouths preceding. Believe bottom has been reached. Do not, however, anticipate much improvement until early next spring, after which we believe business will be as good as ever.

CLEVELAND PNEUMATIC TOOL CO.: Do not anticipate much revival until April, 1905; believe things will then get into pretty good swing and go along for several years in elegant shape.

CLEVELAND TWIST DRILL CO.: Business during past year considerably less than during three previous years; some improvement during the past sixty days. Think bottom reached, and every prospect for fine business for 1905.

CLING-SURFACE CO.: Business steadily improving during all fall months. Believe will continue to improve and indications point to prosperous year during 1905.

R. M. CLOUGH: See little change as yet. Expect better times.

COLUMBUS MCHE. CO.: Look for no great improvement until after first of year. Business very fair past few months and we expect it to continue; with spring there will be real good buying and everything will move along in good healthy way.

CROWE METAL MFG. CO.: Our business a new one, and growing steadily. Pick-up lately indicates we are on up grade again.

CURTIN-HEBERT MFG. CO.: Slight improvement in our business of late.

CURTIS & CURTIS CO.: Improvement since last June. While still behind the booming times of two years ago, certainly improving, and we look for several years of good business to come.

CURTIS & CO. MFG. CO.: Do not anticipate further decline in business, but a somewhat increased demand for our products.

CUSHMAN CHUCK CO.: Great increase of activity among our own customers and for many weeks inquiries and orders have been coming in more freely than for several months; indicates an improvement in the machinery trade generally and also a busy season for us.

W. P. DAVIS MCHE. CO.: Improvement in business within last two months. Believe prospect for business in 1905 good. In manufacturing of machine tools there will not be the demand from the dealers we have had in the past, as we believe their policy will be to buy only for their present requirements, as nearly all have been carrying very heavy stocks. Believe general demand all over the country will be good.

DERRY-COLLARD CO.: Improvement in our business during the past month. We feel there is upward tendency in business; anticipate a good trade during coming months; prospects for 1905 better than for past two years.

DESMOND-STEPHAN MFG. CO.: Are new in the business but business satisfactory and constantly increasing.

DETROIT TWIST DRILL CO.: Improvement. Certainly all the conditions are now favorable.

DIAMOND SAW & STAMPING WORKS: Output for September largest in history of our business. Believe we can look forward to a steady and marked improvement, and that next four years will show no decrease in the volume of trade as compared with the past term of prosperity.

DODGE & DAY: Our Mr. Day, returned from extensive trip through west, reports indications are there will be very material improvement in business shortly.

DRAPER MCHE. CO.: Marked improvement in business during last month; bottom of depression reached; from now on business will steadily become better. From orders placed and inquiries received, we anticipate a good business in 1905.

DRESES MCHE. TOOL CO.: Since October, business improved considerably; outlook very good; think the prospects for 1905 very promising.

EASTERN MCHY. CO.: Business shows improvement past two months. Has been good past three or four years.

EATON, COLE & BURNHAM CO.: Considerable improvement of late; good prospect both for this year and for 1905.

ELWELL-PARKER ELECTRIC CO.: Distinct improvement lately; do not hesitate to say we have considerably passed bottom of depression. As to 1905, are sure it will be a first-class year for every one.

ERIE ENGINE WORKS: Improvement in business conditions of late; anticipating further and early improvements in general business, and hope it will be realized.

ERIE FDY. CO.: Very decided improvement in our business; very hopeful for a good year in 1905.

EXCELSIOR TOOL & MCHE. CO.: Business brightened up lately; feel encouraged to believe business will constantly improve, and that prospects for 1905 are bright.

FANEUIL WATCH TOOL CO.: Did not feel recent depression very much; looks as though we are going to have an extra big year.

FAY & SCOTT: Our business very good up to last July; since, rather quiet; our prospects are bright for 1905.

FENN SADLER MCHE. CO.: Business improved steadily. Prospects for 1905 look very bright to us.

FERRACUTE MCHE CO.: Business prospects for coming year seem good. Have had all the work we could do during the past year. Judging by number of orders we expect to have enough to do in our new fire-proof works.

FITCHBURG MCHE. WORKS: Look forward to good business for ensuing year.

FLATHER & CO., INC.: Decided improvement; busy as can be; large number orders on hand and are receiving more inquiries.

MARK FLATHER PLANER CO.: Have been able to close a few very nice orders at excellent prices. It would appear that business will begin to come in shortly after the opening of new year, probably about February or March; from that time on we anticipate as much or more business than able to take care of for next three or four years.

FOOS GAS ENGINE CO.: For the last six months have had more business than could handle, with every indication of its continuing.

FOOTE, BURT & CO.: Business seems to have opened up in better shape than during October. All signs that we will very speedily have a resumption of good business. Think prospects for 1905 extremely good in our own line and in all machine tool lines.

FOSDICK MCHE. TOOL CO.: Business improved much since first October; now running full time and look forward to good year. Believe there will be fair and steady demand for machine tools.

FOX MCHE. CO.: Inquiries and orders coming in much better; prospects for good fall and winter business very bright.

WILLIAM E. GANG CO.: 1. Yes. 2. Yes. 3. Prospects for 1905 in our line, good.

WM. GANSCHOW: From large number of inquiries both from local concerns and also out of town, business must be commencing to pick up again. No reason on earth why business in 1905 should not be a good deal better than the last year.

WM. GARDAM & SON: Business very even during past year; from number of inquiries prosperous year for 1905 certainly indicated.

GENERAL PNEUMATIC TOOL CO.: Last two and a half months marked increase in amount of business; confident that there will be a steady improvement.

GEOMETRIC DRILL CO.: Marked improvement past few weeks both in inquiries and orders; feel very much encouraged; prospects for 1905 in our line very bright indeed.

GOODELL-PRATT CO.: Believe outlook as regards small tool trade very encouraging; believe—and not without having carefully considered the situation—that 1905 will be biggest year small-tool manufacturers ever enjoyed. Understand us, we do not presume to comment upon conditions existing in the machinery line, for that is foreign to our business.

GIANT MOTOR CO.: Business good for last two months, with best prospects for 1905.

GLASGOW IRON CO.: Think business prospects for 1905 are very good.

GLOBE MCHE. & STAMPING CO.: Sales for 1903 50 per cent. higher than in 1902, and for 1904, fiscal year ending October 1st, 33 1-3 per cent. higher than for the previous year. Now have sufficient business to run six or eight months. Prospect for prosperous year 1905 bright.

GODDARD MCHE. CO.: Business improved somewhat last few weeks. Believe situation will continue to improve; look for much better business in 1905.

GOULD & EBERHARDT: Quite some business right along, anticipate gradual improvement with good steady demand during the coming year.

GRAY & PRIOR MCHE CO.: Glad to say have not felt depression; prospects in our lines for coming year excellent.

GREAVES, KLUSMAN & CO.: Decided improvement in business lately; prospects for 1905 very good.

GUARANTEE ELECTRIC CO.: Surprising increase in business since election; think that for the next year or two it will be steadily on the increase.

HAMILTON MCHE. TOOL CO.: 1. Yes. 2. Under impression we have seen worst of present business conditions. 3. Everything indicates we will have an average year.

HAMMACHER, SCHLEMMER & CO.: 1. Yes—barring slight set-back due to our moving. Believe there will be a healthy, conservative period for some time to come.

HARRISON SAFETY BOILER WORKS: Past sixty days business conditions steady improvement; anticipate full resumption in practically all lines by commencement of new year.

HAYES FILE CO.: 1. Yes. 2. We think we have. 3. We think the outlook very bright.

HAZELTON & DONALD MCHE. CO.: Are of opinion tendency will be to go a little slow for a while, but prospects for 1905 exceedingly favorable.

HEALD MCHE. CO.: Very busy, indeed, ever since we moved our plant to Worcester. Believe that last five or six weeks decided improvement in inquiries, and orders that will be even more pronounced after the first of the year.

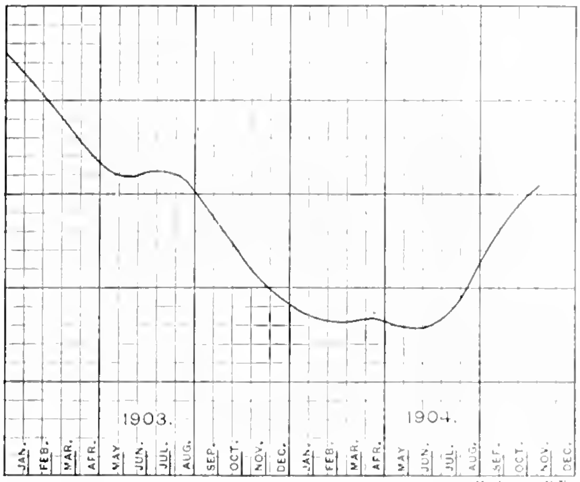
HENDEY MCHE. CO.: Substantial increase past two or three months; have a large number of unfilled orders. Anticipate very good business coming year.

HESS-BRIGHT MFG. CO.: Our business continually improving. Prospects for 1905 very satisfactory.

GEORGE WILLIAM HOFFMAN: Business lately very good until last week or so; depression, I presume, due to election; expect my sales for 1905 to almost double those of previous years.

HILL, CLARKE & CO., Boston, Mass.: Anticipate a fair amount of business during greater part of next year.

HILL, CLARKE & CO., Chicago, Ill.: Your question can be very nicely answered by little curve inclosed herewith; shows that business dropped off about January, 1903, reached its lowest notch in May and June, and



since then has been considerably on increase, and according to outlook ought to be back to normal condition by next spring. What we mean by "normal" would be a condition to compare very close to year 1902.

HISEY-WOLF MCHE. CO.: Think prospects for 1905 are first-class in all lines; look for good healthy business, from January 1st particularly.

HOGGSON & PETTIS MFG. CO.: Business about the same past month or so; look for increase soon, with prospects good for 1905.

B. P. HORTON: Very quiet, but looking forward to steady increase. See no reason why 1905 should not be a record breaker.

E. HORTON & SON CO.: Some improvement of late; anticipating a still further improvement in the near future. Prospects for 1905 good.

E. F. HOUGHTON & CO.: 1. Yes. 2. Running to full capacity. 3. Elegant.

HOWARD IRON WORKS: Have noticed improvement in our business lately. Prospects for 1905 good.

HURWOOD MFG. CO., INC.: Prospects for doing a good business in 1905 rather better than fair.

HYATT ROLLER BEARING CO.: Have noted a general improvement in the machinery lines past four or five months. From indications are going to have increased business in all lines for at least two years to come. Prospects for 1905 are particularly bright in our line.

IDEAL MFG. CO.: Improvement in situation during last two months; inclined to think will be an improvement in business conditions early in 1905.

INTERNATIONAL CORRESPONDENCE SCHOOLS: Our business has annually shown large increase since origin, in 1891. Believe that coming year will be best the Schools ever experienced.

INTERNATIONAL POWER VEHICLE CO.: Improvement very perceptible in our case.

INTERNATIONAL SPECIALTY CO.: Business only started about six months ago; fair demand for our emery wheel dresser; anticipate a good business next year.

IVES MFG. CORPORATION: 1. Yes. 2. Passed bottom of depression. 3. Prospects for 1905 of the brightest.

JACOBSON MCHE. MFG. CO.: Business shows marked advance each week. Think business will be at least up to normal standard in short time if not considerably above.

D. O. JAMES: From present indications future outlook very cheerful.

R. A. KELLY CO.: Look for better trade during 1905 than we have enjoyed for some time past.

KEMPSMITH MFG. CO.: Business in our line picking up nicely; feel that depression has reached its bottom, at least we hope so.

KENDRICK & DAVIS: 1. Fully equal to last year. 2. Yes. 3. Very good.

KEYSTONE DROP FORGE WORKS: Improvement lately; tone, in general, seems to indicate continued improvement. Prospects for 1905 encouraging.

KILBOURNE & JACOBS MFG. CO.: Very decided improvement during the last two months. Prospects for 1905 excellent.

KING MCHE. TOOL CO.: Number of inquiries increasing; think there will be a temporary boom in our line caused by placing of orders by such concerns as have held off until last minute; anticipate good average year in 1905.

LANCASTER PEERLESS EMERY WHEEL CO.: Feel much encouraged; have had several very nice orders since election.

MAIN BELTING CO.: We are right busy; think prospects upward and first-class.

EDW. LINDMUELLER: Decided improvement lately; think have reached low ebb of business depression, and are on the rise. For 1905 prospects very encouraging; anticipate busy season.

LINK-BELT ENGINEERING CO.: Orders since the 8th noticeably more numerous than during period immediately preceding that date. Look for material improvement in business conditions and a [illegible] tide.

LODGE & SHIPLEY MCHE. TOOL CO.: Improvement in [illegible] to 90 days. Business prospects for the future very [illegible]

LUCAS MACHINE TOOL CO.: 1. Evidences of substant[illegible] ment. 2. Think we are well on the road to bett[illegible] Favorable.

WALTER MACLEOD & CO.: Have every confidence that [illegible] will show great improvement over the present one. [illegible] last six months than six months previous. Railroads and [illegible] users buying more generously; look for even better returns in [illegible] future.

F. B. MCCROSKY MFG. CO.: Decided improvement in demand [illegible] our product, beginning early part of October. Believe bottom of [illegible] ent depression was reached some time ago. Prospects for 1905 [illegible] cellent.

MCDOWELL, STOCKER & CO.: Inquiry getting some better. Bel[illegible] there will be early improvement in general business conditions, [illegible] not much before first of coming year.

MANNING, MAXWELL & MOORE: Marked improvement in the ma[illegible] chinery business this month. Believe have reached bottom present bus[illegible] iness depression; anticipate good general business, without marked increase in prices until demand is considerably larger, when we think prices will advance. That, of course, will rest largely with the manu[illegible] facturers, and is a matter they will control, according to amount of business they have in proportion to their capacity. Think prospects in our line for 1905 very good, though do not look for any great boom.

MANVILLE BROS. CO.: Great improvement recently, and think [illegible] sales will be very much increased during coming months.

MAYER & CO.: Tendency of improvement; more inquiries coming [illegible] As for 1905, think it will be beginning of era of prosperity and good feeling.

MEISEL PRESS & MFG. CO.: 1. Yes. 2. Yes. 3. Very good.

OTT. MERGENTHALER & CO.: Some improvement, and we antic[illegible] more.

MERRELL MFG. CO.: Business not improved any as yet, but antici[illegible] pate general improvement in conditions. Prospects for 1905 very bright in our line.

MERRILL BROS.: More inquiries for machinery within last month than for six months previous. Our business no[illegible] depressed [illegible] anti[illegible] pate general improvement.

MERRITT & CO.: Decided improvement in past sixty days; business has steadily grown during past three or four years.

MICHIGAN LUBRICATOR CO.: Decided improvement in trade condi[illegible] tions; anticipate a boom year in 1905.

AUGUST MIETZ: Some improvement in our business lately; expect early improvement in conditions. Prospects for 1905 in our line very good.

MILLER'S FALLS CO.: Very perceptible improvement commencing about October 1st. Conditions favorable for continued increase in volume of business.

MILWAUKEE TOOL CO.: Outlook for 1905 not discouraging for beginning of year; the latter part will be a commendable season, comparatively speaking.

MITTS & MERRILL: Considerable improvement during past month; business for two or three preceding months comparatively light. Look for steady improvement in our business during next year.

MINER & PECK MFG. CO.: Orders now coming in fairly well; quite an increase in inquiries.

MONTGOMERY CO.: Considerable improvement during last two months. Believe winter trade is going to be fairly good, and by spring conditions will be excellent.

MORSE CHAIN CO.: Our orders for drives for machine tools less than usual, but for chain power transmission increasing very rapidly, and have been during last three months.

C. A. MOSSO: My business increased more than double in last year. Am not looking for a boom, but good steady business, with healthy increase for some time to come. Prospects for 1905 were never better.

FRANK MOSSBERG CO.: Steady increase in our business during October; prospects at present writing for 1905 better, and we look for a good business.

MUELLER MCHE. TOOL CO.: Have of late noticed improvement in machinery business. Prospects for 1905 in our line very good.

NATIONAL MCHE. CO.: Have had good year. Outlook very good for 1905.

NATIONAL SEPARATOR & MCHE. CO.: Very good business; looking for amount of business for 1905.

NEW ERA MFG. CO.: The present year, as a whole, will be one of the best in the history of our company, and prospects for 1905 very flattering in our line.

NEW ENGLAND ROLLER GRATE CO.: Prospects for coming year very bright. Our business on steam specialties very good throughout the year.

NEWTON MACHINE TOOL WKS.: Steady increase in our business last two or three months, especially within the last week or so. Do not anticipate any boom; we think by first of year there will be a good steady business, especially so with railroad companies.

NILES-BEMENT-POND CO.: Business with us very much improved; prospects for coming year we consider most promising.

NORTHERN ELECTRICAL MFG. CO.: Marked improvement in inquiries and orders since September. Business at the present time very satisfactory. The prospects for 1905 seem good.

NORTHERN ENG'G WORKS: Quite an improvement both in inq[illegible] and orders placed. Anticipate further improvement in business [illegible] three or four months.

NORTHWESTERN MFG. CO.: Business steadily increased for [illegible] three months. Believe bottom of depression was reached [illegible] months ago and the prospects for next year are [illegible] demand on the increase all the while for high grade apparatus [illegible] as we make.

NORTON EMERY WHEEL CO.: Business very good [illegible] Prospects splendid.

OHIO MCHE. TOOL CO.: Some improvement recently, and look for it to continue. Are looking for a much better business in 1905.

L. H. OLMSTED: Decided improvement in demand for goods during past six weeks; continues at present.

OLIVER MCHY. CO.: Material improvement last three or four months. Large number inquiries, which will undoubtedly lead to future business. Anticipate 1905 being a record breaker.

ONEIDA STEEL PULLEY CO.: Been making all we could and unable to fill our orders. Have not realized there was any depression.

J. L. OSGOOD: Find business in machinery line in this section improved since August. Inquiries increasing and orders coming in for machinery. Indications are 1905 will prove a prosperous year to the machinery trade.

Charles Parker Co. Certainly a decided improvement in business last six weeks or two months. Reached the bottom on business depression. Prospects for 1905 in our line of goods is bright.

W. M. Pattison Mchy. Co.: Cannot find great improvement in business, although last month showed a little. Better prospects for 1905, though we do not consider there will be any rush in the machine tool line.

Pedrick-Smith Co.: Look forward to prosperous year. Mail very encouraging, containing many inquiries; very busy; have started night shift, to get out the orders.

Perkins Mchb. Co.: Improvement of late, starting about 45 days ago; business on the increase, obliged last week to run night and day to keep up with orders.

Perry Time Stamp Co.: 1. Yes. 2. Believe have reached bottom of present business depression. 3. Business prospects for 1905 in our line excellent.

Philadelphia Pneumatic Tool Co.: Sales for October far exceeded those of preceding month. Inquiries good, coming from all portions of country. Anticipate a very prosperous year for 1905.

Phillips Pressed Steel Pulley Works: Too new to have experienced business depression; we hear confidence expressed everywhere.

Phoenix Mfg. Co.: More calls at present; think tide has turned, and good business will be with us.

Phosphor-Bronze Smelting Co., Ltd.: Business shows slight improvement of late.

Pike Mfg. Co.: Confident business will pick up, and are anticipating large demand for our goods for the next six months.

L. W. Pond Mche. & Fdy. Co.: Improvement; numerous inquiries; feel prospects for 1905 in our line very bright.

Potter & Johnston Mche. Co.: Past six or eight weeks domestic demand greatly increased; foreign sales equally satisfactory; present outlook for 1905 points to a banner year.

Power & Speed Controller Co.: Considerable improvement past two months and bottom of the business depression reached; upward tendency. Prospects for 1905 would seem good if present advance continues.

Pratt & Whitney Co.: No serious depression in our business during 1904

Prentice Bros. Co.: Business improved greatly within last three or four weeks.

Geo. G. Prentice & Co.: Consider that bottom of depression reached. Prospects very bright for 1905.

Prentiss Tool & Supply Co.: Our business has shown steady improvement since August 15th. Expect satisfactory business for 1905.

Queen City Mche. Tool Co.: Improvement in business conditions; the machine tool line has taken quite a jump in this vicinity. Look for era of good times.

A. D. Quint: Decided improvement in business, foreign and domestic, in past six weeks. Spring of 1905 will see everything on the boom once more.

Railway Appliances Co.: Marked improvement in our machinery business of late; feel tide has already turned. Prospects for 1905 show promise more business than any time for last eighteen months.

Rand Drill Co.: Prospects for business for 1905 good.

Ransom Mfg. Co.: Expect, from now on, business will be better; look for a banner year in 1905.

Francis Reed Co.: Indications seem to be good in my line for 1905.

Ridgway Mche. Tool Co.: Notice improvement; have booked sufficient orders within last week to give us work for nearly a year.

Robertson Mfg. Co., Inc.: Past month marked improvement; prospects for 1905 very good. Trade on our rapid cut saws especially bright.

Robbins & Myers Co.: Substantial improvement last few weeks over business a number of months preceding. Indications point to a very favorable year.

John M. Rogers Boat, Gauge & Drill Works: Decided improvement in the general business conditions.

Roth Bros. & Co.: Prospects in our line look very bright.

Rowbottom Mche. Co., Inc.: Had fair business right along; have every confidence 1905 bringing complete revival of good business.

Royersford Fdy. & Mche. Co.: Quite an improvement in our business within last two months. Anticipate a very general improvement in conditions. Our prospects for 1905 exceedingly bright.

Ruggles Coles Eng'g Co.: Very decided improvement last month. Look forward to large business the coming year.

Saginaw Mfg. Co.: Considerable improvement in our business of late; prospects for 1905 excellent.

Sawyer Tool Mfg. Co.: Present business very good; outlook for future bright.

Screw Cutting Co. of America: Believe we shall have all we can do in 1905.

Schellenbach & Radcliffe: We have all we can possibly get out with our capacity until January, 1905. Our prospects for next year very good indeed.

Scott & Sons: 1. Yes. 2. We have. 3. Good.

Sebastian Lathe Co.: Believe we are entering on another era of prosperity. Fully expecting a good demand for our tools for the coming year.

Skinner Chuck Co.: 1. Yes. 2. Yes 3. Very good.

Sloan & Chace Mfg. Co.: Very decided improvement lately; expect business will at least equal 1903 and will probably be much better.

J. T. Slocomb Co.: Expect satisfactory business during coming year.

Ernst G. Smith: Had an average amount of business, and feel confident business will greatly increase in 1905.

J. D. Smith Fdy. Supply Co.: Our business increased about 20 per cent. past two months; if present growth continues, will not be long before we are doing as much as we did last year.

J. E. Snyder: Business past few months rather quiet. Getting some foreign orders, but domestic trade slow. Will see a good fair business during 1905.

Speed Changing Pulley Co.: 1. Yes, 50 per cent. 2. Yes. 3 Splendid.

Sprague Electric Co.: Recent improvements; prospects 1905 in our line are exceedingly good

Springfield Mche. Tool Co.: Considerable improvement in our business commencing September first. Believe that a steady improvement in general business conditions has now set in. For 1905 a fair business to be expected.

Standard Eng'g Co.: Better inquiry noted in our line; sufficient amount of machine orders on hand to keep us busy for at least three months. Believe general conditions are on the mend.

Standard Roller Bearing Co.: Considerable increase in our orders lately; appears to us business for 1905 will be very heavy. Busy all the time; have just doubled size of our plant.

Standard Welding Co.: Business in this city has been good throughout; have full confidence in immediate future; are looking forward to nice business during entire year of 1905.

Stark Tool Co.: Bright outlook in the near future; inquiries coming in; several orders on hand.

Steel Ball Co.: Demand for our lubricators great; factory running to fullest capacity; our business growing rapidly, forced to add facilities.

Steffey Mfg. Co.: Number orders received this month considerable advance over those received corresponding month last year. Prospects very good for 1905.

John Steptoe Shaper Co.: Every reason to believe coming year will be a good one.

Sterling Emery Wheel Mfg. Co.: Quite a change the last week; believe business will improve from now on. Prospects for 1905 bright.

Stewart Heater Co.: Experienced no depression in business for past four or five years. Confident business will continue for 1905 as in past few years.

D. M. Steward Mfg. Co.: Our trade increased past sixty days more than 25 per cent.; little doubt of good business for some considerable time in the future.

Stockbridge Mch. Co.: Very marked improvement past two weeks, inquiries and orders. Several propositions "hanging fire" past year, been closed. Expect gradual picking-up in business generally.

Stoever Fdy. & Mfg. Co.: Feel we have reached bottom of present depression, and any change must be for the better.

H. T. Story: Past summer and fall received more orders than during any previous season. Prospects for 1905 are good.

Stover Engine Works: Feel thoroughly convinced have reached the bottom of depression; look forward to one of largest gasoline engine years we have yet experienced.

Stow Flexible Shaft Co.: Utterly unable to make forecast for the next year; the hope is that it may be better.

Stow Mfg. Co.: Early spring months showed best business we ever had. Decided falling off July, August and September; steady improvement in October which has continued up to date. Everything points to continuation of good business.

Stratton Bros.: Business past two months up to average for September and October; for past ten months decidedly ahead of first ten months of last year. Expect unusually large trade coming season.

A. Streit Mche. Co: Have more inquiries on hand than at any time before; look for a very good year.

Charles A. Strelinger Co.: Outlook both for immediate present and for the year to come exceedingly good.

C. E. Sutton Co.: Slight improvement in our business within the last thirty days. Do not anticipate improvement in general business conditions before spring of 1905.

Tabor Mfg. Co.: We look for a better year in 1905 than we have yet enjoyed.

Thiem & Co.: All of our business has been good last few years, although have noticed brisk improvement in business for past two months. Our prospects for 1905 very good.

Thomas & Lowe Mchy. Co.: Have experienced great improvement during past few weeks both as to inquiries and sales, which we consider healthy indication.

Three Rivers Tool Co.: Our business has grown steadily; believe there will soon be very decided improvement in general conditions; looking forward to large business for 1905.

Toledo Mche. & Tool Co.: Believe we are near end of business depression. See no reason why business should not assume its normal proportions.

Toronto Mche. Co.: Note greater volume of business last few weeks, believe business in general will settle down to normal conditions for coming year.

Transue & Williams Co.: Believe business prospects in 1905 in our line of work very bright.

Trump Bros. Mche. Co.: Quite busy in some of our lines on accumulated orders, but new business not coming in as freely as we should like, for the past sixty days.

W. W. & C. F. Tucker: 1. Yes. 2. This is the tendency. 3. Very bright.

Turner Brass Works: Frankly state we do not think as far as business is concerned there is any depression whatsoever. Our prospects for 1905 very bright indeed.

Turner, Vaughn & Taylor Co.: 1. Yes. 2. Think business will come steady and healthy.

H. B. Underwood & Co.: Fairly busy during the entire year; have not encountered business depression; have kept on our regular force of employes, and lately have taken on some new ones. Prospects for 1905 very encouraging.

Utica Drop Forge & Tool Co.: Business improved last two months. Outlook is bright.

Vandyck Churchill Co.: Are looking forward to good, steady, satisfactory amount of business during 1905.

Veeder Mfg. Co.: Have had a very prosperous year indeed and anticipate even a better one next year.

Von Wyck Mche. Tool Co.: We personally have experienced a decided improvement in last five weeks. Prospects for 1905 exceedingly bright.

Wallace Supply Co.: Not noticed any recent improvement; believe, however, bottom of the depression reached and prospects for 1905 are very good.

O. S. Walker & Co.: While we do not look for a boom, anticipate fairly good business for winter. Prospect for 1905 seems likely to be fully up to the average.

Edgar T. Ward & Sons: 1. Yes. 2. Improving all the time. 3. Good.

Washburn Shops: Improvement in business the past month. Are anticipating a good year.

Waterbury Mche. Co: Past month considerable improvement. Looking forward to good year's work for 1905.

Watson-Stillman Co.: Our business has received a decided impetus; quietest record in several years July and August; future conditions appear very satisfactory.

Webster & Perks Tool Co.: Do not believe we suffered as much as some; certainly anticipate steady improvement in general business conditions. Regard prospects for 1905 as most promising.

Wells Bros. Co.: Business last four weeks improved somewhat, yet not up to usual standard; indications point to rapid improvement after first of the year.

WESTCOTT CHUCK CO.: Prospects now excellent for continued and increased improvement.

WESTERN TOOL & MFG. CO.: Since the first of month enjoyed marked improvement in trade. Machinery dealers are beginning to stock up, which indicates that trade is picking up with them. Also improvement in our trade with railroads, a good sign of business conditions.

WHITCOMB MFG. CO.: Marked improvement in planer business last few weeks; think business during 1905 and 1906 will be of good volume.

WILEY & RUSSELL MFG. CO.: Haven't observed any great falling off in our business. Very good for this time of year.

WILLIAMS, BROWN & EARL: Business picking up; we have never struck bottom, as this year's business is ahead of last year's business. Looking for great business year.

WILLIAMS TOOL CO.: Trade is somewhat irregular, coming to us in spurts and then laying off for a time, but there seems to be a feeling that 1905 will be the beginning of another prosperous season, and trust it will prove so.

WILMARTH & MORMAN CO.: Shipments for September 10 per cent better than for August; October 10 per cent. better than September, yet neither month equal to corresponding month year ago; impression is general conditions better, with prospect of good year ahead.

WINDSOR MCHE. CO.: Our business improved somewhat last six weeks; anticipate early improvement over condition existing for the last year; believe our prospects for 1905 good.

WINKLEY CO.: Believe will be a material improvement coming year; are planning according to these ideas.

WOODWARD & POWELL PLANER CO.: Indications are we will have a fair trade this coming year.

C. C. WORMER MCHY. CO.: Feel that depression will be ended in near future, and that after January 1st general conditions will improve.

WORCESTER MCHE. SCREW CO.: From present outlook we expect to be very busy within next three months and with all the business we can possibly attend to.

W. C. YOUNG MFG. CO.: Improvement in business within last sixty days; do not anticipate anything like a boom during coming year; simply a good, healthy business.

* * *

THE NATIONAL MACHINE TOOL BUILDERS' CONVENTION.

The meeting of the National Machine Tool Builders' Association was held at the Hoffman House, New York, November 15 and 16. No action was taken at this meeting in regard to prices, although the subject was discussed in view of the advance in prices of materials entering into the construction of tools. The executive committee were empowered to call a special meeting of the Association to consider the matter further, if this should be deemed advisable before their next regular meeting. Another subject discussed was in regard to placing of large orders by dealers when tools are in good demand, with the possibility of cancellations when there is a drop in the market. It was thought best that no concerted action be taken in the matter, and resolutions were passed simply advocating that the placing of large stock be discouraged, each member, however, managing independently, according to his own personal interests.

In view of the differential tariffs that have been adopted by some foreign countries, particularly Russia, France and Canada, prejudicial to the importation of American machine tools, as a result of American duties on certain products imported from these countries, a committee was appointed to investigate the subject and report to the executive committee, so that a suitable plan of action could be outlined by them for the next meeting.

At the second afternoon session a step was taken which, it is hoped, may eventually lead to the adoption of standard specifications for motor equipments for machine tools. The session was opened by a paper by Fred A. Geier, of the Cincinnati Milling Machine Co. He contended that it would first be necessary to decide upon a standard speed range for variable-speed motors. In milling machine driving a speed range is required at the spindle of from 25 or 30 to 1. By using a motor with a $2\frac{1}{2}$ to 1 speed variation, and then applying double back gears to the machine, this range can be obtained without difficulty; and by using motors with shunt field control, such as are now supplied by electrical manufacturers generally, plenty of speeds can be obtained between gear speeds. The Ward Leonard Co. supply rheostats with from 35 to 120 steps for small motors.

The Cincinnati Milling Machine Co. have standardized the electric drive arrangement for their milling machines, and are prepared to supply them with any one of half a dozen different makes of direct-current, variable-speed shunt-wound motors with a $2\frac{1}{2}$ to 1 variation in speed. This does not completely end the trouble, however, because all of the motors differ in shape and size, so that special parts are necessary in adapting them to the machine. In order to manufacture motor drive parts for machine tools economically by making them up in lots for stock, motor frames must be standardized in the following respects: 1, size and shape of base; 2, distance from center of driving pulley to center of base; 3, height of motor from bottom of base to center of armature shaft; 4, diameter of armature shaft. The minimum speed of motor should be somewhere below 700 revolutions per minute, and a speed variation of $2\frac{1}{2}$, or at most 3 to 1, would meet the problem satisfactorily. While the advantages of such standardization are at once obvious for machine tool builders, it is believed that they would be as great from the standpoint of the electrical manufacturer, as they would enable him to enter into competition on an even basis with his competitors, and he would be able to make up these motors and carry them in large quantities. The combination of the reduced cost of motor and of tool would materially reduce the now almost prohibitive selling price of motor-driven tools.

At present prospective purchasers of electrically-driven machinery become much discouraged, and often drop the matter, when they find they must wait a long time for delivery. All this would be eliminated by standardization.

W. H. Powell, of the Bullock Electric Mfg. Co., outlined the leading methods of speed control now in vogue. He then stated that in all of these systems, and also where motors are operated at a standard speed, the size and weight of the motor are dependent to a great extent on the minimum speed at which the motor is required to develop its full rated power. The slower the minimum speed the greater will be the size and weight for a given horse power.

As a gear or chain drive is used on motors operating tools the maximum speed of the motor is dependent on the tooth speed of the motor pinion or chain constructed; or upon the maximum ratio of speed reduction between the driven shaft and the motor shaft. The maximum speed of the motor on most machine tools varies from 1,000 to 1,800 revolutions per minute. Assuming 1,500 revolutions as an average value for the maximum speed, Mr. Powell then went on to show how the output of a given size of motor frame and armature core varies with the different methods of speed control. He explained that of the different systems the multiple voltage system would give the greatest horsepower output for a certain size of frame and weight of machine, provided the speed range were the same with all the systems. The multiple-voltage system, however, requires a separate balancing set, and an increase in the number of transmission wires to the motors. There is therefore a demand for variable-speed motors operated on the two-wire system. For this system motors with special commutating poles or compensating coils have been placed on the market with a speed range as high as 6 to 1. A properly designed motor without these special parts can be operated through a speed range of 3 to 1 without undue heating at the lower speeds, and without sparking at the higher speed; but no matter what the design of motor or the method of speed control, the size and weight, and consequently the cost, are dependent on the slowest speed at which the motor is required to develop its full rated power. It is, therefore, desirable to keep the speed range down to a reasonable amount which in his judgment is 3 to 1, with a minimum speed of 400 to 660, depending on output of motor.

Other representatives of the association and of different electrical companies also made remarks, and finally a committee was appointed to confer with manufacturers of electric motors and submit recommendations as to standard mountings and dimensions at the next meeting, which is to be held at Washington, D. C.

A feature of the Machine Tool Builders' convention was the special train run by MACHINERY for members and their guests through the entire length of the Subway, luncheon being served on the train at 157th Street. There was a large attendance of machinery manufacturers and dealers on this train, more than twice as many being present as at any previous function for the Association.

A sheet containing an explanation of some of the important facts in regard to the Subway was distributed to the guests, and as these will be of interest to many readers, they are published herewith.

SUBWAY NOTES WORTH PRESERVING.

The general form of the subway is that of the letter Y, with the base at the southern extremity of Manhattan Island, and the fork at 103d Street and Broadway, one branch running up the western side of the city, and the other branch passing beneath the upper end of Central Park, thence in an easterly direction to the Borough of the Bronx.

The main downtown station is at Brooklyn Bridge, from which a single-track loop passes around under City Hall Park, where City Hall station is located.

At Astor Place is a station connecting with the new Wanamaker store, now building. This is destined to be one of the most important trade centers of the city.

At 14th Street is the first express station. At 23d Street the subway station is somewhat novel in that there is provision for underground stores with show windows. At 34th Street the subway goes lengthwise under the Park Avenue tunnel, through which the Madison Avenue surface cars run.

At 42nd Street is the next express station, connecting with the Grand Central Depot. The time required to reach the Grand Central from Brooklyn Bridge by an express train is about 8 minutes. Express trains run through to 96th Street.

At 42nd Street an abrupt turn is made, and the subway passes along 42nd Street to Broadway, thence uptown under Broadway.

At 96th Street (also at City Hall loop) where it has been necessary for the passenger tracks to cross, grade crossings have been avoided by having one track or set of tracks pass under the other at the intersecting points.

From about 125th Street to 133d Street the road emerges and passes over the Manhattan Viaduct. It then tunnels under a height of land to a depth of some 150 feet at the deepest point. Trains now run on this branch to 157th Street, and when the track extensions are completed they will go to Kingsbridge Station, a total distance of 13½ miles from Brooklyn Bridge.

Branch Lines.

The branch running from 103d Street to the Bronx has not been opened to the public, but is so far completed that trains will be run to 145th Street, Manhattan, on this line in about two weeks, and later they will run under the Harlem River to the Bronx. This part of the subway will be of particular interest. The tubes under the river are built up of cast iron segments covered with concrete, the interior diameter being 15 feet. The approaches to the river are of arched concrete construction.

The subway is also being extended south from City Hall Park under Broadway. This is known as the Brooklyn Extension, and will run to South Ferry, thence under the East River to Brooklyn, thence nearly to Prospect Park, connecting with the Long Island Railroad.

Construction.

From Brooklyn Bridge to 96th Street the line has four tracks, then three tracks to 145th Street. On the Bronx branch there are two tracks in the section now building. The Brooklyn extension will also be a two-track line. From Brooklyn Bridge to 96th Street, where the express service is given, the two inside tracks are for express trains, and the two local tracks for local trains. An interesting feature of certain of the local stations is that the grade of the local tracks is raised at the station above the level of the express tracks in order to obtain quick acceleration for the local trains in starting and at the same time maintain a level grade for the express service.

Concrete construction was extensively used in the subway. The typical structure, where the subway is near the surface, consists in a flat roof of concrete supported by I-beams and columns at frequent intervals between the tracks. The side walls are of concrete in which are laid vitrified conduits for the electric cables. This construction is modified according to requirements. In some cases concrete arches are used and in others reinforced concrete construction. To make the structure impervious to moisture, there has been laid beyond the side walls, under the floor, and over the roof a course of felt washed with hot asphalt. Where tunnelling at a considerable depth was necessary, concrete lining was generally employed.

The track construction is of the usual standard with broken stone ballast, timber cross ties, and 100-pound rails. It is to be noted that the third rail is protected by an overhead guard.

The subway stations were the pride of the city before they were disfigured by the advertising signs placed in them by the operating company. The color effects of the tiling, the varied designs of the different stations, the attractive ceilings, the light and spacious appearance of many of the stations, make them unusually attractive, and the intention was to so modify the decorative design as to enable one to recognize a station by its appearance as well as by the conspicuous signs erected at each station.

Power House.

The power house for operating the subway trains—the largest steam plant in the world—is on the west side of the city, between 58th and 59th Streets. The plant provides for a single row of large vertical engines and electric generators, aggregating 100,000 horse power at normal rating. A sectional scheme was adopted for the plant, each section comprising one chimney, twelve boilers, two engines with generators, condensing equipment, etc. Four of these sections are contemplated, and in addition a steam turbine outfit is in operation, consisting of three turbines of about 2,000 kilowatt capacity.

Cars.

The subway cars are a modification of the type that has been used on the elevated roads of New York City. These have the motorman's compartment located on the platform. The side of the compartment is formed by a door which can be placed in three positions: (1) to separate the cab from the rest of the platform, (2) to close the opening at the rear of the car, in which position it is placed on the rear platform of the train, and (3) swung back to enclose the controller, in which position it is left on all the platforms except the front and rear, so that the entire space is available for the ingress and egress of passengers.

The platforms have doors instead of gates arranged to slide into pockets in the side framing. The side walls of the cars incline inward slightly toward the top. The lower sashes of the windows are fixed to prevent passengers from injury by leaning out and coming in contact with the subway posts; the upper sashes, however, can be lowered.

A part of the rolling stock consists of steel cars designed to be fire- and "collision"-proof. The interior finish of these cars is largely of aluminum, and while it lacks the beauty of the mahogany finish of the wooden cars, this objection may be offset by the sense of safety felt by the passengers.

The motor equipment of the cars is unusual. A train of eight cars is equipped with motors aggregating 2,000 horse power, and in consequence a high degree of acceleration is obtained. The rate of energy absorption in starting these trains is not far from double that taken by the heaviest trains on steam roads when starting from stations. By the use of the multiple-unit system of electrical control, the motors on the several cars are operated from the controller at the front of the first car. In an eight-car train, the first, third, fifth, sixth and eighth cars will be motor cars, which arrangement enables the train to be shortened by uncoupling cars from the rear.

Lighting.

The subway is lighted independently of the current operating the trains. It is for this purpose that the steam turbines in the power station are employed. This arrangement was made in consequence of the accident in the subway of Paris in 1903, when, owing to a collision, the tunnel was in total darkness. The lamps in the subway itself are so shielded that their glare will not blind the motormen.

Signals.

The trains are protected by an electro-pneumatic block and interlocking system, which has been worked out to a degree of perfection probably not before attained. The plans for the operation of trains contemplate local trains at one-minute intervals, and express trains at two-minute intervals. This means that so many thousand people will be traveling in the subway with trains near together that it would not be safe to entrust their lives entirely to the motormen. The signals are there-

fore connected with pneumatic stop levers which rise beside the right-hand rail of each track when a signal is set against a train, and if the motorman should allow his train to pass the signal the current would be shut off automatically and the brakes applied. The length of blocks was determined by many careful experiments upon the length of track required for a train to stop with the brakes applied. Instead of the "home" and "distance" signals as usually employed on steam roads, the so-called overlap system of signaling is used, by which a train that has stopped is always protected by two home signals in the rear, indicating an absolute stop, and three caution signals in addition to the automatic stop at the second home signal at the rear of a train.

* * *

NOTES UPON BALANCING HIGH-SPEED MACHINERY.

In the article upon the shop methods of the De Laval Steam Turbine Company in the November number was an illustration of a machine for the accurate balancing of the rotary parts of turbines. Reference was made in the article to the so-called "critical speed" of bodies rotating with high velocity and the purpose of what is here written is to explain this and certain other points connected with the subject of balancing.

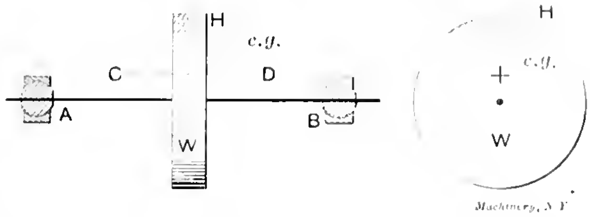


Fig. 1.

In Fig. 1 is a disk W mounted on a shaft A B turning in ball-and-socket bearings, as indicated. One side of this disk is supposed to have a dense section at H, making it heavier than the opposite side. The center of gravity of the wheel, therefore, will lie to one side of the shaft A B, say on the axis C D. Now if this shaft and disk be rotated, the centrifugal force generated by the heavier side will be greater than that generated by the lighter side diametrically opposite to it, and the shaft will deflect toward the heavy side, as in Fig. 2, causing the center of the disk to describe a small circle, indicated by the dotted line at a. To locate the point at which a weight should be added, or on the other hand, at which metal should be drilled out in order to bring the piece into balance, a piece of chalk is held so that the high side of the disk will just touch it as it comes around. The weight necessary to balance, to be told by trial, is then added opposite to the high side where the mark appears; or else, if the balancing is to be done by drilling, metal is removed on the same side with the mark. In the most accurate balancing it is advisable to use a steel point held rigidly, but which can be fed up gradually until the point makes a faint scratch on the edge of the disk.

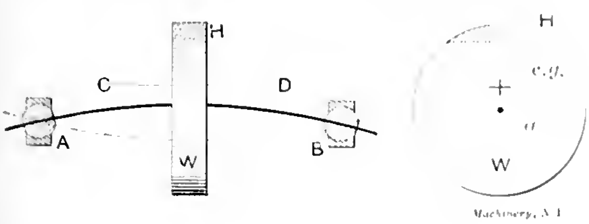

Fig. 2.

The foregoing conditions hold until a comparatively high speed is reached, depending upon the weight of the disk and flexibility of the shaft. A point will eventually be reached, however, at several thousand revolutions a minute, when there will momentarily be excessive vibration, and then the parts will run quietly again. The speed at which this occurs is called the critical speed of the wheel, and the phenomenon itself is called the settling of the wheel. The explanation is that at this speed the axis of rotation changes and the wheel and shaft, instead of rotating about their geometrical center, begin to rotate about an axis through their center of gravity, or about the axis C D in Fig. 1. This is illustrated in Fig. 3, where the wheel and shaft have taken a new position in which the axis C D, if extended, would pass through the centers of the two bearings, while the shaft is deflected so that it traces a circle shown by the dotted line b in Fig. 3. It is to be noted, however, that this circle is now on the H, or heavy, side of the disk instead of on the other side as before, so that now if one were trying to locate the point where weight should be added in order to balance the disk, he would find that the chalk mark came on the light side of the disk, and that the weight should be added on the same side.

Mr. Konrad Anderson says,* It is supposed that the settling of a rotating body occurs when the number of revolutions is equal to the number of vibrations which the shaft makes with the wheel mounted upon it. That is, a shaft and wheel have a

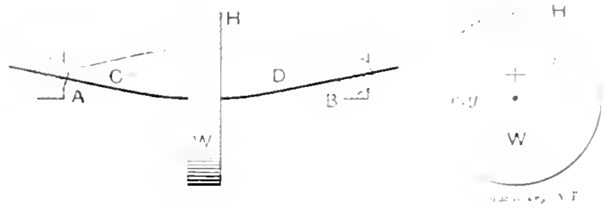

Fig. 3

certain time of vibration, just as does a pendulum or spring and when this synchronizes with the time of rotation the change is supposed to occur. In the De Laval turbine the flexible shaft and wheel are in such proportions that the settling takes place very quickly, and the critical speed is from 1-5 to 1-8 of the normal number of the revolutions of the wheel. Mr. Anderson gives the following empirical formula for determining the critical speed, in which C is a constant to be found by experiment for wheels and shafts, or other rotating parts of a certain design. Having determined the constant for one size he finds the formula to apply very nearly to every size of similar proportions.

n = critical speed.
P = force in pounds to bend shaft a certain distance.
Q = weight of turbine wheel.
C = constant.

$$n = C\sqrt{\frac{P}{Q}}$$

In referring to the subject of balancing, Francis Hodgkinson states† that "in the cases of heavier and bigger bodies, which would have a lower rotative speed, the marks do not come exactly on the light side. They may sometimes come as much as 90 degrees ahead of the light side. The exact angle can

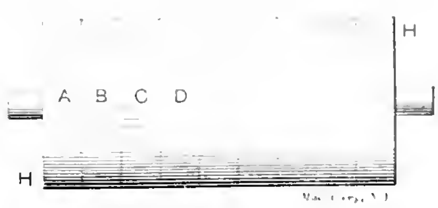

Fig. 4

only be found by experiment, and at best this is only a cut-and-try method. With experience, however, work may be put in very accurate balance."

In the illustrations thus far shown, the body to be balanced is represented as a disk supported by a flexible shaft. While it is only in special cases that the flexible shaft would be used, it serves to illustrate the principle of balancing better than if the shaft were rigid. If a disk were mounted on a rigid shaft and the rotative method of balance were to be applied, it would be necessary to support the shaft in bearings loosely connected to their pedestals, which would allow the shaft and disk to vibrate freely under the action of the forces generated.

In attempting to balance a cylinder, like Fig. 4, the heavy section is likely to come at or near one end, as shown at H, and there might, in fact, be another heavy spot diametrically opposite at the other end, as at H', so it is obviously better to divide the cylinder into a number of disks, A, B, C, D, etc., and balance each one separately. This is not always possible, however, as in the case of the running parts of electric

* Trans. Inst. Eng., Shipbuilders in Scotland, N...
† Proc. Eng. Soc., West Pa., Nov...

generators, for example, in which the winding is liable to throw it out of balance. The only way with such parts, which are usually of a cylindrical shape, is to mount them in loose bearings, as mentioned above, and run them up to speed by belt or other available means. There was published in MACHINERY for August, 1899, a description of an apparatus for this method

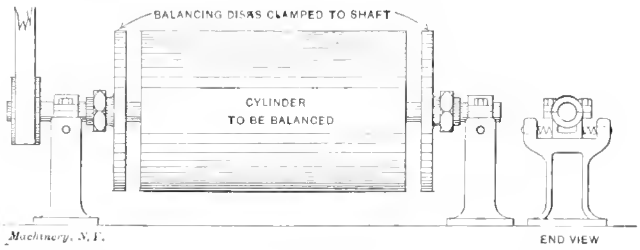

Fig. 5.

of balancing that has been used in balancing the cylinders of wool carding machines which run at a speed of about 1,000 revolutions a minute. The plan is illustrated in Fig. 5. The cylinder to be balanced is carried by a shaft supported by bearings loosely attached to their pedestals, and are preferably held to a slight extent by springs, although these were not used in the original design. On each end of the shaft is a carefully-balanced disk having a taper, split sleeve on which screws a taper nut, for the purpose of clamping the disk to the shaft in any desired angular position. Two diametrically opposite holes are drilled near the edge of each disk for the purpose of attaching balancing weights. When the cylinder is run at speed the end that is out of balance will throw out and is marked with a piece of chalk. The cylinder is then stopped and the disk at that end moved around until one of the holes comes opposite the mark, when a weight of what is thought to be the right size is attached and another trial is made. After repeated trials for each end of the cylinder the correct running balance is attained and then balance weights are made, weighing the same as those attached to the disks, and fastened to the cylinder in the same relative positions occupied by the weights on the disk. By this method there is no difficulty in applying the appropriate weight to the correct end of the cylinder.

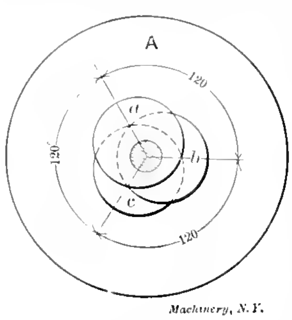

Fig. 6.

Some years ago William Sellers & Co., Inc., Philadelphia, conducted a series of tests upon an experimental steam turbine, similar in principle to the present Curtis turbine. As the disks rotated at very high speed, some convenient method of balancing was sought and the plan illustrated in Fig. 6 was originated. This will be the last to which reference will be made in the present article. In the figure *A* is the disk to be balanced and *a*, *b* and *c* are three thin disks turned up in the form of eccentrics and mounted on the shaft with the main disk. The bore of the eccentric was a close fit on the shaft, so there will be some frictional resistance between the eccentrics and the shaft; yet they were not so tight that it was necessary to drive them in place. The eccentrics were spaced 120 degrees apart and as the main disk attained its speed the eccentrics gradually shifted, automatically, until they reached such positions that apparently brought themselves, together with the disk and shaft, into perfect running balance. Just why the vibrations of the shaft were such as to cause this behavior of the eccentrics is a problem for the mathematicians to handle, but such is the fact, and we will leave it for others to explain.

* * *

F. B. Bristol, of the Bristol Co., Waterbury, Conn., was killed in an automobile accident on the evening of November 21. Mr. Bristol had been delayed at the works and wishing to gain time started for his home in his automobile at a high speed. He collided with a train while crossing the tracks at Platt's Crossing and was killed. Mr. Bristol was 45 years of age.

A LOST (?) INVENTION.

"Fame and fortune await the lucky individual who can rediscover the combination of metals from which the Egyptians, the Aztecs and the Incas of Peru made their tools and arms. Though each of these nations reached a high state of civilization, none of them ever discovered iron, in spite of the fact that the soil of all three countries was largely impregnated with it. Their substitute for it was a combination of metals which had the temper of steel. Despite the greatest efforts, the secret of this composition has baffled scientists and has become a lost art. The great explorer Humboldt tried to discover it from an analysis of a chisel found in an ancient Inca silver mine, but all that he could find out was that it appeared to be a combination of a small portion of tin with copper. This combination will not give the hardness of steel, so it is evident that tin and copper could not have been its only component parts. Whatever might have been the nature of the metallic combination, these ancient races were able so to prepare pure copper that it equaled in temper the finest steel produced at the present day by the most scientifically approved process. With their bronze and copper instruments they were able to quarry and shape the hardest known stones, such as granite and porphyry, and even cut emeralds and like substances. A rediscovery of this lost art would revolutionize many trades in which steel at present holds the monopoly. If copper could thus be tempered now its advantage over steel would be very great and it would no doubt be preferred to the latter in numerous industries. It is a curious fact that though this lost secret still baffles modern scientists it must have been discovered independently by the three races which made use of it so long ago."

The above item from a Sunday paper is an example of many such floating about which both reflect and impress an exaggerated sense of the importance of a so-called lost invention or art. The writer says: "A rediscovery of this lost art would revolutionize many trades in which steel at present holds the monopoly." Why would there be any revolution? Is any man sighing for a copper razor, or does any boy want a brass jack-knife blade? There is no evidence to prove that the tempered copper tools of the ancients were capable of holding a keen edge like steel; on the contrary they were probably very crude and unsatisfactory substitutes for what we now have. As a matter of fact there is no difficulty in making hard alloys. The United States Government Board, appointed twenty-five years ago to test iron, steel and other metals, reported through their chairman, Prof. R. H. Thurston, in that portion relating to copper-tin alloys that alloys of copper 72.89, tin 26.85, tin 29.88, copper 68.58, tin 31.26; copper 67.87, tin 32.10; and copper 65.34, tin 34.47 were all so hard that they could not be turned in a lathe with steel tools. These and other hard combinations have been generally known to the trade for years, but of what good are they? Copper and its alloys are more costly than the ordinary grades of tool steel, and the only apparent advantage possessed is that they are incorrodible. It is difficult to understand that this would be the cause for any revolutionary change, and we are forced to the conclusion that such statements are what, in current slang, is known as "hot air."

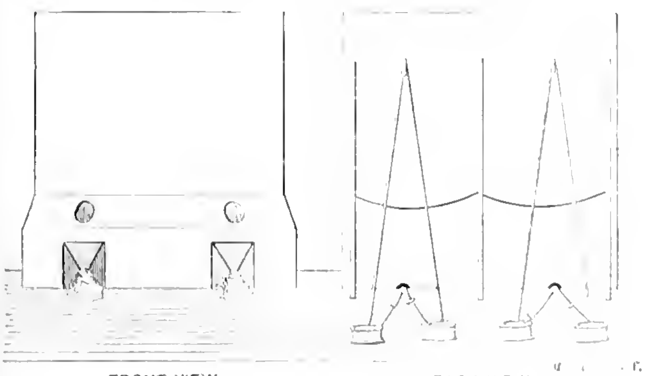
* * *

In common with other affairs of life some of the most simple and apparently obvious facts of steam engineering have only been learned after long experience and endeavor in a contrary direction to natural laws. Years ago before the days of the distillers on board ship for supplying fresh water to the boilers it was the practice in the United States Navy to use salt water for the "make-up," *i. e.*, to supply the water lost by leakage and other wastes. The rule was never to allow the salinity of the boiler water to exceed 1½ per cent of saturation. But, of course, it happened more than once that this rule had to be broken on account of leaky boilers, stress of weather or other reasons which make it impossible or unsafe to blow off and replace with sea water. Under such circumstances the surprising result was always noted that the scale deposits were more friable and easily broken loose from the sheets and tubes so that cleaning the boilers was an easier task than when the salinity had been kept down to the prescribed percentage. The reason, of course, was that when the salinity was kept at a low percentage more sea water had to be pumped into the boilers which introduced more lime and other scale-making properties. The lime being thrown down at once, formed a hard insoluble scale that could be removed only with difficulty. With less seawater introduced less lime was deposited, hence known as "hot air."

IRON AND ITS EARLY MANUFACTURE IN ENGLAND.

A. R. BELL.

That iron was first worked by the Phœnicians is only a probable conjecture, but they were, we are told, skilled in metallic ores, and proofs remain of their having worked the tin mines in Cornwall. There is every evidence, however, that iron was worked in England during the time it was occupied by the Romans, and during the Danish settlement in England the art of manufacturing iron was much improved. It appears malleable iron was made during that period in a footblast furnace, Fig. 1, the simplicity of which is interesting, showing what may be effected by very limited means. The excellent quality of the iron turned out from these rude furnaces compares favorably with that now supplied by the great iron works possessing huge capital and extensive laboratories, for when the art was but little advanced the most tractable ores were selected and charcoal was invariably used as fuel, circumstances which in themselves are sufficient to account for the iron being of high quality. Each furnace measured about 8 by 16 inches at its mouth, and was about 3 feet deep, terminating in the form of a funnel over a shallow pit inclining outward. The furnaces were constructed in a bed of clay about 3 feet high and 3 feet wide, against which a light wall about 10 feet in height was raised to protect the bellows and the furnaceman located immediately behind. Each bellows consisted of a circular rim of wood about 6 inches in diameter and nearly 2 inches high,



FRONT VIEW BACK VIEW

Fig. 1. An Early Form of Foot Blast Furnace.

fixed on a clay floor and covered with cowhide, with a hole in the center to admit air and to receive a cross stick fastened by a cord to an elastic stick above. Each pair of bellows was worked by a boy, who rested his back against a rope for the purpose of support and stepped alternately from the orifice of one bellows on to that of the other, at each step forcing a blast of air into the furnace through a tube of bamboo. The furnaces were charged with a mixture of charcoal and iron ore broken into small pieces. The fires were kept as strong as possible until the ore was reduced and the fused metal collected in a cake on the ash-pit.

At the time when separating the metal by footblasts was in vogue, the art of casting iron was unknown, or at least not practiced, but in the sixteenth century blast furnaces were of a sufficient size to produce, with ores and the charcoal of wood, from two to three tons of pig iron per day. This output, however, was only attained in suitable situations and where water power was available, while the greater part of the ore was made into bar iron in a refinery; at the smaller works it was made malleable before being withdrawn from the furnace. When wood became scarce, pit coal was substituted for making pig iron. Mr. Simon Sturtevant in 1512 had a patent granted him for this purpose, but the process proved to be unsuccessful. It is strange that although pit coal was known long before this period and large quantities were shipped to Holland and Belgium, where it was used in the smith's forge and in other manufactures, yet in England the prejudice against its use in the manufacture of cast iron was so keen that when it was first proposed every obstacle that could be devised was brought in its way, consequently none of the adventurers who attempted to use it were successful. In 1619 Captain Buck, Major Wildman, and others constructed air furnaces in the Forest of Dean, in which they placed large clay pots for containing the requisite preparations of ore and charcoal, the flame of pit coal being employed for heating the furnaces. It was expected that by tapping the pots below, the separated metal would flow out, but it was found that the heat was not sufficiently intense to produce an entire separation of the metal, the pots cracked, and the work was abandoned. At this time the price of iron was advancing in consequence of many of the iron works having stopped for want of fuel, and those who were able to obtain supplies of

Fig. 2. Early Form of Coke Oven, Beehive Pattern

wood were making high profits from the manufacture. Dudley in his "Metallum Martis" states that his father and himself had smelted iron with coke in large quantity, but that Oliver Cromwell and several of his favorites, who wished to become partners and were refused, ruined the establishment. The brittle quality of English bar iron, made from coke at this period, and the great expense of that which was made from charcoal, owing to the increasing scarcity of wood, were most likely the causes of the great decline in the home manufacture which then took place, and importations from Russia and Sweden were made on a large scale. Later the steam engine afforded the British manufacture a means of renewing the industry; the small furnaces supplied with air from bellows

Fig. 3

worked by oxen, horses or men were given up, and larger furnaces were introduced with blowing machines to make an increase of the column of air and effect a more complete combustion. Experience also proved that the produce of the furnace could be increased by enlarging the diameter of the steam cylinder and rendering the vacuum therein more perfect.

The making of coke was performed on a rectangular-shaped hearth prepared by beating the earth to a firm flat surface and padding it over with clay. On this the pieces of coal were piled inclining one to another, those of the lowest layer being set so as to touch the hearth with the smallest surface. The piles were usually from 30 to 50 inches high and from 9 to 16 feet square, and contained from 40 to 100 tons of coal. Vents were left reaching from top to bottom into which burning fuel was thrown, and were afterward closed by pieces of coal driven firmly in; thus the kindled fire was forced to creep along the bottom and eventually burst out at the sides. If the coal contained pyrites the combustion was allowed to continue after the smoke had disappeared to extract the sulphur. The fire generally lived from 60 to 70 hours, but the coke was not removed for at least 12 and sometimes 14 days. The annoyance attending this process by the evolution of the immense quantities of smoke and the tremendous waste of volatile products induced Lord Dundonald in 1781 to improve the system, and he introduced what were known as tar works. The ironmasters sent the raw coal to the tar works and received in return coke, the "tar works" being compensated for their trouble by retaining the valuable commercial products, tar-pitch, varnish and ammonia. Coke kilns, or ovens, were first introduced near Sheffield about 1840. They were hemispherical or beehive in shape (see Fig. 2), about 10 feet in diameter at the base and about 2 feet at the crown with a circular opening at the top for introducing the coal, and once heated, were allowed to burn day and night without interruption. The method of charging a coke oven was as follows: Sufficient small coal was thrown in at the top

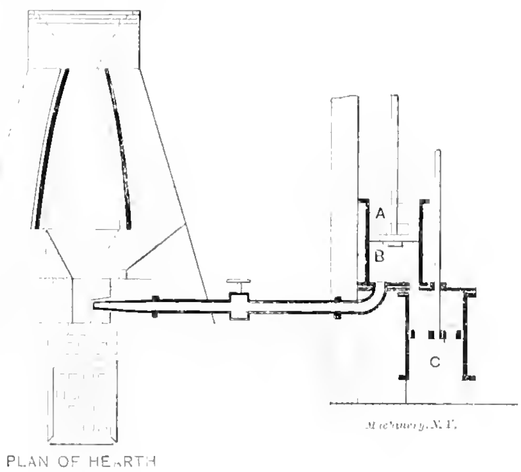


Fig. 4

to fill the oven up to the springing of the arch. It was then leveled with a rake, and the doorway at the side filled with loose bricks. The heat acquired by the oven from its previous charge was sufficient to light up the new one, the combustion being accelerated by the air finding its way through the joints of the blocks in the doorway. In a few hours the combustion reached such a height that it was necessary to reduce the influx of air, and the doorway was therefore plastered up with wet mud and sand, leaving only the top row of bricks loose for the inlet of air. After twenty-four hours of burning this inlet was also closed, and only the chimney remained open until the flame was dead, when a few loose stones were laid over the aperture at the top, and covered up with a thick bed of mud. All was then air-tight and was allowed to remain in that condition for about twelve hours to complete the operation, after which the doorway was opened and the coke raked into iron barrows for its removal.

The process of roasting iron previous to smelting in a furnace, seems to have been introduced mainly by Mr. Teague, of Calford, Gloucestershire. He took out a patent in 1832 for smelting iron, in which he proposed to economize by roasting the ore, and instead of the calcination being a distinct process, he combined the operations of roasting and smelting. For this purpose he constructed around the chimney shaft near the top a series of four small reverberatory furnaces, each provided with a damper at the top, and a lateral door which opened outward. Through these doors the ores to be roasted were introduced on to iron plates, which formed the bottom surface. The ascending flames from the smelting furnace were prevented from passing out vertically, as usual, by means of a trap door, *A*, as shown in sketch, Fig. 3, this causing the hot gases to pass through the oven and impinge on the ore, thus depriving it of its volatile combinations. When the ores were sufficiently operated upon they were thrust forward into the smelting furnace, and while the roasting furnaces were being recharged, the trap door,

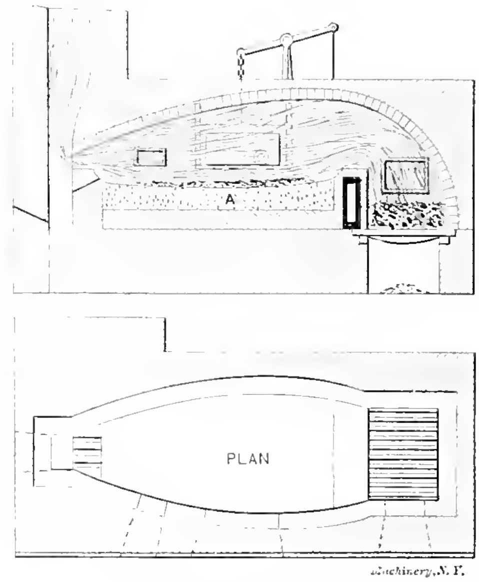

Fig. 6.

A, was open to the shaft so that the flames might ascend directly by it. An early form of smelting furnace introduced by Mr. David Mushet is shown in Fig. 4, the external form being that of a truncated pyramid. This type of furnace differs in no essential details from the present-day one, excepting in the blowing machinery. The regulating cylinder shown at *A* was about 8 feet in diameter, and the floating piston, *B*, was loaded with weights varying according to the power of the blowing engine. The blowing cylinder, *C*, was about 6 feet in diameter and 7 feet stroke. The following leading dimensions of the furnace will be of interest: The hearth was about 2 feet square at the top of the boshes, the furnace was about 12 feet in diameter and about 8 feet high. The top of the furnace was about 3 feet in diameter, and the internal cavity of the furnace from the top of the boshes was about 30 feet high. The plan of the foundation, built of stones and bedding sand, is shown. To start the furnace loose fuel was thrown in at the bottom and a few baskets of coke introduced to become thoroughly ignited; the cavity was then gradually filled. The first charge received but a small portion of iron-stone compared with the weight of coke,

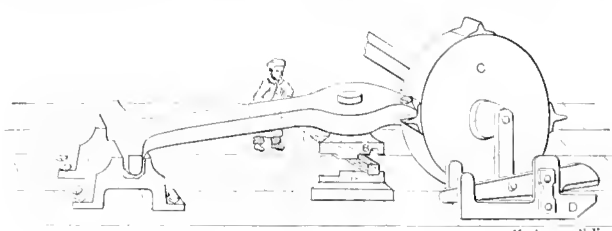

Fig. 7.

but after a few days the iron-stone was gradually increased in proportion, and when once started these furnaces were allowed to burn for several years. For smelting by means of anthracite coal, Mr. Mallin invented the furnace shown in Fig. 5. For his experiments he used a hearth of only 11 inches in diameter at the tuyeres, the blast being introduced as represented in the plan. He found that the blast required to work the furnace had to be under a pressure of at least 2½ pounds to the circular inch, and the quantity of air required for an ordinary furnace would not be less than 28,000 cubic feet per minute. At one time the prejudice against the use of anthracite was very strong, and it was used for a long

time in parlor and kitchen grates before it gained the attention of iron masters. The first attempt of puddling iron for depriving it of carbon and oxygen to render it malleable, was carried out in a furnace illustrated by Fig. 6. At *A* a basin of sea sand was spread in a concave shape supported by bricks on solid masonry, and on this bed of sand the metal was placed and exposed to the heat of the flames. The amount of air was regulated by dampers.

In Fig. 7 is shown an early form of shingling or blooming hammer, consisting of an anvil, *A*, with its block. On to this the shingler drew out of the furnace a stout flat bar, the end of which was brought to welding heat, and laid on the ball under the hammer, *B*, where they were welded and formed into one piece. The shingler was then enabled to turn the ball about upon the anvil, and meet every blow of the hammer, while the drum, on which were fixed four wipers or cogs, revolved, causing the hammer to be lifted, and then allowing it to fall by its own weight. The face of the hammer, it will be noticed, was not flat, but had channels and projections, and placing the bloom under these projections cross ways caused it to extend, or if placed in the other direction its breadth was increased. Attached to the crank at the side of the drum, was a pair of shears, as shown at *D*, used for cutting off the rough edges on the blooms. It sometimes happened through mismanagement on the part of the puddler that the bloom was not sufficiently freed from impurities for treatment under the hammer, and its indisposition was shown by a hissing or bubbling. It was then thrust back to the puddler, and he had to pay a fine for his carelessness in drawing it out of the furnace too early.

NORMAN G. MEADE.

Norman G. Meade.

The most economical method of repairing electrical machinery in a manufacturing establishment, or electric railway plant, is a subject that should command the attention of the superintendent and electrician. The exorbitant charges of electrical repair concerns and the unnecessary delay in transportation of apparatus make it a practical necessity for companies of any magnitude to do their own repairing. In the present article a few suggestions are given for re-filling commutators. As the commutator is the part of a direct-current machine that is subjected to the greatest wear, its re-filling constitutes a large portion of the repairman's work.

It is always advisable, when possible, to purchase hard drawn copper strips, drawn to gage, and cut them to required lengths. Old commutators are frequently so far out of date that standard sizes of segments will not do. A very good commutator can be made from a copper casting, similar in shape to the assembled commutator, that is, cylindrical in form and enough larger than the original commutator to allow for finishing, Fig. 1. Large castings may be cored out at ends, *a* and *a'*, for collars, thus saving some stock and considerable labor, as it is then only necessary to make a finishing cut after segments are assembled. Bore out the rough casting and drive it on an arbor and place in "centers" of a milling machine. Use a 1-16 inch saw about four or five inches in diameter. Cut as many slots in the casting as there are to be segments, *b*, Fig. 2. By using an indexed head this is a very simple process. Cut the slots to within about 1-8 inch of through, as shown at *c*. The slots for armature leads should be cut in after the commutator is assembled and turned. Now, drive out arbor and catch casting in a vise and finish cutting through the slots with a hack-saw. Two blades put in the frame at the same time will make a cut about equal in width to that made by the saw in milling machine. File off any burrs that remain on segments and drill a hole in each one on flanged portion *a*, Fig. 3, in diameter about twice the width of slot cut for lead wires, and a little deeper. This hole aids greatly in soldering in armature leads, as the solder flows at once to the bottom of slot. The insulation between the segments should be micanite about 1-32 inch in thickness. As the segments are sawed up by a 1-16 inch saw, the rough casting must be made large enough to allow for the difference.

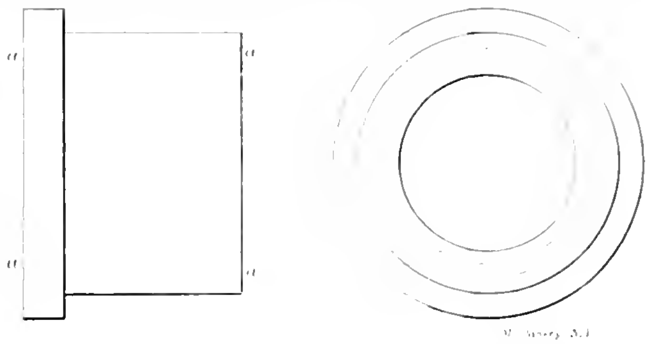

Fig. 1

For instance, in sawing up a casting into 32 segments, two inches of the circumference would be wasted. Using 1-32 inch micanite would make up for one inch only, so that the rough casting must be one inch greater in circumference—over and above the stock allowed for finishing—than the original size of the old commutator.

The next step is to assemble the segments in a suitable clamp, as shown in Fig. 4. This is a cast-iron split ring, the two parts, *c* and *c'*, being held together by bolts *d* and *d'*. A plan of section *c* is shown; *a* and *a'* are dowel pins, and *b* and *b'* are clearance holes for bolts *d* and *d'*. Great care must be taken in assembling the segments to have them all straight, that is, parallel with the axis of the commutator. Now, chuck the clamp, with the segments, in the lathe, and bore out the center to required diameter, then bore out the ends to correspond with the old commutator. A templet of tin made to fit the end bore of the old commutator is very convenient for gaging the new one.

It is more economical to make several commutators at one time, so that a temporary shaft, with collars and clamping nuts, should be provided. Such an arrangement is shown in Fig. 5, *d* being a short length of cold-rolled steel threaded at *c* and *c'*; *a* and *a'* collars bored out to slip over shaft, and *b* and *b'* clamping nuts. The temporary shaft should be firmly secured to the newly-bored segments before removing the clamping ring. This done, the ring may be removed and the new commutator will be ready for turning, as shown in section at *c* and *c'*, Fig. 5.

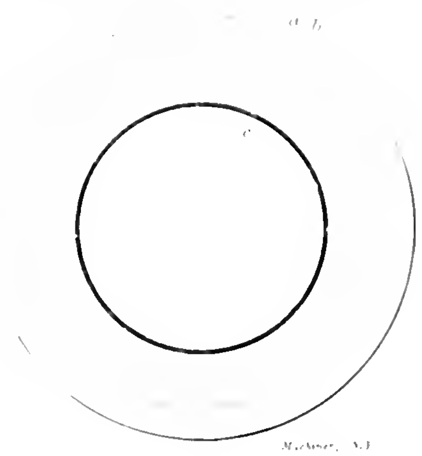

Fig. 2

Before turning, the commutator should be heated until the shellac oozes from the micanite, then placed on end on a surface-plate with a hole for shaft to extend through. This plate is shown at *d*, Fig. 6.

Place a try-square on the plate and sight along the blade

NORMAN G. MEADE was born in Philadelphia in 1876. He has worked for the McIntosh & Seymour Co., the Auburn Light, Heat and Power Co., and the Hamilton-Corliss Engine Works in the capacity of electrician. His specialty is electrical engineering and electrical equipment of manufacturing plants.

to see that the edge of one of the segments coincides with it, as at *b* or *c*. If not, by using a small cold-chisel and hammer, drive the segment one way or the other until plumb. Go all around the commutator in this manner. After straightening all the segments, tighten up the clamping nuts again and allow the shellac to dry. After the finishing cut is taken, the com-

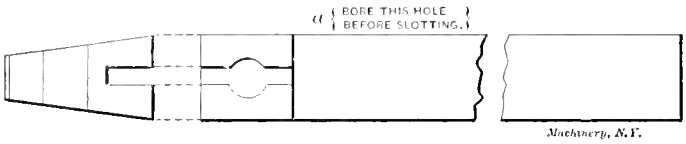

Fig. 3.

mutator should be returned to the milling machine and the slots cut for lead wires, as shown at *a*, Fig. 2. When all burrs have been removed, we are ready to put on the retaining band, which firmly holds the segments in place until used.

Fig. 7 shows a method of putting on the band. The segments, *a*, are placed between lathe centers, and a heavy piece of manila paper is wrapped around them, as shown at *e*.

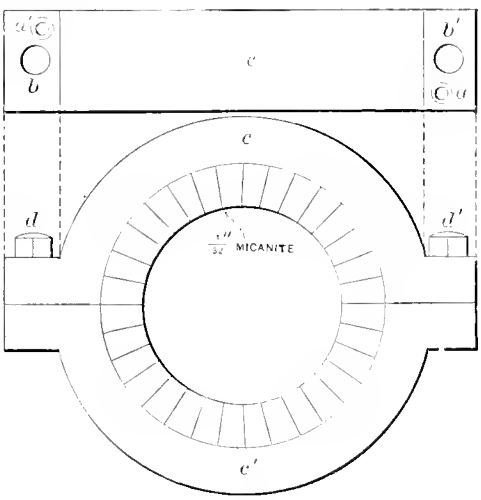

Fig. 4.

This is held in place temporarily by a cord, which also serves to hold in place a piece of 1-32 inch brass, *b*. Now cut two fiber friction blocks, *f* and *f'*, to fit in the toolpost, bore a hole and insert a pin in each, *g* and *g'*, to keep the blocks in place. Any amount of tension can be placed on the blocks by the clamping screw *n*.

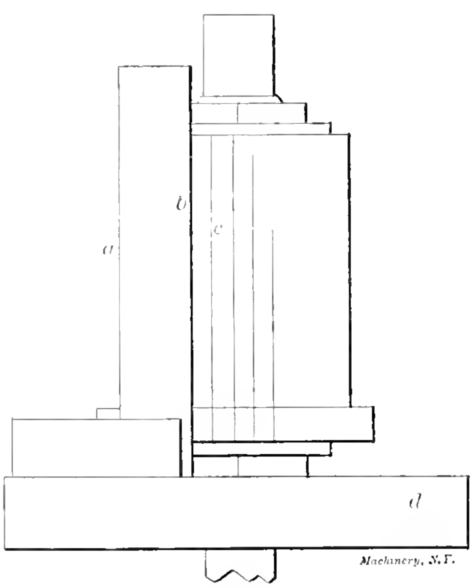

Fig. 6.

Take the end of a coil of No. 16 brass wire, and pass it between friction blocks, *f* and *f'*, and catch it in one of the slots, as at *c*. Turn the assembled segments two or three revolutions until the wire is brought over the paper *e*, then cover about one-half the length of the segments closely and very tight. When the desired amount of wire has been wound on, turn the ends *i* and *i'* of the brass strip *b* over on wire, and hammer down, bringing the turn *h* close up to the band. Flow solder over the band with an iron and cut off the ends of wire. The commutator may then be removed from temporary clamping device, when it will have the appearance shown in

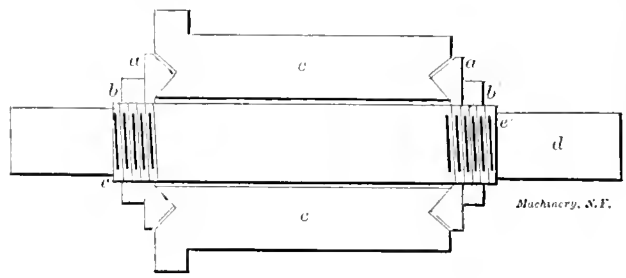

Fig. 5.

Fig. 8. A temporary clamping device, the clamping ring, and templets, can be used indefinitely. One clamping ring can be used for several sizes of commutators by using split bushings.

When removing old segments from a commutator, care should be taken to keep the molded mica insulation on the ends intact. If this is broken it can be replaced by canvas

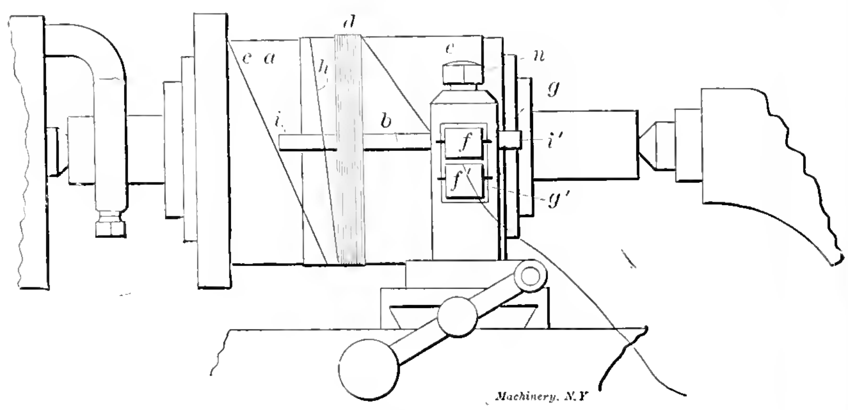

Fig. 7.

disks, shown in Fig. 9, made up of several pieces shellaced together to obtain a thickness equal to the molded mica. Place the old commutator sleeve, with the rear collar attached, end down on a bench and slip the canvas disk over sleeve to bottom. A hole in the disk should fit tightly over the sleeve, and the outside diameter be about one inch greater than that of

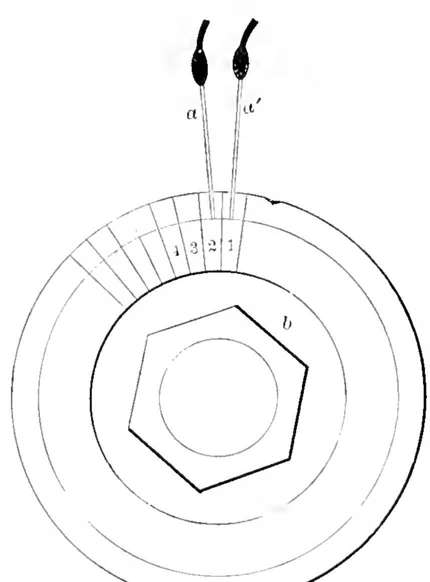

Fig. 14.

the commutator. A thin sheet of flexible micanite must be wrapped around the commutator sleeve, to insulate it from the inside of segments. After placing the assembled segments *b*, over the sleeve, slip on the upper canvas disk *a*, Fig. 10, then collar *b*, finally tightening up nut *c*. Canvas disks should be put in with shellac, wet. After screwing up the nut firmly,

allow all dampness to dry out thoroughly. The canvas disks will then protrude between collars and segments as shown at *a*, Fig. 11. Trim off smoothly, giving a finished appearance like *a* in Fig. 12.

The completed commutator is now ready for testing. A very convenient and fairly accurate method is shown diagrammatically in Fig. 13. A sixteen candle-power incandescent lamp is connected in series with the mains, and two flexible cords with solid copper tips, *b* and *b'*. Fig. 14 shows the application of the testing arrangement. The copper tips, *a* and *a'*, are placed on adjoining segments, as at 1 and 2. If there is a short-circuit, the lamp will light. Test each segment in turn in this manner. Then, by placing one of the tips on the end of the collar, as at *b*, and touching the other to each segment in turn, any leakage from segments to core will be found. If no leak is found the commutator is ready for use.

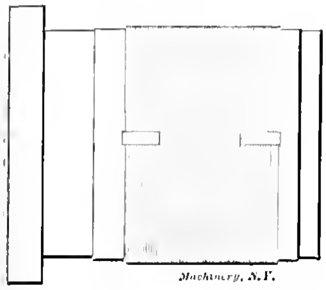

Fig. 8.

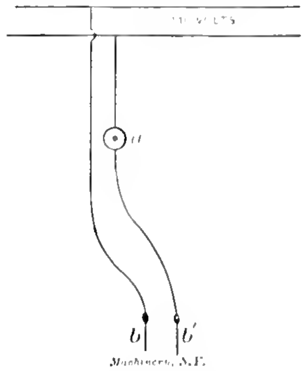

Fig 13

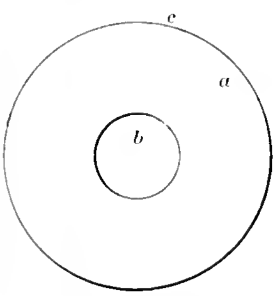

Fig. 9.

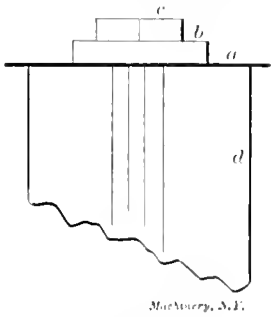

Fig. 10.

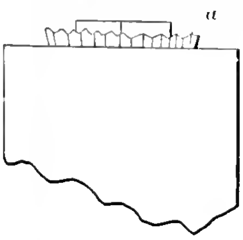

Fig. 11

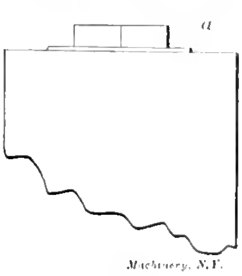

Fig. 12

If a leak or short-circuit appears, the trouble must be located and remedied before using.

Small copper chips wedged in the micanite by the turning-tool often cause a short-circuit between segments. A careful inspection inside and out after turning, will generally disclose any such defect.

* * *

THE SLIDE RULE—POSITION OF THE DECIMAL POINT.

S. E. WOODBURY.

The following method of locating the position of the decimal point in the result of multiplication or division when using the ordinary slide rule is submitted as being very much easier to learn and use than the several methods usually presented in the instruction books.

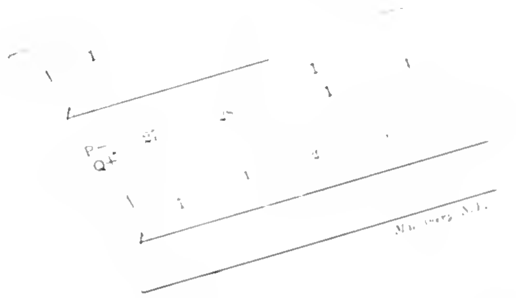
In the bottom of the groove under the slide at the left-hand end of the slide rule may be written the characters $\frac{P-}{Q+}$ (see cut). A clew to the method of using these marks is suggested by the fact that they are sometimes covered by the slide.

Assume the rule—The number of digits in a product is equal to the sum of the digits of the factors; and, the number of digits in a quotient is equal to the number of digits in the dividend less the number of digits in the divisor. This rule is true when the result is obtained with the slide projecting to the left, covering the characters $\frac{P-}{Q+}$

When the result is obtained with the slide projecting to the right, the number of digits in the result is corrected according to the indication of the characters, which are then visible. If the result is a *product* the number of digits is equal to the number obtained by the rule above given *less* one, as is indicated by *P*—. If the result is a *quotient* the number of digits is equal to the number obtained by the rule above given *plus* one, as is indicated by *Q*+. Since the correction is always one it is not included in the characters. This method is best used with the *C* and *D* scales; but can be used as well with the *A* and *B* scales after it is once understood.

If the same characters are written in the right-hand end of the groove, prefixed by *I* (signifying inverted slide), thus $I\frac{P-}{Q+}$ the decimal point in calculations effected with the inverted slide can be located equally as well.

Below are given examples in the four cases, more fully illustrating the use of the method. A little practice will



quickly reduce the operation to a simple mental calculation of scarcely any additional effort, besides reading the results from the scales.

Note.—In dealing with decimal quantities, the number of negative digits equals the number of zeros after the decimal point.

Multiplication.		Division.	
33.2 × .515 = 17.1		13.2 ÷ 30.4 = .434	
Digits in 33.2..........	+ 2	Digits in 13.2........	+ 2
Digits in .515..........	0	Digits in 30.4.........	+ 2

* * *

To harden and temper large fluted reamers with the appliances afforded by the average shop is trying enough by daylight, but when it must be done at night the combination of adverse conditions would ordinarily appal the average toolmaker. At night it is useless to attempt drawing the temper by the color, hence the resort to a fusible alloy to denote the proper heat for the desired temper. A toolmaker tells how he tempered a large reamer after dark for a rush job in a shipyard. After hardening the reamer, he heated it throughout until it would just melt an alloy made of equal parts of tin and lead. The temperature at which this melts corresponds closely to a straw color. Large tools should have the temper drawn at once after hardening, in order to relieve the internal strains; otherwise they are liable to crack.

TOOLMAKING.—12.

FORMING TOOLS AND MILLING MACHINE CUTTERS.

E. R. MARKHAM.

Forming tools are used when a number of pieces of exactly the same shape are to be made. They are extensively used on screw machine and similar work where it is desirable to duplicate a given shape, and are very valuable for giving the desired shape to tools of irregular contour when duplication of form is desirable. Forming tools are made either flat or circular, as seems best, or as the work to be done requires. When used for giving tools the required shape in the lathe or planer they are ordinarily made flat; if they are for backing off formed milling machine cutter teeth they are always made flat; when used on screw machines for giving a desired shape to the work they are made either flat or circular, although the latter form is more common.

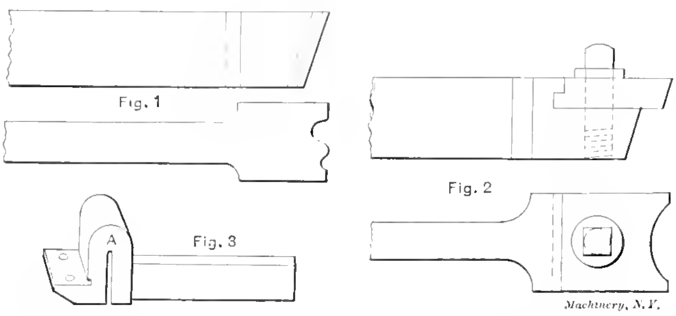

Fig. 1 Fig. 2 Fig. 3

Machinery, N.Y.

Flat forming tools are made solid; the tool and shank may be one piece, as shown in Fig. 1, or the cutter and shank may be made separate, as shown in Fig. 2. If but one forming tool is to be made, make the solid tool; but if many tools are to be made it is much cheaper to make a shank, as shown in Fig. 2, and separable cutters for the different jobs.

To reduce the tendency to chatter when heavy cuts are taken it is sometimes advisable to make a spring holder, as shown in Fig. 3. When tools of this character are subjected to heavy cuts they yield somewhat, thus producing a smooth cut. To give the spring portion, *A*, a spring temper it is necessary to make this holder of tool steel. The blades must of course be made of tool steel and may be planed up in long strips and cut to the desired lengths. The character of the work must in a measure determine the carbon of the steel used in the blades. For the general run of work, however, steel containing 1¼ per cent. carbon will be found satisfactory; if the facilities for hardening are such that the heats can be graduated very carefully it is safe to use steel of a higher temper than that mentioned.

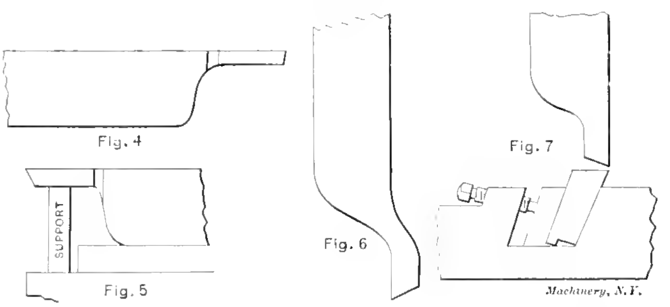

Fig. 4 Fig. 5 Fig. 6 Fig. 7

Machinery, N.Y.

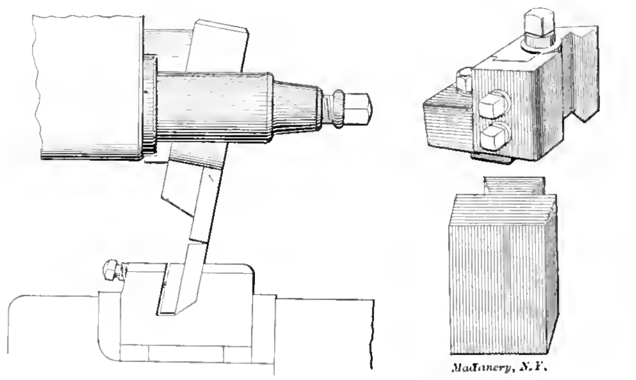
When tools of the description shown in Fig. 1 are made it is often customary to make the portion which is to receive the shape or form like that shown in Fig. 4 in order to save labor when making the form on end. This works very nicely when light cuts are taken with the tool, or if the cutting surface of the tool is not too great; but for heavy cuts the tool will chatter unless supported as shown in Fig. 5.

When very smooth surfaces are desired it will be found necessary to run the stock slower than when cutting with tools of other form. Forming tools to be used in the shaper or planer, and where a smooth surface is desirable, may be made as shown in Fig. 6. These are known as spring tools, and irregular surfaces such as occur on the faces of bending dies and similar tools may be produced with these spring tools very quickly and very smoothly. This form of tool also works nicely when applied to other than forming tools, as cut-off tools, smoothing tools for flat surfaces, etc., for use in the shaper and planer.

In the making of solid flat forming tools extreme care should be exercised in the operation of forging. Tools of this class are subjected to great strain, and in order to insure satisfactory results should never be overheated, and should be hammered in a manner that makes them the strongest possible. After forging, the tool should be carefully annealed, as this operation insures best results when the tool is hardened.

The bottom (or base), the portion on which the tool rests, should be perfectly aligned by milling, planing, or if possible, by grinding; otherwise it would not be possible to produce the same form at different seatings. The top of the tool blank should be machined flat, and parallel to the surface it rests on, after which the form should be laid out, using a templet for this purpose.

The method used in working the desired form in the face of the tool depends on circumstances. If many tools of a given form are required, or if many pieces are to be made with a tool which would necessitate grinding it several times, a method must be used that insures uniformity of shape the entire vertical length of the face of the tool. If the tool is to be used but a little the desired form may be produced by filing; but as it would be almost impossible to file an irregular shape that would maintain its form the entire length of the face, each time the tool was ground, the shape of the pieces machined would change with each grinding.



Machinery, N.Y.

Fig. 8 Fig. 9.

The tool may be held at the desired angle in the vise of the planer, shaper, or milling machine, if the form is to be produced by machining. The usual practice is to have a fixture which holds the work at the desired angle of clearance. According to the writer's experience forming tools to be used for the general run of work should be given a clearance of 10 to 15 degrees, that is the included angle to the top of the tool should be from 80 to 75 degrees. However, if the tool is to be used for backing off the teeth of formed milling machine cutters, it is necessary to give a clearance of 18 to 22 degrees.

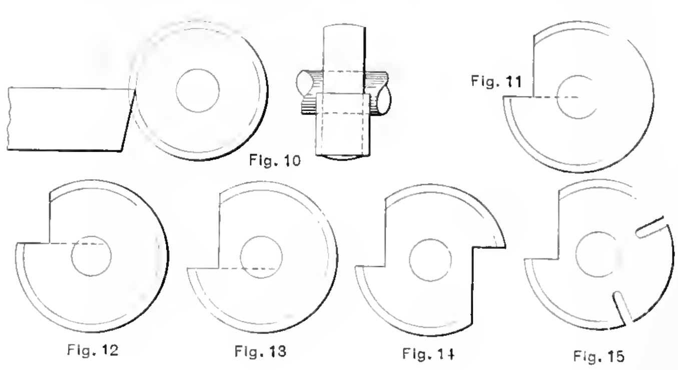


Fig. 10 Fig. 11 Fig. 12 Fig. 13 Fig. 14 Fig. 15

Machinery, N.Y.

It will be apparent that tipping the tool in the vise, as described, prevents duplicating the shape of the master tool, if that is held in a vertical position in the toolpost of the

shaper or planer, as shown in Fig. 7. To overcome this difficulty the master tool may be made enough different in shape to produce the desired shape; or the tool may be held in the toolpost, or in a special holder, at the same angle as the blank, as shown in Fig. 8, and it will produce a shape corresponding very closely with its own.

When forming tools are used continually, the form shown in Fig. 9 is considered in most shops the most satisfactory. The cutters are made separable, and held in the holder at the desired angle. As the cutters are held very rigidly extremely heavy cuts can be taken without the tool slipping or chattering. This tool recommends itself where the same form is to be duplicated right along, as the cutters are very easily and cheaply produced after the master cutters have been made. The shape may be worked in the face of the tool either by milling or planing; the former method is, generally speaking, the more satisfactory.

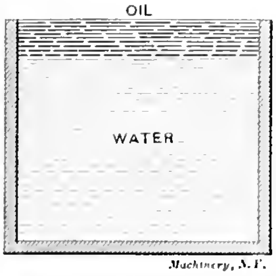

Fig. 16.

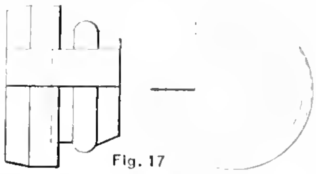

Fig. 17

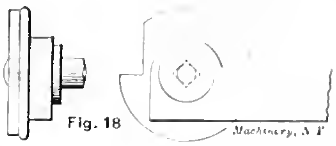

Fig. 18

Circular Forming Tools.

Circular forming tools are used very extensively on screw machine and similar work. They commend themselves on account of the ease with which any number of them may be produced, provided a master tool is used in producing the shape, as shown in Fig. 10. If the master tool is properly made, and does not project very far from the toolpost, it should produce a very smooth surface, provided the cutter blank is held on a short mandrel and is run extremely slow for the finishing cut. If the exact shape is not essential it may be given a very smooth finish by polishing with fine emery and oil on a soft pine block. This practice, while common, should never be resorted to when accuracy in contour is essential.

To provide a cutting edge the tool is milled as shown in Fig. 11. It is necessary to have the cutting surface radial as shown, if we desire to duplicate the exact shape of cutter. If the cutting edge is above the center, as shown in Fig. 12, the tool will not cut; if below the center, as shown in Fig. 13, it will cut very nicely but will not produce a correct shape. In many shops it is considered advisable to make the cut, as shown in Fig. 13, to insure rapid cutting, the form of the tool being somewhat different, to compensate for this. Before hardening, the name or the number of the tool is stamped on it. It is customary in some shops to mill two cutting edges, as shown in Fig. 14, in order to reduce the tendency to crack when the tool is hardened; at other times it is considered advisable to make two extra cuts, as shown in Fig. 15. However, if the tools are heated very carefully and dipped in a bath similar to that illustrated in the October number of MACHINERY (Fig. 19), the contraction is so uniform that there is little danger of cracking. It is necessary, of course, when using this bath to dip the tool so that the water issuing from the perforated pipes strikes the face of the tool. The pipe at the bottom that throws a vertical jet of water, should be closed to prevent the water being forced against one side of the tool, as this would cause unequal contraction.

If it is necessary to use an ordinary bath of water, or brine, the tool should be worked around well in the bath. When it is cooled the strains should be removed by reheating sufficiently to reduce the tendency to crack. If the form of the tool is such that it is not necessary to draw the temper it is ready for use after the cutting surface has been ground. If it is necessary to draw the temper, it may be done by heating in a kettle of oil, gaging the temperature by means of a thermometer; or the sides may be brightened and the temperature gaged by the color. Usually, however, sufficient toughness may be produced by drawing to a temperature that would not produce any temper color. In such cases it is necessary to use the heated oil and thermometer, as described. In some instances the brittleness may be reduced sufficiently by placing in a kettle of water which may be gradually heated until it boils, allowing the water, with the tool in it, to boil sufficiently long to insure the tool being uniformly heated to the temperature of the water (212 degrees F.). A method used in some shops with excellent results, consists in quenching the tool in a bath of water having a layer of oil about 1 inch on the top, as shown in Fig. 16. The heated steel passing through the oil into the water acquires a thin coating of oil, which lessens the shock incident to plunging red-hot steel into cold water.

The writer has had excellent results when hardening both flat and circular forming tools by the method previously described as "Pack hardening" (in the May issue of MACHINERY). The tools stood up nicely, and the tendency to crack was entirely eliminated; and in the case of circular forming tools which had threaded holes, the tendency to shrinking out of size was reduced to the minimum.

Circular forming tools having large and small portions adjoining, as shown in Fig. 17, are many times made of two or more pieces; this simplifies the operation of making and tools of this character can be hardened with less liability of breaking than if made in one piece. When possible the smaller portion should be recessed into the larger, as shown. This does away with the tendency of the smaller portion to crumble at the end which comes against the larger portion.

Forming tools of small diameter cut more rapidly than larger ones when the cutting edges of both are radial, as the metal below the cutting edge recedes more rapidly, thus giving a greater amount of clearance.

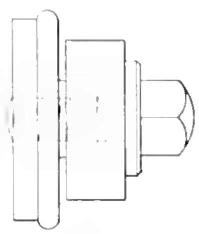

Fig. 19

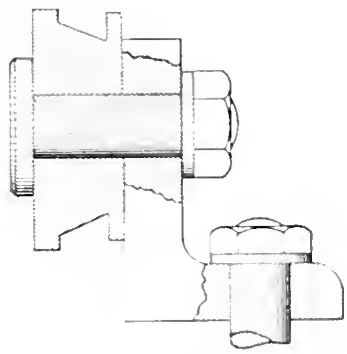

Fig. 20

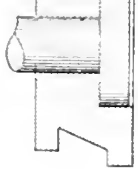

Fig. 21

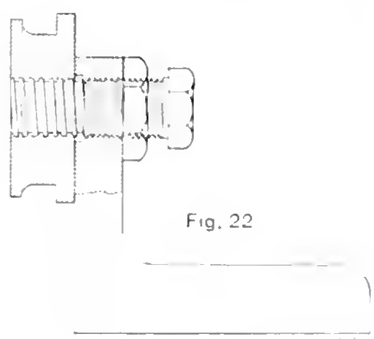

Fig. 22

Tool Holders. It is necessary to provide a holder for circular forming tools, the design depending altogether on the class of work to be done. For use in an ordinary hand screw machine the one shown in Fig. 18 answers nicely. If the work is light the flat side of the tool is drawn against the side of the holder by means of a screw. Fig. 19 shows a tool having a taper projection on one side which fits a taper hole in the holder. The holder, if made this way, should not be hardened; at least the walls of the taper hole should not be hard.

When the tool is to be used in the automatic screw machine the holder is usually of a different design than if for a hand machine. Especially is this the case when heavy work, or work which would bring a great strain on the tool, is to be

done. The more common holder is that shown in Fig. 20, and is made in the form of an angle iron. The bottom of the holder is usually provided with a tongue which fits in the slot in the tool rest. The fixture is securely fastened to the rest by means of bolts, as shown. If the head of the bolt projecting beyond the surface of tool is objectionable it may be made flush, Fig. 21. When extremely heavy cuts are to be taken the form of holder described above may not hold the tool securely, and in such cases it is often considered advisable to make a holder like that shown in Fig. 22. The tool should have a square thread in the bore, the pitch of which is 1-5 or 1-6 inch (that is 5 or 6 threads per inch) right or left hand, according to which side of the holder it is to be located on when in use, so that the tool will have a tendency to tighten when cutting. To get a fine adjustment the thread in the holder must be of finer pitch than that in the tool, and of the same hand. It is obvious that extreme care must be exercised when cutting the thread in the holder, to insure its being at right angles with the face against which the tool is to rest.

Milling Machine Cutters.

No one branch of machine shop work has made greater strides than the process of removing stock by means of rotating cutters used in connection with milling machines. The progress has been especially marked since the introduction of grinding machinery and of wheels made of abrasive materials, making it possible to leave the cutters as hard as is consistent with toughness.

The introduction of formed cutters has made practical the manufacture of intricate forms which can be ground on their cutting faces without changing their shape. The writer can remember as a boy making cutters of irregular shape which,

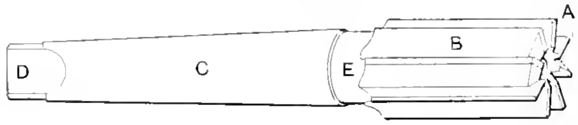

Fig. 23

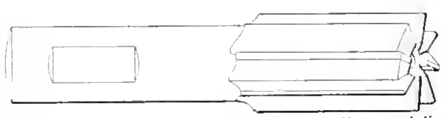

Fig. 24

after hardening, were softened sufficiently while tempering to permit of their being sharpened when dull by scraping with a three-cornered scraper, hardened very hard. This operation could only be repeated a few times before it was necessary to anneal them and re-work to shape.

The use of formed mills makes it possible to mill intricate shapes which it was formerly necessary to produce by planing; and much more cheaply.

End Mills. This form of milling machine cutter is provided with a shank which is held in a collet or in a chuck, and in many shops this is called a shank mill. Generally speaking the shanks are made tapering, as shown in Fig. 23, and the collet has a corresponding tapered hole to receive the shank. In some cases, however, the shanks are made straight, as in Fig. 24, and then the collet has a straight hole of the size of the shank. The cutter is held in place by means of a setscrew, or the shank may be held in a chuck, although this is not a common method. The collet referred to is used to save stock, as otherwise it would be necessary to use steel sufficiently large to make a shank of the size of the hole in the milling machine spindle.

End mills are made right- and left-handed. The one shown in Fig. 23 is called a left-hand mill; a right-hand mill has its teeth cut so as to necessitate running the cutter in the opposite direction.

For the general run of work steel containing 1¼ per cent. carbon answers nicely for mills of this description. If extreme care is taken when hardening, steel containing a higher percentage of carbon may be used and will be found more satisfactory. The stock should be enough larger than the cutting portion of mill to permit turning off the decarbonized surface of the steel. When the ends are faced to length, and a chip has been turned off, to clean the surface, one end is run in the steadyrest and the center is cut as at *A*, Fig. 23. The object of recessing the end is to furnish a cavity for the cutter to enter that is used to cut the teeth on the end. It also facilitates the operation of grinding the teeth on the end.

If the mill is to have a tenon on the end, as indicated at *D*, this may be turned to size and milled, as shown. It should be a trifle (1-32 inch) thinner than the width of the center key slot in the collet. The tapered portion, *C*, is made sufficiently large to allow of grinding after the cutter is hardened, in order to insure its running true. The cutting portion, *B*, is also turned a trifle (say .01 inch) large, to provide

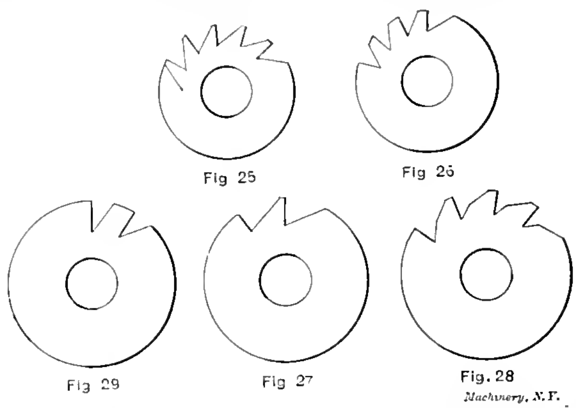

Fig 25 Fig 26
Fig 29 Fig 27 Fig. 28

for grinding; and the portion *E* should be 1-32 inch smaller than the large end of the taper, unless specific instructions as to size are given on the drawing.

End mills have their teeth cut both straight and spiraling, according to the uses to which they are to be put. To insure a strong tooth, or one that will resist the strain incident to cutting, due regard must be paid to its shape. Not only must the tooth be strong but it must be cut deep enough to hold chips and not clog. A thin tooth, like that shown in Fig. 25, will spring into the stock when cutting, which puts an additional strain on the tooth and causes it to break. The tooth must not be too broad across the top (Fig. 26) or it will not be possible to grind it satisfactorily. Fig. 27 shows a cutter whose teeth are strong and deep enough to hold the chips and yet work in a satisfactory manner. At times it is desirable to have cutter teeth of the form shown in Fig. 28. This is done by first cutting around with an angular mill that will produce a tooth like that in Fig. 29, and then turning the index head and finishing the tooth to the shape shown in Fig. 28. This tooth answers nicely when the cutter is to be subjected to great strain, as when cutting irregular surfaces, or where it will come in contact with corners of the work.

The number of teeth to cut in an end mill cannot be stated arbitrarily; this will depend altogether on circumstances. There is a tendency in many shops to make cutters having too many teeth rather than too few.

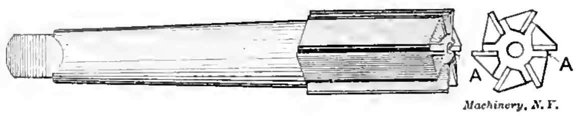

Fig. 30.

When it is necessary to cut into the surface of a piece of work with the end of the mill and then feed along, as in die work, internal cams, etc., the teeth are sharpened or given clearance, on the inside, and so are able to cut a path from the point where the mill is sunk into the work. The teeth being very coarse allow of heavy cuts. This is especially the case when cast iron is the material being machined. After cutting the teeth on the end of the mill a thin metal-splitting saw of comparatively small diameter should be run through close to the face of each tooth, making the cut shown in Fig. 30 at *A*. This cut is to permit backing off the inner edge of the tooth, which gives the mill a cutting tooth on the inside as well as on the outside, and allows it to cut away the projection made when the mill was fed into the work.

For end mills with spiral teeth it will be necessary to have

a spiral that will cause the shank of the mill to stay in the collet rather than draw it out. The subject of spiral teeth will be considered in another part of this article, under milling machine cutters with spiral teeth.

T-Slot Cutters. It is customary to provide with T-slots all machines which are to hold the work by means of bolts. These slots were formerly cut on a planer, with a tool like that in Fig. 31. When many slots are to be cut this is an expensive method and has been almost entirely superseded by the use of a milling cutter made especially for this pur-

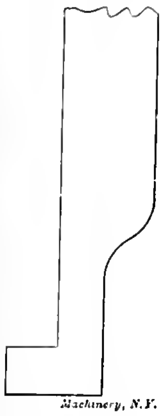

Fig. 31.

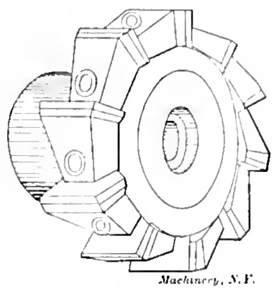

Fig. 38.

Fig. 40.

pose, and termed T-slot cutter, Fig. 32. This form of cutter is made 1-32 inch larger than its designated size, to allow for grinding; that is, a ¾-inch T-slot cutter would be ¾ inch + 1-32 inch diameter when ready for use, unless the T-slot is to be cut to given dimensions. Teeth must be provided on the sides of this form of mill, as shown in Fig. 32.

It is advisable to harden mills of this description the entire length of the necked portion marked *B*, especially if the neck is of small diameter. Draw the neck to a blue color when tempering, and the cutting portion to a straw color. The teeth of T-slot cutters should be coarse and of a form that insures the greatest strength possible, allowing of course sufficient space between teeth to accommodate chips.

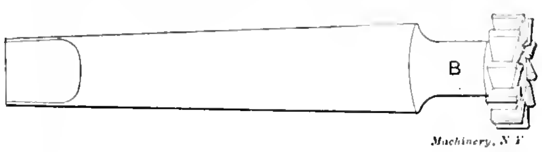

Fig. 32.

Fly Cutters. This is the simplest form of milling machine cutter, and is often used when but one piece, or a limited number of pieces of irregular shape, is to be produced. It recommends itself for experimental and similar work, on account of cheapness and the ease with which it can be made. As shown in Fig. 33 the cutter, which is single, is held in a holder known as a "fly cutter arbor." This cutter is given its shape and clearance by several methods. If the shape is not very intricate it may be produced by filing. To make a fly cutter from a forming tool the square piece of steel for the cutter is held in the fly cutter arbor and the shape produced by the forming tool. To get the necessary clearance the face

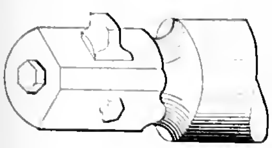

Fig. 33

Fig. 34

Fig. 35

Fig. 36

of the tool is set somewhat back of the center, as shown in Fig. 34. This is readily done as the stock used for the cutter need not be as large as the hole in the arbor. It is held in position by pieces of steel used as blocks, and is then securely fastened by setscrews provided with the arbor. After being hardened the cutter is placed in the holder so that the face is radial, Fig. 35, and it will be found to have the necessary clearance.

A commonly used method for getting the desired clearance consists in placing the face of the stock to be used for the cutter radial but locating the outside as near the arbor as is practical, as shown by dotted lines *A*, Fig. 36. After forming and hardening it is set to cut in the position marked *B*, and it will be found to have the necessary clearance.

While fly cutters are very useful for certain purposes they are seldom employed where many pieces are to be machined. Having but one cutting tooth they necessarily cut very slowly.

Face Milling Cutters. This form of cutter is used quite extensively on certain classes of work and is especially valuable for use on surfaces too large to be machined with the ordinary type of cutter held on a milling machine arbor. For work to be milled with a cutter held on an arbor, as shown at *A*, Fig. 37, it is necessary to use a cutter whose diameter is twice the size of the surface being machined, plus the diameter of the arbor. When a face mill is used, as at *B*, the diameter of the cutter need only exceed the width of surface being milled by a trifle.

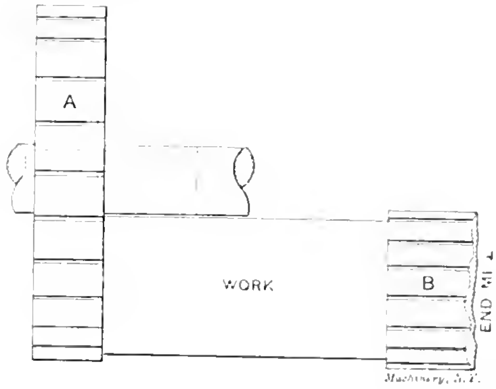

Fig. 37

For large work mills having inserted teeth are used, Fig. 38. The body of the mill is made of machinery steel, or cast iron, and the teeth of tool steel, hardened, or else of high-speed steel. When the machine employed is sufficiently strong to resist the extra strain incident to high speeds, use high speed steel in making the teeth, for the amount of work produced per machine may thus be more than doubled. The advantages claimed for cutters having inserted teeth are that while the cost of making the first cutters may not be any less than for a solid one, the teeth may be renewed when worn out, at a comparatively low cost. Then again it is not, generally speaking, advisable to harden milling machine cutters above 6 inches in diameter in a shop provided with only ordinary facilities for doing work of this character.

Fig. 39

It is considered best practice in most shops to make cutters of this description with taper holes. The arbor, of course, has a corresponding taper and is provided with a key which prevents the cutter turning on the arbor. The arbor is provided with a screw which draws the cutter onto the taper, as will be seen in Fig. 39, while Fig. 40 represents a sectional view of a cutter, showing it recessed to receive the screw head.

If the cut is to extend more than ¾ inch on the face of the mill, the teeth are made spiral; but if the cut does not exceed this width the teeth are made straight, mills with straight teeth being less costly.

The various methods used to hold the teeth in place will be considered in the next article, which will deal with milling machine cutters in general.

* * *

The increase in mechanical efficiency of engines with forced lubrication has been clearly shown by recent engines built by the B. F. Sturtevant Co. at Hyde Park, Mass., and fitted with a forced pump lubricating system. An increase of from 8 to 10 per cent is shown, and with their latest type of vertical single engines a mechanical efficiency averaging 94 per cent.

THE DEVELOPMENT AND USE OF HIGH-SPEED TOOLS.*

The high-speed steels of the present day are combinations of iron and carbon with: (1) Tungsten and chromium, (2) Molybdenum and chromium, (3) Tungsten, molybdenum and chromium.

Influence of Carbon.—A number of tool steels were made by the Armstrong Whitworth Co. with the carbon percentage varying from 0.4 per cent to 2.2 per cent, and the method of hardening was to heat the steel to the highest possible temperature without destroying the cutting edge, and then rapidly cooling in a strong air blast. By this simple method of hardening it was found that the greatest cutting efficiency is obtained where the carbon ranges from 0.4 per cent to 0.9 per cent, and such steels are comparatively tough. Higher percentages are not desirable because great difficulty is experienced in forging the steels, and the tools are inferior. With increasing carbon contents the steel is also very brittle, and has a tendency to break with unequal and intermittent cutting.

Influence of Chromium.—Having thus found the best carbon content to range from 0.4 per cent to 0.9 per cent, the next experiments were made to ascertain the influence of chromium varying from 1.0 per cent to 6.0 per cent. Steels containing a low percentage are very tough, and perform excellent work on the softer varieties of steel and cast-iron, but when tried on harder materials the results obtained were not so efficient. With an increased content of chromium the nature of the steel becomes much harder, and greater cutting efficiency is obtained on hard meterials. It was observed that with an increase of chromium there must be a decrease in carbon to obtain the best results for such percentage of chromium.

Mention may here be made of an interesting experiment to ascertain what effect would be produced in a rapid steel by substituting vanadium for chromium. The amount of vanadium present was 2.0 per cent. The steel readily forged, worked very tough, and was hardened by heating to a white heat and cooling in an air blast. This tool when tried on medium steel stood well, but not better than the steel with the much cheaper element of chromium in it.

Influence of Tungsten.—This important element is contained in by far the greater number of the present high-speed steels in use. A number of experiments were made with the tungsten content ranging from 9.0 per cent to 27.0 per cent. From 9.0 per cent to 16.0 per cent the nature of the steel becomes very brittle, but at the same time the cutting efficiency is greatly increased, and about 16.0 per cent appeared to be the limit, as no better results were obtained by increasing the tungsten beyond this figure. Between 18.0 per cent and 27.0 per cent it was found that the nature of the steel altered somewhat, and instead of being brittle, it became softer and tougher, and whilst such tools have the property of cutting very cleanly, they do not stand up so well.

Influence of Molybdenum.—The influence of this element at the present time is under investigation, and our experiments with it have so far produced excellent results, and it was found that where a large percentage of tungsten is necessary to make a good rapid steel, a considerably less percentage of molybdenum will suffice. A peculiarity of these molybdenum steels is that in order to obtain the greatest efficiency they do not require such a high temperature in hardening as do the tungsten steels, and if the temperature is increased above 1,800 degrees F. the tools are inferior, and the life shortened.

Influence of Tungsten with Molybdenum.—It was found that the presence of from 0.5 per cent to 3.0 per cent molybdenum in a high tungsten steel slightly increased the cutting efficiency, but the advantage gained is altogether out of proportion to the cost of the added molybdenum.

Influence of Silicon.—A number of rapid steels were made with silicon content varying from a trace up to 4.0 per cent. Silicon sensibly hardens such steels, and the cutting efficiency on hard materials is increased by additions up to 3.0 per cent. By increasing the silicon above 3.0 per cent, however, the cutting efficiency begins to decline. Various experiments were made with other metals as alloys, but the results obtained were not sufficiently good by comparison with the above to call for comment.

An analysis of one of the best qualities of rapid steels produced by the author's firm (Armstrong, Whitworth Co.) is as follows: "A.W." Steel.—Carbon, 0.55 per cent; Chromium, 3.5 per cent; Tungsten, 13.5 per cent.

What may be said to determine a high-speed steel, as compared to an ordinary tool steel, is its capability of withstanding the higher temperatures produced by the greatly increased friction between the tool and the work due to the rapid cutting. An ordinary carbon steel containing, say, 1.20 per cent carbon when heated slightly above the critical point and rapidly cooled by quenching in water becomes intensely hard. Such a steel gradually loses this intense hardness as the temperature of friction reaches, say, 500 degrees F. The lower the temperature is maintained the longer will be the life of the tool, so that the cutting speed is very limited. With rapid cutting steels the temperature of friction may be greatly extended, even up to 1,100 degrees F. to 1,200 degrees F., and it has been proved by experience that the higher the temperature for hardening is raised above the critical point and then rapidly cooled, the higher will be the temperature of friction that the tool can withstand before sensibly losing its hardness. The high degree of heating (almost to melting point, in fact) which is necessary for hardening high-speed steel forms an interesting study in thermal treatment and is indeed a curious paradox, quite inverting all theory and practice previously existing. In the case of hardening ordinary carbon steels very rapid cooling is absolutely necessary, but with high-speed steels the rate of cooling may take a considerably longer period, the intensity of hardness being increased with the quicker rate of cooling.

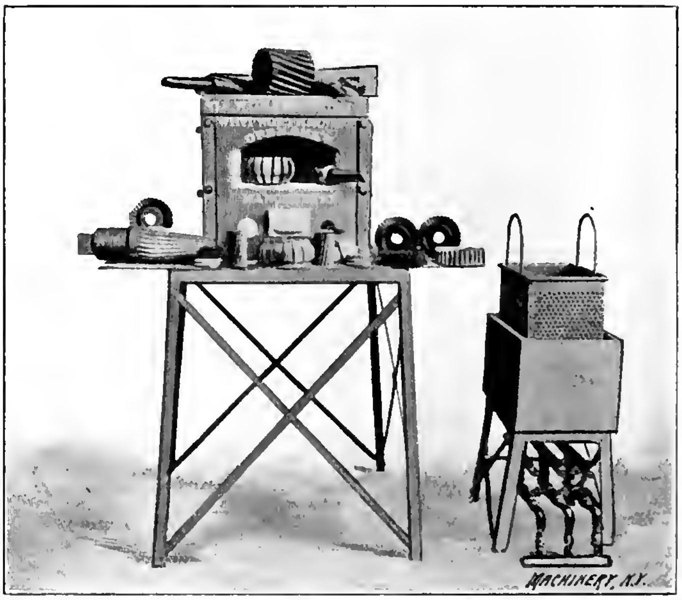

Fig. 1. Muffle Furnace for Hardening Milling Cutters made of High-speed Steel; also Tank and Dipping Cage for Tempering them in Oil.

Heat Treatment of High-speed Steel.

Turning now to some points in the heat treatment of high-speed steel, one of the most important is the process of thoroughly annealing it after working into bars. Accurate annealing is of much value in bringing the steel into a state of molecular uniformity, thereby removing internal strains that may have arisen, due to casting and tilting, and at the same time annealing renders the steel sufficiently soft to enable it to be machined into any desired form for turning tools, milling cutters, drills, taps, screwing dies, etc. The annealing of high-speed steel is best carried out in muffle furnaces designed for heating by radiation only, a temperature of 1,400 deg. F. being maintained from twelve to eighteen hours according to the section of the bars of steel dealt with. Further advantage also results from careful annealing by minimizing risks of cracking when the steel has to be reheated for hardening. In cases of intricately-shaped milling tools having sharp square bottom recesses, fine edges, or delicate projections, and on which un-

* Abstract of paper read by Mr. J. M. Gledhill before the Iron and Steel Institute, October, 1904.

equal expansion and contraction are liable to operate suddenly, annealing has a very beneficial effect toward reducing cracking to a minimum. Increased ductility is also imparted by annealing, and this is especially requisite in tools that have to encounter sudden shocks due to intermittent cutting, such as planing and slotting tools, or others suddenly meeting projections or irregularities on the work operated on.

In preparing high-speed steel ready for use the process may be divided principally into three stages: forging, hardening, and grinding. It is, of course, very desirable that high speed steel should be capable of attaining its maximum efficiency and yet only require treatment of the simplest kind, so that an

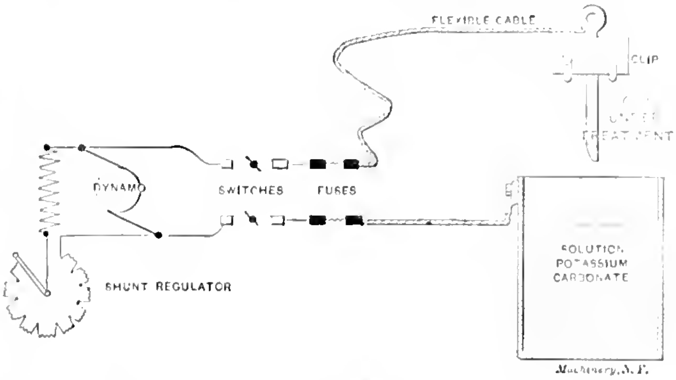

Fig. 2. Apparatus for Hardening Tools Electrically in a Bath of Potassium Carbonate.

ordinarily skilled workman may easily deal with it, otherwise the preparation of tools becomes an expensive and costly matter, and materially reduces the advantages resulting from its use. Fortunately, the treatment of the rapid steel produced by the author's firm is of the simplest; simpler in fact than ordinary carbon steels or the old self-hardening steels. Great care had to be exercised in the heating of the latter steels, for if either were heated above a blood-red heat, say 1,600 degrees F., the danger of impairing their efficiency by burning was considerable; whereas with the high-speed steel, heating may be carried to a much higher temperature, even up to melting point, it being practically impossible to injure it by burning. The steel may be raised to a yellow heat for forging, say 1,850 degrees F., at which temperature it is soft and easily worked into any desired form, the forging proceeding until the temperature lowers to a good red heat, say 1,500 degrees F., when work on it should cease and the steel be reheated.

In heating a bar of high-speed steel preparatory to forging (which heating is best done in a clear coke fire) it is essential that the bar be heated thoroughly and uniformly, so as to ensure that the heat has penetrated to the center of the bar, for if the bar be not uniformly heated, leaving the center comparatively cold and stiff, while the outside is hot, the steel will not draw or spread out equally, and cracking will probably result. A wise rule in heating is to "hasten slowly."

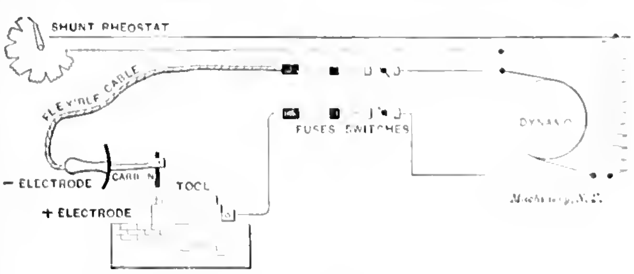

Fig. 3. Apparatus for Hardening Tools by the Electric Arc.

It is not advisable to break pieces from the bar while cold, the effect of so doing tending to induce fine end cracks to develop which ultimately may extend and give trouble; but the pieces should be cut off while the bar is hot, then be reheated as before and forged to the shape required, after which the tool should be laid in a dry place until cold.

The temperature for hardening high-speed steel varies somewhat according to the class of tool being dealt with. When hardening turning, planing, or slotting tools, and others of similar class, the point or nose of tool only should be gradually raised to a white melting heat, though not necessarily melted, but even should the point of the tool become to a greater or less extent fused or melted no harm [illegible]. The tool should then be immediately placed in an a[illegible] and cooled down, after which it only requires grinding an[illegible] ready for use. Another method which may be descr[illegible] preparing the tools is as follows: Forge the tools as before and when quite cold grind to shape on a *dry* stone or emery wheel, an operation which may be done with the tool fixed in a rest and fed against the stone or emery wheel by a screw, no harm resulting from any heat developed at this stage. The tool then requires heating to a white heat, but just short of melting, and afterward completely cooling in the air blast. This method of first roughly grinding to shape also lends itself to cooling the tools in oil, which is specially efficient where the retention of a sharp edge is a desideratum, as in finishing tools, capstans and automatic lathe tools, brass-workers' tools, etc. In hardening where oil cooling is used the tools should be first raised to a white heat, but without melting, and then cooled down either by air blast or in the open to a bright red heat, say 1,700 degrees F., when they should be instantly plunged into a bath of rape or whale oil, or a mixture of both.

Referring to the question of grinding tools, nothing has yet been found so good for high-speed steels as the wet sandstone, and the tools ground thereon by hand pressure, but where it is desired to use emery wheels it is better to roughly grind the tools to shape on a dry emery wheel or dry stone *before* hardening. By so doing the tools require but little grinding after hardening, and only slight frictional heating occurs, but not sufficient to draw the temper in any way, and thus their cutting efficiency is not impaired. When the tools are ground on a wet emery wheel and undue pressure is applied, the heat generated by the great friction between the tool and the emery wheel causes the steel to become hot, and water playing on the steel while in this heated condition tends to produce cracking.

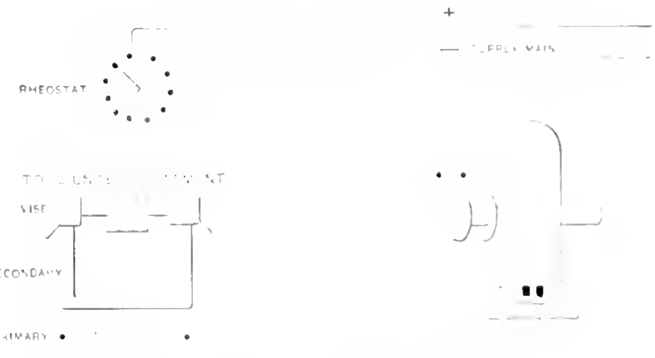

Fig. 4. Apparatus for Tempering Milling Cutters Electrically.

With regard to the hardening and tempering of specially formed tools of high-speed steel, such as milling and gear cutters, twist drills, taps, screwing dies, reamers, and other tools that do not permit of being ground to shape after hardening, and where any melting or fusing of the cutting edges must be prevented, the method of hardening is as follows:

A specially arranged muffle furnace heated either by gas or oil is employed, and consists of two chambers lined with fire clay, the gas and air entering through a series of burners at the back of the furnace, and so under control that a temperature up to 2,200 degrees F. may be steadily maintained in the lower chamber, while the upper chamber is kept at a much lower temperature. Before placing the cutters in the furnace it is advisable to fill up the hole and keyways with common fire-clay to protect them. The cutters are first placed upon the top of the furnace until they are warmed through, after which they are placed in the upper chamber, Fig. 1, and thoroughly and uniformly heated to a temperature of about 1,500 degrees F., or, say, a medium red heat, when they are transferred into the lower chamber and allowed to remain therein until the cutter attains the same heat as the furnace itself, [illegible] about 2,200 degrees F. and the cutting edges become a bright yellow heat, having an appearance of a glazed or greasy surface. The cutter should then be withdrawn while the edges are sharp and uninjured, and revolved before an air blast until the red heat has passed away, and then while the cutter is still warm —that is, *just* permitting of its being handled—it should be plunged into a bath of tallow at about 200 deg. F. and the

temperature of the tallow bath then raised to about 520 degrees F., on the attainment of which the cutter should be immediately withdrawn and plunged in cold oil.

Of course there are various other ways of tempering, a good method being by means of a specially arranged gas-and-air stove into which the articles to be tempered are placed, aud the

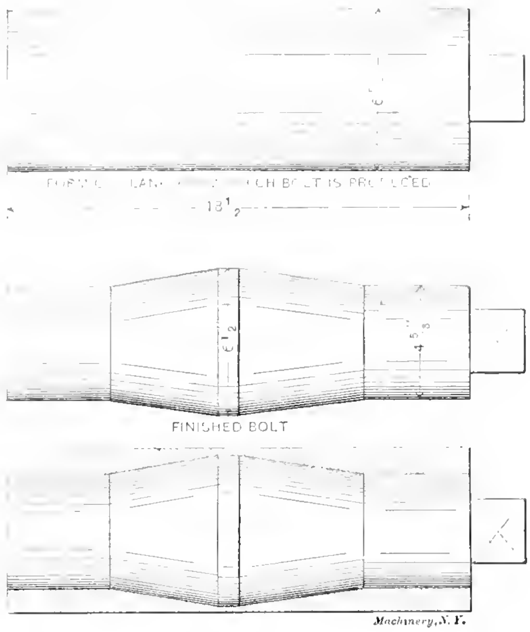

Fig. 5. Showing Stock and Finished Armor Bolts Turned at a Cutting Speed of 160 feet per minute. Mean Depth of Cut, 3-4 inch; Traverse, 1-32 inch Reduction in Weight, 62 pounds. Forty of these Bolts were Turned in ten hours with "A. W." Steel.

stove then heated up to a temperature of from 500 degrees F. to 600 degrees F., when the gas is shut off and the furnace with its contents allowed to slowly cool down.

Another method of heating tools is by electrical means, by which very regular and rapid heating is obtained, and where electric current is available, the system of electric heat-

tank. The tool to be hardened is held in a suitable clip to ensure good contact. Proceeding to harden the tool the action is as follows:

The current is first switched on, and then the tool is gently lowered into the solution to such a depth as is required to harden it. The act of dipping the tool into the alkaline solution completes the electric circuit and at once sets up intense heat on the immersed part. When it is seen that the tool is sufficiently heated the current is instantly switched off, and the solution then serves to rapidly chill and harden the point of the tool, so that no air blast is necessary.

Another method of heating the point of tools is by means of the electric arc, the heating effect of which is also very rapid in its action. The general arrangement and form of the apparatus here employed being as illustrated in Fig. 3.

The tool under treatment and the positive electrode are placed on a bed of non-conducting and non-combustible material and the arc started gradually at a low voltage and steadily increased as required, by controlling the shunt rheostat, care being taken not to obtain too great a heat and so fuse the end of the tool. The source of power in this case is a motor generator consisting of a continuous-current shunt-wound motor at 220 volts, coupled to a continuous-current shunt-wound dynamo at from 50 to 150 volts. Arcs from 10 to 1,000 amperes are then easily produced and simply and safely controlled by means of the shunt rheostat.

Tempering.—Electricity is also a very efficient and accurate means of tempering such forms of tools as milling, gear, hobbing and other similar cutters, also large hollow taps, hollow reamers, and all other hollow tools made of high-speed steel, where it is required to have the outside or cutting portion hard, and the interior soft and tenacious, so as to be in the best condition to resist the great stresses put upon the tool by the resistance of the metal being cut, and which stresses tend to cause disruption of the cutter if the hardening extends too deep. By means of the apparatus illustrated in Fig. 4 this tempering or softening of the interior can be perfectly and quickly effected, thus bringing the cutter into the best possible condition to perform rapid and heavy work.

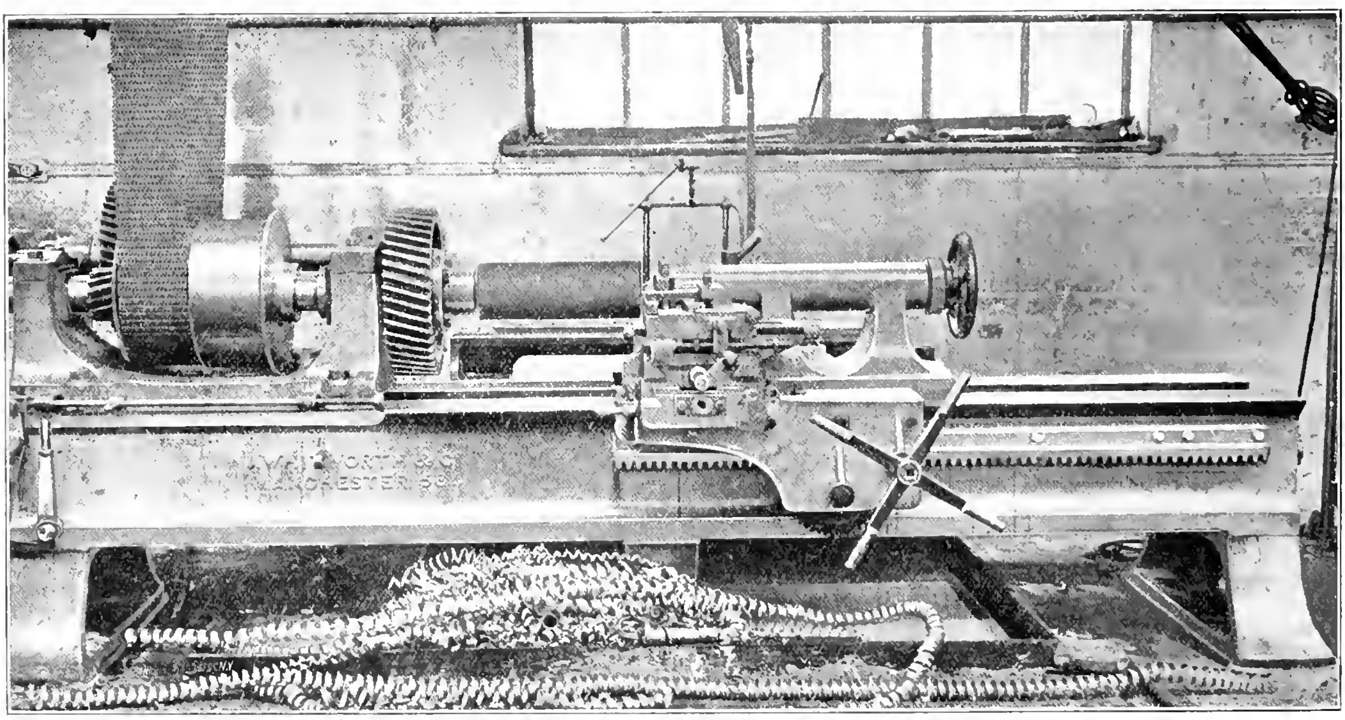

Fig. 6. Lathe used for Turning Armor Bolts. Removed 2,480 pounds of Steel Chips in ten hours.

ing is quick, reliable, and economical. A brief description of this kind of heating may be of interest. One method adopted for electrically heating the points of tools, and the arrangement of apparatus is shown in Fig. 2. It consists of a cast-iron tank, of suitable dimensions, containing a strong solution of potassium carbonate together with a dynamo, the positive cable from which is connected to the metal clip holding the tool to be heated, while the negative cable is connected direct on the

Tempering of hollow cutters, etc., is sometimes carried out by the insertion of a heated rod within the cutter and so drawing the temper, but this is not entirely satisfactory, or scientific, and is liable to induce cracking by too sudden heat application, and further because of the difficulty of maintaining the necessary heat and temperature required, and afterward gradually lowering the heat until the proper degree of temper has been obtained. In electrical tempering these difficulties

are overcome, as the rod is placed inside the cutter quite cold, and the electric current gradually and steadily heats up the rod until the correct temperature is reached. Then it can be held at such temperature as long as is necessary, and the current can be gradually reduced until the articles operated on are cold again, and consequently the risk of cracking by too sudden expansion and contraction is reduced very greatly. The apparatus used is very simple, as will be seen by reference to Fig. 4. It consists of a continuous-current shunt wound

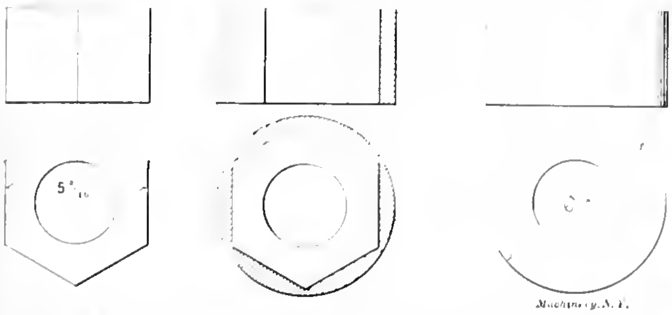

Fig. 7. Examples of Rapid Work with High-speed Milling Cutters. Speed of Cutter, 150 feet per minute; Maximum Depth of Cut, 1 1-2 inches; Reduction in Weight, 7 1-2 pounds; 90 Sleeves produced in ten hours. Total Weight of Metal removed, 675 pounds.

motor directly coupled to a single-phase alternating-current dynamo of the revolving field type giving 100 amperes at 350 volts, 50 cycles per second, the exciting current being taken from the works supply main. The power from the alternator is by means of a stepdown transformer, reduced to current at a pressure of 2 volts, the secondary coil of the transformer consisting of a single turn of copper of heavy cross-section, the extremities of which are attached to heavy copper bars carrying the connecting vises holding the mandrel upon which the cutter to be tempered is placed. The secondary induced current, therefore, passes through a single turn coil, through the copper bars and vises and mandrel. Although the resistance of the complete circuit is very low, still, owing to the comparatively high specific resistance of the iron mandrel, the thermal effect of the current is used up in heating the mandrel which gradually attains the required temperature, slowly imparting its heat to the tool under treatment until the shade of the oxide on the tool satisfies the operator. The method

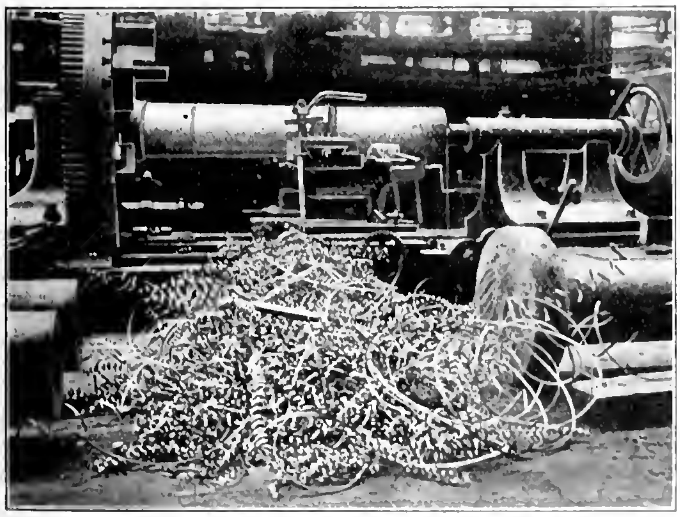

Fig. 8. Chips and Shavings produced in 45 minutes' work, Cutting Speed 150 feet per minute; Depth of Cut, 3-16 inch, Traverse, 1-16 inch

adopted to regulate the heat of the mandrel is by varying the excitation current of the alternator by means of the rheostat. An extremely fine variation and perfect heat control is easily possible by this arrangement.

Some Results of the Use of High-Speed Steel.

It is sometimes contended that on the whole not much advantage or economy results from using high speed steel, but it is easy to prove very greatly to the contrary. That great economy is effected is beyond all doubt, from whichever point of view the question is looked at; for it is not only rapidity of cutting that counts, but the output of machines is correspondingly increased, so that a greater production is obtained from a given installation than was possible when cutting at low speeds with the old tool steel, and the work is naturally produced at a correspondingly lower cost, and of course it follows from this that in laying down new plant and machines the introduction and use of high-speed steel would have considerable influence in reducing expenditure on capital

Fig. 9. Making Hexagon Nuts from Rolled Bars with Cutters of "A. W." High-speed Steel. Ninety Nuts are produced in a day of ten hours

account. It has also been proved that high-speed cutting is economical from a mechanical standpoint and that a given horse power will remove a greater quantity of metal at a high speed than at a low speed, for although more power is naturally required to take off metal at a high than at a low speed (by reason of the increased work done) the increase of that power is by no means in proportion to the large extra amount of work done by the high-speed cutting, for the frictional and other losses do not increase in anything like the same ratio as a high-cutting speed is to a low-cutting speed. A brief example of this may be given in which the power absorbed in the lathe was accurately measured, electrically.

Cutting on hard steel, with 3-16 inch depth of cut, 1-16 inch feed and speed of cutting 17 feet per minute, a power of 5.16 horse power was absorbed, and increasing the cutting speed to 42 feet per minute, the depth of cut and feed being the same, there was a saving in power of 19 per cent for the work being done. Another experiment with depth of cut 3/8 inch and traverse 1-16 inch compared with 1-16 inch traverse and 3-16 inch depth of cut, showed a saving in power of as much as 28 per cent, and still proceeding with a view of increasing the weight of metal removed in a given time the feed was doubled (other conditions being the same) and a still further saving of power resulted. In a word, as in the majority of things, so it is with rapid cutting, the more quickly work can be produced the cheaper the cost of production will be.

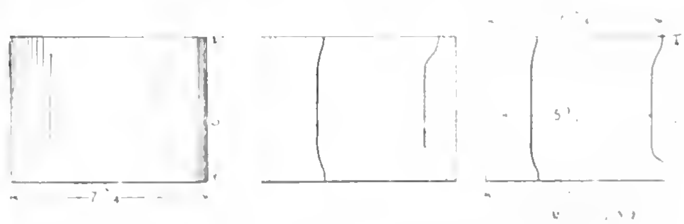

Fig. 10. Sleeves of Armor Bolts. Cutting Speed, 160 feet per minute. Maximum Depth of Cut, 1 1-8 inch. Traverse, 1-32 inch. 60 Sleeves in ten hours

Again as regards economy there is not only a saving effected on the actual machine work, but since the advent of high speed cutting it is now possible, in many instances, to produce finished articles from plain rolled bars, instead of following the old practice of first making expensive forgings and afterward finishing them in the machine. By this practice not only is the entire cost of forging abolished, but the machining on the rolled bar can be carried out much quicker and cheaper in suitably arranged machines, quicker even than the machining of a forging can be done.

A remarkable sample of the gain resulting from the use of

high-speed cutting from rolled bars is illustrated in Fig. 5, the articles in this case being securing bolts, made by the author's firm, for armor plates. Formerly where forgings were first made and then machined with ordinary self-hardening steel, a production of eight bolts per day of ten hours was usual. With the introduction of rapid-cutting steel, forty similar bolts from the rolled bar are now produced in the same time, thus giving an advantage of five to one in favor of quick cutting, and also in addition abolishing the cost of first rough forging the bolt to form; in fact, the cost of forging one bolt alone amounted to more than the present cost of producing to required form twelve such bolts by high-speed machining. The cutting speed at which these bolts are turned is 160 feet per minute, the depth of cut and feed being respectively 3/4 inch and 1-32 inch, the weight of metal removed from each bolt being 62 pounds, or 2,480 pounds in a day of ten hours, the tool being only ground once during such period of work, and from such an example as this it will be at once apparent what an enormous saving in plant and costs results. On the same principle the sleeves (see Fig. 10) for these bolts are produced from bars, sixty being made in one day of ten hours, this being even a greater saving on the old system than the bolt example shows.

An illustration of the lathe on which this work is done is also shown in Fig. 6. It is a 12-inch lathe of special design and strength for rapid and heavy cutting, and has a link driving belt of 7½ inches wide, running at a very high velocity and driven by its own motor, so that the power absorbed can always be observed whether the lathe is running idle or cutting.

Equally remarkable results are obtained by operating on stock bars with high-speed milling cutters, and one example, amongst many, may be cited, which is shown in Fig. 7. Here hexagon nuts for 3¾ inches diameter bolts are made from rolled bars, the cutting speed of milling being 150 feet per minute, giving a production of ninety nuts per day, against thirty formerly. More than ninety nuts could have been produced had the machine been more powerful.

Many other examples of rapid work in planing, milling, drilling, and turning in the Armstrong Whitworth Co.'s and other shops were given by the author.

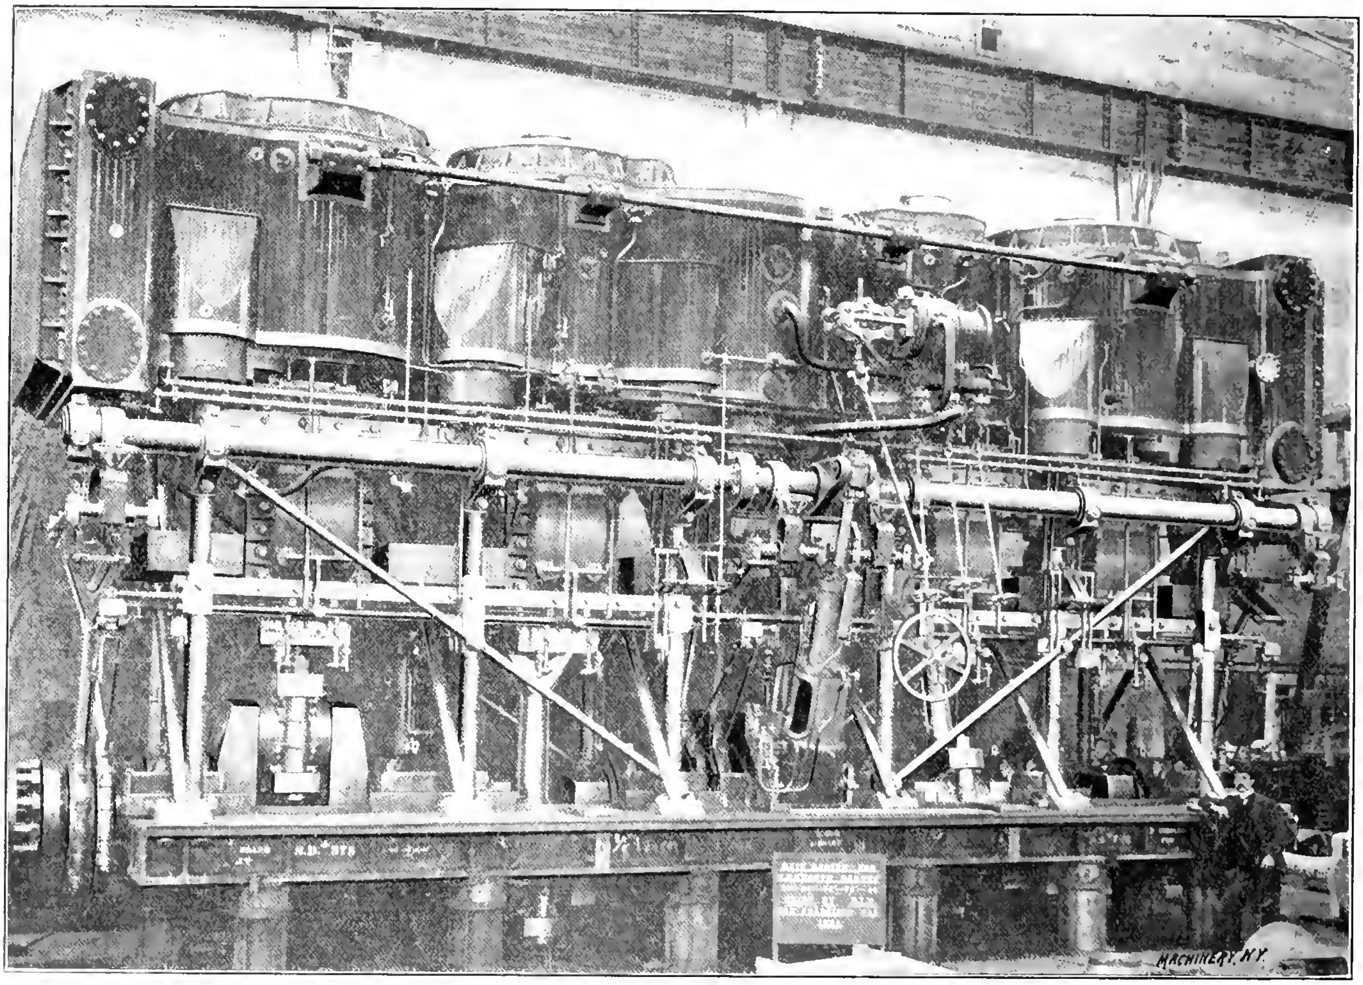
ENGINES FOR U. S. ARMORED CRUISERS NOS. 6 AND 9, THE CALIFORNIA AND SOUTH DAKOTA.

EARL N. PERCY.

The accompanying half-tone shows an interesting and in some ways wonderful type of steam engine. It is a naval engine of nearly 13,000 indicated horse power, each boat having two, which on the Colorado aggregated 25,000 horse power.

It is a four-cylinder triple-expansion engine with one high-pressure, one intermediate and two low-pressure cylinders. The cylinders are 38½ inches diameter, high-pressure, 63½ inches, diameter of intermediate pressure and diameter of each low-pressure, 74 inches by 48 inches common stroke. The low-pressure cylinders are on each end, and the high-pressure cylinder is forward. These engines are rated at 11,500 horse power each at 120 revolutions, with 250 pounds steam pressure.



One of the Main Engines for the United States Armored Cruiser South Dakota—13,000 I. H. P.

The frame is built entirely of nickel steel rods, to secure lightness, and the bed is of cast steel. Each cylinder is fitted with a liner fastened at the bottom, and provided with a gland on top to allow for expansion. Between each liner and casing is a steam jacket, which is supplied direct from the boilers. The pistons use cast iron snap rings, set out by springs. Watson's packing is used exclusively on all rods. The slide valves are balanced for steam pressure and for weight. The reversing engine is oscillating, being swung on trunnions, thus doing away with crosshead and connecting rod. The main throttle is worked by the large wheel. The auxiliary throttle bypasses the main throttle, and is used for warming up, and operating at slow speeds. The other valves are passovers for warming up, and starting engines. The numerous levers, aside from the reverse, are for the drain cocks.

Separate steam, twin beam airpumps are used. The condenser for each engine has about 14,400 square feet of cooling surface. There are two main exhaust pipes for each engine, four in all, each 27 inches diameter. The main steam pipe for each engine is 13 inches diameter. The condenser takes a 21-inch stream of circulating water thrown by a 10 and 18 x 10-inch compound engine running 200 revolutions per minute. The centrifugal pump runner is 38 inches diameter. Each condenser has 6,280 tubes 5/8 inch diameter, 14 feet long. The shells are 7 feet 5 inches diameter, and the tubes are spaced 15-16 inches apart.

Steam is supplied by sixteen Babcock & Wilcox marine water tube boilers having an aggregate heating surface of 70,941 square feet, and grate surface of 1,600 square feet. Each boiler has a Howden hot air forced draft system, with its own heater and blower engine, and is entirely independent of the rest of the plant except for the steam connections.

The connecting-rods are only 96 inches long, giving a very short connection, with excessive angularity, but making the engine low and compact. The guides are of the slipper type, being on one side only, with overlapping lips. As the engines turn outboard when going ahead, they are operated from the back. While the view is somewhat obstructed, it gives great tactical advantages.

The entire engine is supplied with water service to cool bearings and guides. The shafts and crankpins are hollow, and this space is utilized to force oil into the crank bearings. The eccentrics are oiled by telescope tubes and all other parts by a system of forced drips. All parts can be reached directly if any of the automatic gear fails.

These vessels are of 13,400 tons displacement, and must make upward of 22 knots per hour, the Colorado averaging 22 1/4 knots on her trial trip. They are 502 feet long, 66 feet 6 1/2 inches wide and draw about 25 feet of water. They are armored and have two turrets equipped with 8-inch guns. Besides the four 8-inch breech-loading rifles in the turrets, there will be fourteen 6-inch rapid-fire guns, eighteen 3-inch rapid-fire guns, twelve 3-pounder semi-automatic guns, four 1-pounder heavy semi-automatic guns, two 3-inch field pieces, two machine guns, 0.30 inch caliber, and six automatic guns 0.30 inch caliber.

All wood on these boats is fireproofed. The ship's equipment includes a laundry equipped with one washer, one hydro-extractor, one mangle, two sets of tubs, one tank, dryer, etc., all driven by an electric motor.

* * *

VERTICAL BOILERS IN POWER PLANTS.

The large power plants which have recently been erected in the more populous cities for street railway work, etc., have come to follow certain standard lines of construction. This is especially so in regard to the boiler plant, where the approved arrangement is a double row of water-tube boilers with a center passage between them; above the boilers the economizers; and above all and directly under the roof of the structure, the coal bins, from which the coal descends to the automatic stokers. In a letter to the *Engineering Record*, Mr. George I. Rockwood asks, "Does it pay merely because land is expensive to put 18,000 tons of coal into a bunker 100 feet high in the air, on top of boilers of great weight in themselves, if a boiler house of only one story and of only 3,000 brake horse power can be built for $33.30 per boiler horse power, and occupies but 1.28 square feet of land per boiler horse power?"

This was offered in comment on the immense boiler plant of the Rapid Transit Station in New York City, and the 3,000 horse power plant referred to is one recently established at the Atlantic Mills, Providence, R. I., by Mr. Rockwood. In place of water-tube boilers, he used vertical boilers of his own design similar to the Manning type, and the space thus saved enabled him to place the coal bunkers on the floor, with not only a saving in the cost of foundation but in expensive steel work required to support the coal pockets when located above the boilers. Mr. Rockwood figures that the Rapid Transit boiler plant occupies 1.52 square feet of ground area per boiler horse power. This space includes the coal storage, the boilers, pumps, piping and economizers. The Atlantic Mills plant occupies 1.28 square feet per boiler horse power, including everything except the coal bins, but the economizers, boilers, and all the apparatus are on one floor, and the expense of heavy steel construction is avoided, since a building one story high and strong enough simply to support the roof is all that is required.

Before attempting to decide Mr. Rockwood's question, one must form an opinion as to the advantages of horizontal water-tube and vertical boilers. The water-tube boiler is generally conceded to be the safest type extant, and on the whole an extremely satisfactory boiler. The small space occupied by the vertical boiler is so great an advantage that it may be asked, "Are its disadvantages if any, sufficient to offset this saving in space?" In the water-tube boiler the sediment is deposited in a mud drum, well out of the way of the hot gases, and circulation of the water is rapid; there is no probability of burning out any of the tubes. In the upright boiler, however, the tube sheet is directly over the fire, and is certain to be covered to a greater or less extent with sediment and scale. In this respect it is subjected to the same dangers as the horizontal tubular boiler, namely burning out of that part of the boiler which is directly over the fire, provided the sediment and scale are not removed. It is held, however, that the danger from this deposit is not so great in the case of the vertical boiler as in the horizontal boiler. When a section of the shell is overheated in the latter, it must be patched, and the patch and rivets come in the worst possible place for such repairs. With the vertical boiler it is hardly possible for matters to reach so bad a state. When overheating begins, the tubes and tube sheet become weakened to such an extent that leaking at once occurs around the tubes, and if the deposit gathers over the whole tube sheet, there will be a sufficient rush of steam and water to completely extinguish the fire. If, on the other hand, the heating is local, only a small quantity of water will escape and may possibly not be noticed by the firemen until the tubes in that part of the boiler have become burned. In that case they must be renewed, whereas in the former case it will merely be necessary to expand them into the boiler sheet again.

When the boilers of the Atlantic Mill plant were first used, two of them troubled by leaking, and investigation showed a thick deposit of scale, although the boilers had been thoroughly cleaned and washed out with soda water before the fires were lighted. The water was also known to be free from lime, and the explanation of the scale formed was not forthcoming at once. Later it was determined that the deposit was formed of mill scale which came from the new tubes of the boilers. We do not know whether it is common for boiler manufacturers to pickle the boiler tubes in acid before putting in place, but this experience shows the necessity of it. The boilers had been filled with water some days previous and the tubes had undoubtedly rusted slightly. The boilers were to furnish steam for a Westinghouse-Parsons steam turbine. These turbines are governed by a rapidly reciprocating valve which delivers the steam in impulses, and at first the accompanying vibration was transmitted to the piping and boilers which probably shook off the loosened particles of scale, causing the trouble. The result was one of the unexpected things that so often happen, and is apparently an element that must be considered in starting up new boilers under similar circumstances.

TIMBER PRESERVING PLANT.

The rapid destruction of the great forests of this country has forced upon the railroads the very serious problem of the supply and preservation of timber, and many efforts have been directed toward perfecting processes to preserve the ties from insects and decay. In a recent installation by the Ayer & Lord Tie Co., of Chicago, the timber being treated is placed in air tight cylinders, where it is first subjected to steam under pressure to remove all air from the pores of the wood, after which the air and steam are exhausted by a Deane wet vacuum pump. When all vapor and gases have been removed, creosote is pumped into the tank and forced into the wood by a pressure pump of the Deane duplex type. A Clayton air compressor is next used to force air into the tank, displacing the creosote and returning it to an elevated storage reservoir. This process is said to give as good results as any now employed for tie preservation.

MACHINERY

DESIGN—CONSTRUCTION—OPERATION.

PUBLISHED MONTHLY BY

THE INDUSTRIAL PRESS,

66-70 WEST BROADWAY, NEW YORK CITY.

LESTER G. FRENCH, Editor.
FRED E. ROGERS, Associate Editor.

The receipt of a subscription is acknowledged by sending the current issue. Remittances should be made to THE INDUSTRIAL PRESS, and not to the Editors. Money enclosed in letters is at the risk of the sender. Changes of address must reach us by the 15th to take effect on the following month; give old address as well as new. Single copies can be obtained through any newsdealer.

We solicit communications from practical men on subjects pertaining to machinery, for which the necessary illustrations will be made at our expense. All copy must reach us by the 5th of the month preceding publication.

DECEMBER, 1904.

NET CIRCULATION FOR NOVEMBER, 1904,—22,214 COPIES.

MACHINERY is published in four editions. The practical work of the shop is thoroughly covered in the Shop Edition—$1.00 a year, comprising more than 430 reading pages. The Engineering Edition—$2.00 a year—contains all the matter in the Shop Edition and about 250 pages a year of additional matter, which includes a complete review of mechanical literature, and forty-eight 6 x 9 data sheets filled with condensed data on machine design, engineering practice and shop work. The Foreign Edition, $3.00 a year, comprises the same matter as the Engineering, but is printed on thin paper for transmission abroad. RAILWAY MACHINERY, $2.00 a year, is a special edition, including a variety of matter for railway shop work—same size as Engineering and same number of data sheets.

THE PROGRESS OF THE CONNECTICUT.

The rivalry between the private shipyards of the Newport News Shipbuilding Co. and that of the Government as represented by the New York Navy Yard in the building of the two 15,000-ton battleships *Louisiana* and *Connecticut* was briefly alluded to in the November issue. There is a general public interest in the matter as there is a sentiment abroad that the Government should be in a position to build its own naval vessels, if for no other reason than to make a healthy competition. There is also a general interest in the competitive results, because the Government yard is working under the handicap of an eight-hour day, while the private yards pay less wages for nine hours of service. The disadvantage under which the Government yard works is still greater than indicated by the length of the working days, inasmuch as the employes receive full pay for about seven legal holidays, and fifteen days leave of absence during the year. This makes twenty-two days, or over seven per cent. of the total number of working days in the year for which it pays but receives no service. On the other hand the Government yard pays no interest upon the investments represented by its shops, and it has to earn no dividends, hence whatever the actual cost of the vessel, there will need be nothing added to represent interest charges, or profit.

But it may be a fact that the eight-hour day and the holidays with full pay are no more serious drawback to the Government in the competitive building of battleships than are some of the many red-tape restrictions that are thrown around the operation of its ship yards. In any manufacturing enterprise, a demand for certain materials is certain to arise that could not well be anticipated, and it will be highly desirable to get them with the least possible delay. This the Government yard cannot do. It must go through the formality of advertising for bids and must in general take the lowest bid which may or may not represent the exact product desired. At the present time the New York Navy Yard has no 5/8-inch bolts in its stores, partly owing to an unexpected demand from another quarter, and it will be a matter of some weeks before the supply can be gotten. The private shipyard could and would, if necessary, order a hundred kegs by telegraph, but the New York Navy Yard cannot order a solitary bolt without going through the formality of advertising for bids. To make government work successful it would seem, therefore, imperative to, in some way, modify these restrictions on getting material promptly as required. In general, of course, it is possible to anticipate the main wants for material and provide for them long before they are required, but it is the small matters that cannot always be anticipated that cause vexatious delays.

The progress of the *Connecticut* is satisfactory from the point of view of the amount of work done. The report of the chief naval constructor, Rear Admiral W. L. Capps, states that the *Louisiana* was 54 per cent. completed and the *Connecticut* 49 per cent. at the times of launching, which were some weeks apart, but from what we have personally learned we do not think that all of this difference practically exists. The machinery of the *Connecticut* is well along toward completion, thanks to the efficient superintendence of Captain J. A. B. Smith, who is in charge of the Steam Engineering Department. The propelling engines were completed some months ago, and are now nearly erected in the vessel, although a period of only two months has elapsed since the launching. This quick work is due to an innovation in the matter of shop erection. The usual plan is to only erect the bare engine in the shop with none of the piping and other appurtenances that require so much time for installation on board ship. The engines of the *Connecticut* were erected complete in the shops in all details as far as possible. The water and oil service piping was placed, the sheet steel lagging covers were fitted and the thousand-and-one other matters that require much time and hard labor were done in the shop under the most advantageous conditions. Again, the engines were not taken apart to the extent that is generally the case. The pistons were left in the cylinders, being clamped in the top heads so the pistons did not project much below the stuffing-boxes. The frames were separated in units of six columns each and clamped together so as to be lowered onto the keelson with practically no change in their alignment. In this way the assembling of the engines has been greatly simplified, and because of the careful work done in the shop, practically little fitting has been necessary in the erection.

An encouraging aspect of the work on the *Connecticut* which will go a long way toward settling the matter of profitable competition is the enthusiasm and hearty service of the employes. In the popular mind, unfortunately, "government work" smacks of inefficiency and dilatory ways, but the conditions that may have been notorious in the past, seem no longer to be so much in evidence. It is claimed that the political faith of an employe is not a potent factor in securing place or preferment; all machinists applying for work must register, and as men are required they must be taken on in turn from the registry list. This method, while having the drawback of compelling the officials to give employment to all comers who pass the registry requirements, does not compel them to retain incompetent help, and it shields them, *if they so desire*, from the evils of political preferment. Hence there seems to be no reason why the handling of labor in the Government ship yards cannot be as efficiently accomplished as in private ship yards, if the officials in charge are of the right sort, and in the New York Navy Yard we believe there is as keen a desire on the part of those responsible as in any private concern. There may be some surprises in store for those who claim that the private shipyard is the only place where Government work can be efficiently and cheaply done.

* * *

The first thing a machine-tender must learn is that journals and bearings cannot be run without oil, or that if they are run without it they will not last long. The necessity of lubricant on working surfaces is not, however, confined solely to structures commonly dignified by the name of machines. Many of the ordinary appliances of common use would work much better and last much longer if occasionally a drop of oil was put where it is needed. Even with this conceded there are very few who would ever think of oiling umbrella joints, but it is said to greatly increase their durability. Oiling not only makes the joints work easier but it prevents rust, which, perhaps, is more destructive than the actual wear.

ENGINEERING REVIEW.

CURRENT EVENTS, TECHNICAL AND MECHANICAL—LEADING ARTICLES OF THE MONTH.

Some astonishing quantities of dust and dirt are reported as having been removed from apparently cleanly carpeted rooms by the vacuum or sucking process, which has previously been alluded to in these columns. The Fifth Avenue Presbyterian Church in New York City, a large edifice, was recently cleaned in this manner, the spoil being thirteen barrels of dirt sucked out of the carpets and crevices in the floors!

According to a statement in the *Philadelphia Record*, a concern has been organized for the utilization of the vast number of pine stumps that encumber the pine lands of Michigan and Wisconsin. The old stumps are subjected to destructive distillation which produces turpentine, tar, charcoal, and other characteristic products, and in addition what is said to be an excellent quality of lubricating oil. The discovery that lubricating oil can be obtained in this manner is new and this will be the first attempt to exploit the process commercially.

The experimental steel tracks laid about two years ago on Murray Street between Church Street and Broadway for the benefit of heavy trucking, have been torn up. The street has been repaved with wooden blocks and the steel rails will not be relaid. The experiment has demonstrated that steel tracks are a failure for city traffic consisting of horse-drawn vehicles. Although the rolling resistance to the wheels is greatly reduced with them, they were found to be a great menace to the horses. Horses frequently slipped and fell, sometimes breaking their legs or otherwise seriously injuring themselves. The use of the steel highway will become practicable only when the horse has been displaced by the self-propelled vehicle.

The *National Provisioner* says that glue, when combined with chromates and exposed to light, loses its solubility in water, and can, therefore, be used as a cement for articles exposed to moisture. The following is a suitable formula: White glue, 5 to 20 parts; water, 20 parts; potassium bichromate, one to two parts; water, 10 parts. Make the solutions of the glue and of the potassium bichromate in separate portions of water, as indicated above, the glue being dissolved by heat; stir in the solution of bichromate; mix well and then pour the mixture into tin boxes and allow it to congeal therein. For use, take a sufficient quantity of the glue, melt in a cup standing in boiling water; place a layer uniformly on the fractured surfaces, press them together, and expose the articles to the sun for a few hours.

A writer in *Sparks* intimates that low-carbon steel, say about .75 to .80 carbon, will harden deeper than high-carbon steel containing 1.30 to 1.35 carbon. Low-carbon steel has a much higher heat conductivity and a lower specific heat than high-carbon steel, and these reasons alone may account for the difference, although it is probable that the difference in the chemical action of the constituents of the two steels is also partly responsible. The heat conductivities of .50 and 1.33 carbon steel are about as 2 to 1; hence a large piece of steel of low carbon will give up its heat in the bath appreciably quicker than one of high carbon. It also has a slightly lower specific heat so that it contains from 1 to 2 per cent. less heat to give up. There is a surprising difference in the thermal conductivity of hard steel, soft steel and wrought iron, the coefficients being 0.062, 0.111 and 0.152 respectively.

One of the interesting applications of concrete is that of using it for setting posts and similar work, which, if set in the ground unprotected, would soon rot away. A wooden post treated with tar and set in a hole on a flat stone and surrounded by a firmly tamped bed of concrete is practically indestructible and will furnish a sound, substantial foundation for years to come. The same plan is used to some extent in setting of trolley poles, especially, when made of iron. The small diameter of the pole does not give the necessary stability to prevent its being racked out of place by the surging of the trolley wire. But if an ordinary hole dug for such a pole is filled with concrete it forms a mass 25 or 30 inches in diameter and of a length equal to the depth of the hole, which is solidly united to the pole, giving the latter several times the stability that it would have if set in earth alone. Moreover, the concrete preserves the iron for practically all time against corrosion, and it might reasonably be expected that poles so set may rust away above ground before the portion protected by concrete is appreciably affected.

From time to time, says a recent consular report, great efforts have been made by manufacturers and other producers to get rid of the middleman in trade, but so far these efforts have been of little avail. This has been particularly the case in Japan, and those manufacturers in America and England who have believed that they could benefit themselves by eliminating middlemen have had some disastrous experiences. Salesmen have been sent to Japan with this object in view, and endeavors were made to open up direct relations with the Japanese consumers. The result oftentimes has been the wasting of valuable time on commercial letters from students, schoolboys, and other irresponsible parties, whose motive in writing was merely that of curiosity or to get catalogues without the remotest idea of ever ordering goods; or orders have been filled from firms of no commercial standing with the obvious result of getting a lot of bad accounts. Theoretically, no doubt, the existence of the middleman is an economic loss, it being true that he produces nothing while he makes his living. Yet in practice it is found that his knowledge of markets and of business gives him a position in the social economy which would be difficult to otherwise fill. In other words he lubricates the wheels of business; machinery works with less friction with the application of oil, although the oil is not absolutely necessary to make the machine work.

Like most great and enduring enterprises Lloyd's had a small beginning. It is now to the world of shipping and marine insurance what the house of Rothschild is to the banking world. Lloyd's dates from the latter part of the reign of Queen Elizabeth, and had its origin in a small coffee house in Tower Street, kept by Edward Lloyd. He was an enterprising man, and through his business contact with seafaring men and merchants enlisted in foreign trade, foresaw the importance of improving shipping and the method of marine insurance. He was the founder of the system of maritime and commercial intelligence which has been developed into its present effectiveness. Before the time of Edward Lloyd maritime insurance in England was conducted by the Lombards, some Italians, who founded Lombard street, but after Lloyd embarked in the business, Britons conducted marine insurance in London. Lloyd's moved to Pope's Head Alley in 1770, and in 1774 removed to the present quarters in the Royal Exchange. In 1871 Lloyd's was incorporated by act of Parliament. This act defined the objects of the society to be: (1) the carrying on of the business of marine insurance by members of the society; (2) the protection of the interests of members of the society in respect of shipping, cargoes, and freights; (3) the collection, publication, and diffusion of intelligence and information with respect to shipping.—*Consular Report.*

In the transactions of the Lake Superior Mining Institute, Mr. James R. Thomson refers to the very difficult conditions under which deep mine hoisting engines operate. For instance, the big Nordberg quadruple engine hoist at Tamarack lifts from an approximate depth of 5,000 feet and makes from eighteen to twenty trips an hour, thus giving the skip or car an average rate of travel of about 35 miles per hour. The work is of such a peculiar nature that compound or triple

expansion engines are unfitted for it. The load consists of the weight of the ore, the weight of the skip and the weight of the rope. This latter weight is greatest when the skip is at the bottom of the shaft, and decreases as it nears the top. The engine must start with the maximum load, attain full speed in six or seven revolutions, and stop short all within, say, one minute, and after a longer or shorter period of idleness must repeat the operation. Lake Superior hoisting experience has fully demonstrated that simple Corliss engines or other engines of automatic variable cut-off give more economical results than fixed cut-off engines. The economy of using compound or triple expansion engines is indefinite and negative. In this connection the Rateau regenerator and steam turbine work a considerable economy in hoisting plants. The main engines exhaust into a closed regenerator and from this the steam supply of a steam turbine exhausting into a vacuum is taken. The turbine drives an electric generator which supplies current for lights, auxiliary apparatus, etc.

An important difference between the construction of wire ropes and hemp ropes is in the laying of the strands. From time immemorial hemp ropes have been made with the twists of the strands opposite to those of the rope, the object, of course, being to prevent unraveling. Wire ropes were originally made in the same way, but a few years ago a construction known as "Lang's lay" was introduced, in which the twists of both the strands of the wire rope are in the same direction. This makes a very important difference in the wear of ropes running over pulleys or sheaves. In a wire rope made like a hemp rope the wear is concentrated on the crowns of the wires where they pass over the top of each strand, since this portion is the one that comes in direct contact with the sheave groove. In the Lang's lay system the crown is not so acute, and a much larger continuous surface of any wire is exposed to the wearing action, that is, the wear is more nearly parallel with the length of the wires. Oiling wire ropes also has a great effect upon their life. Tests made on ropes oiled and unoiled have demonstrated that oiled ropes will give from two to five times the service of those unoiled. But perhaps the greatest factor in the life of a wire rope is the diameter of the sheave over which it runs. If the diameter of the sheave is so small that with ordinary loads the elastic limit of the outer wires of the rope is exceeded every time the rope passes over the sheave its life will be very short. But if the diameter of all sheaves is made at least 40 times that of the rope, its life will be long.

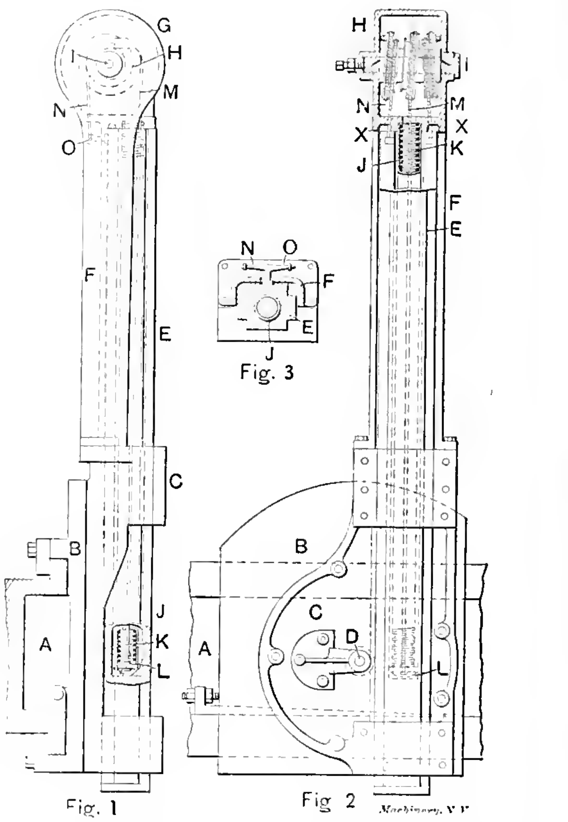
COLD-SOLDERING BANDSAWS.

The brazing of bandsaws with silver solder is an operation requiring considerable skill on the part of the workman, and is an objectionable process because the high temperature necessary to melt the silver solder also draws the temper of the saw at the joint. One of the junctures where the tempered and untempered parts of the blade join is likely to be the point where the next break takes place. Since the breaks are repaired by making lap joints, it follows that a saw becomes shorter and shorter with each repair, and after it has broken a number of times it is shortened so much that it can no longer be used without inserting a new piece, which is objectionable as it makes two joints instead of one to give trouble. A so-called "cold-soldering" process for bandsaws is being exploited by a British concern, that is of interest. By the new process, to which the name "Forkor" has been applied, the joint is made by a method of cold-soldering which is very simple, and requires no apparatus beyond a clamp, spirit lamp, and a pair of broad-faced pliers. The broken ends of the saw are, first of all, filed for a length of from three to four teeth, and then brushed over with a white fluid, the composition of which is at present a secret. The ends, thus coated with the liquid, are warmed by the spirit lamp and rubbed with a stick of solder until the surface is well covered with metal; after which a second layer of the liquid is applied. The ends are then clamped in position and heated again until the solder melts, and are then pressed firmly together with the pliers to squeeze out the excess of solder. After dressing with a file the saw is ready for use.

The advantages of the process, says the *Engineering Review*, are that the temper of the saw is not affected, and should a break occur again it always takes place at the joint. As, therefore, there is no shortening of the saw, it can be used for a much longer period than would be possible were the brazing process used. The time occupied is less than half that necessary for brazing, and, moreover, the saw can be used at once. The cost of making a joint, it is claimed, does not exceed two pence.

BALANCING ARRANGEMENT FOR THE RAMS OF BORING MILLS.

In boring and turning mills the ram or tool holder is usually balanced by means of a cord or chain and weight, but this arrangement is not all that could be desired. To provide a better arrangement the spring balancing device shown in Figs. 1, 2, and 3, has been designed and patented by J. E. Mathewson, of Broadheath, near Manchester. Referring to the illustrations, which with the description are copied from the *Mechanical Engineer*, *A* indicates the cross slide of the machine, the construction of which is well known; *B* is the saddle, and *C* is the ram frame which is pivoted at *D* to the



Balancing Arrangement for the Rams of Boring Mills. See "Machinery," March, 1904.

saddle. *E* is the ram or tool holder which slides in guides in the frame *C*. On the top of the frame *C* is secured a support *F* which supports the box *G* containing the fusee or equivalent equalizing device *H* and the bearings for an axle *I* carrying the same. The ram *E* is hollow, and contains a coiled spring *J* inclosed by a tube *K*. The spring at the top abuts against the under side of the box *G*, and at the bottom rests on a cylindrical block *L* to which the cord or flexible connection *M* is attached. This cord after passing round a fusee is secured to the axle *I* in any convenient manner. On the same axle there are mounted two fusees to which cords *N* are attached, the other ends being secured to arms *O* secured to the back of the ram *E* and extending through a slot in the ram guide, as shown clearly at Fig. 3. As the ram *E* is lowered to bring the tool to its work the axle *I* is rotated by the fusees, and the spring *J* will be compressed through the cylindrical block *L* which is drawn up by its cord *M*, and when the ram is released the spring will return it to its normal position, all of which movements will be clearly understood on reference to the cut.

THE "AUTOPYROPHON."

The "autopyrophon," is a new and simple automatic fire alarm which acts only when a sudden wave of heat is generated in an inclosed space, but is not influenced by a general and evenly high temperature. It is only 3.91 inches high, 2.76 inches broad, and 0.78 inch deep, hence it can be easily fixed anywhere. It consists of a small glass tube bent in the shape of a capital U. This tube, the ends of which are closed, is half filled with mercury, the other upper half containing a highly volatile liquid—for instance, sulphuric ether. One of the upper parts of the glass tube is surrounded by a cover of some non-heat conducting material, so that a sudden rise of temperature affects only the other or free part of the glass tube. In case the temperature rises evenly the whole apparatus is affected and no warning signal is given. If, however, the temperature in the room is suddenly raised, as by the outbreak of a fire, the ether above the mercury in the glass tube, which is unprotected, evaporates, and the pressure of the generated vapors causes the mercury to sink in the tube while it rises in the opposite part. Both parts of the tube are fitted with an electric wire fused into the glass, so that when the mercury stands equally high in both tubes the electric current passes through and the apparatus remains silent, but should a movement of the mercury take place because of a sudden rise of temperature, the electric circuit or contact is impeded, and any kind of electric alarm may be set into motion at any distance and at as many places as required. The apparatus also indicates impediments and interruptions of the electric current. The substances need no renewal and the apparatus acts an indefinite length of time.

The United States Consul-General of Munich, Germany, who was present at a recent demonstration of the device, states that the alarm was raised within eight seconds from the time a small heap of shavings was set on fire in the corner of an ordinary sized room. In this case the apparatus was fixed near the ceiling at the end of the room, opposite that where the shavings were burning. It is calculated that one apparatus which costs about $3 00 is needed for an area of 600 to 800 square feet.

RADIAL STAYBOLTS FOR OIL-BURNING BOILERS.

Railway Master Mechanic, October, 1904.

It has always been a serious problem to maintain locomotive boilers on oil-burning engines owing to the increased intense heat over the coal burning engines. Radial staybolts have been the greatest source of complaint, owing to their leaking, and heads dropping off, and this has compelled the railroads to substitute a bolt which will withstand the enormous strains under oil-burning conditions. With radial staybolts having large button heads, the most trouble experienced has been that the heads drop off after they have been calked but a short time, and also on account of too much iron at a

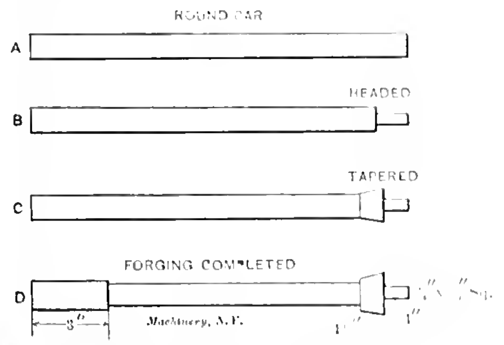


Fig. 1. Successive Steps in the Forging of a Radial Staybolt

point too far away from the water. When the burning oil is shut off the only heat retained in the firebox is in the brick arch and brick walls. This heat is not sufficient unless a good fire is retained, and the boiler is caused to contract very rapidly. The stresses set up by these alternate expansions and contractions are very severe. Unless the handling of the engines, and the keeping of a regular fire are watched very carefully, radial stays, staybolts, and flues give much trouble by getting loose in the holes.

A bolt which is now being used on several railway [illegible]tems is shown by the accompanying line drawings, which [illegible] trate the method of manufacture and application. T[illegible] sheet end of the bolt is made tapering and is cut ve[illegible] to the sheet and hammered up well, thereby making [illegible] as well as steam tight. This bolt up to the present time has been found to meet the requirements better than any other bolt yet tried.

These staybolts are made on the bolt header in the blacksmith shop, and taken direct to the bolt cutter in the boiler shop and finished complete, with the exception of nicking,

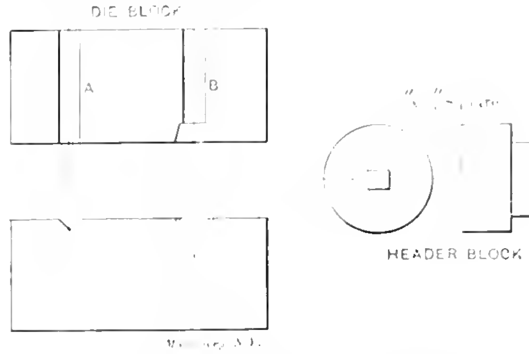

Fig. 2. Die Block and Header Block

which is done in a small chuck lathe, made especially for this purpose. By this process the lathe work is entirely dispensed with.

Taper staybolts, as applied in the San Bernardino shops of the A., T. & S. F. Ry., are of the form shown by Fig. 6, of proper length and diameter to fit holes. The straight thread part is somewhat larger than the body of the bolt, and the taper end has a flare of about one-eighth inch to the inch. A square head is forged at this end to permit the application of a wrench in placing the bolts. These staybolts are forged in an "Ajax" bolt-header, the die block being of the form shown by Fig. 2, with a triangular groove *A* and a countersunk cavity *B*, of shape and dimensions determined by the size of bolts to be headed. The rough bar, of the desired length, is first squared for a distance of one inch at one end. The bolt is then placed in position in the cavity *B* and the heading die-block having a cavity to fit the square head of the bolt, forces the hot bolt into *B*, forming the flared end. The straight end is formed in the usual manner in a straight block. The successive stages of the operation of forging are shown at *A*, *B*, *C*, and *D*, in Fig. 1.

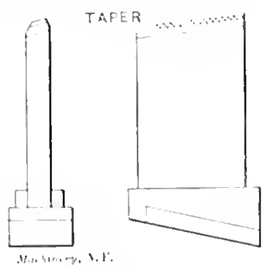

Fig. 3

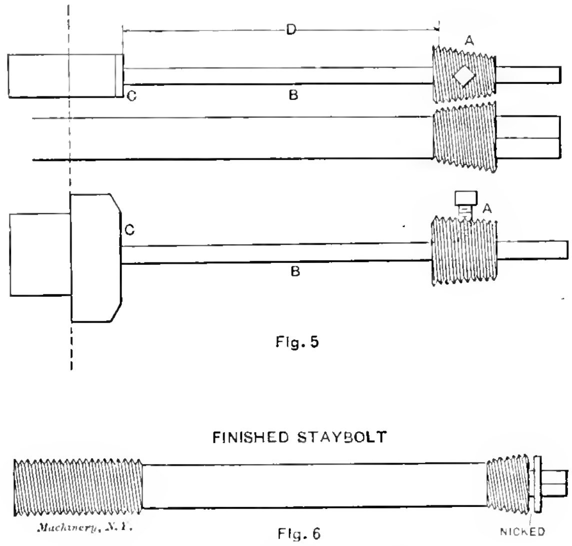
Fig. 4

The holes in the sheets are tapped with a spindle tap, both threads being cut in one operation. The threads in the two sheets come in perfect alignment and are continuous. In order that the staybolt may follow the threads of the two holes, it is necessary that the threads at both ends of the staybolt be continuous, that is, they must "catch up." These threads are ordinarily chased in a lathe, which insures this condition, but a very simple and effective device makes it possible to cut these threads in a double-headed staybolt cutter; in this way a considerable saving in cost is effected. Tapered dies are made for the bolt cutter of the required sizes, as shown in Fig. 3. The staybolt is placed in the machine with the tapered shank in position for cutting in the dies, held in a simple chuck, shown by Fig. 4. This chuck has a cavity of the proper size to hold the square head of the staybolt, and is rounded and tapered at that end to allow it to follow the staybolt into the dies. This chuck is held in the vise of the machine, and the bolt forced into the dies, which

are regulated in the usual manner for the proper diameter to fit the tapped holes. After the thread has been cut on the tapered end of the bolt, it is placed in the vise, being held at about its middle with the straight shank in position for threading. The dies are, of course, changed to the straight cutting form. Placing the bolt haphazard in the vise will not insure making the threads "follow," and consequently a gage, as shown in Fig. 5, is used to accomplish this end. This gage consists of a block *A*, held on a spindle *B*, by a setscrew. The block *A* is threaded the same as the staybolt, but the taper is reversed to allow the threads to mesh with those of the tapered end when in position. The shoulder *C* is made to rest in the jaws of the vise while holding the staybolt in position for cutting. The distance *D* from the shoulder to the bottom of any thread on the block *A* is set so that it will contain a whole number of threads. For example, if twelve threads per inch are used, *D* would be set in inches and twelfths, etc. This



Method of Locating Staybolt by Gage · Finished Staybolt.

having been done, the distance from the shoulder in the other direction, to the threads on the other end of the staybolt will also be such as to contain a whole number of threads, and the requirement is fulfilled that the threads shall follow, and the staybolt will fit the threads of the holes.

The threads on both ends having been cut, the staybolt is placed in a small cutting-off machine, and nicked just under the head, so that the square head may be easily chipped off after the bolt is in place.

[These staybolts are, we infer, cut in a bolt cutter having a leadscrew which positively controls the movement of the carriage. The gage shown in Fig. 5 must first be adjusted by a staybolt in perfect lead, *i. e.*, one cut in a lathe. It is located in the correct position in the vise by closing the dies on the straight-thread end, and the gage is then set by it; it in turn serves to locate the staybolts as explained.—EDITOR.]

EXPERIMENTAL WORK ON SOLID EMERY WHEELS.

Extract from Paper presented by Mr. T. Dunkin Paret at the May 12, 1904, meeting of the Franklin Institute.

The main cause of bursting emery wheels is heat, but just how heat operates is somewhat of a mystery. The conclusion seems natural that wheels which are poor conductors of heat are the most unsafe. In such wheels the heat created by friction at the circumference works slowly toward the center, and the outer rim expands with speed disproportioned to that of the center. Such expansion might result in cracks transverse to the face and other cracks radiating from face to center. As a matter of observation, the wheels which are unsafe are those whose substance conducts heat easily, and which quickly get hot all through. Such wheels throw off broken edges and irregular chunks, and burst without any definite system of cracks. It follows from this that wheels entirely mineral are not, as a class, so safe as those in which the mineral grains are surrounded and separated by gums, glue, and other organic matter.

The adhesion of metal to the surface of the wheel is also, to some extent, an effect of heat. It may be that wheels with this defect overheat and soften the metal, or the adhesion may be due either to the chemical constitution of the wheel or its physical structure. It is a clearly ascertained fact that free-cutting wheels are not characterized by such adhesion, and that slow-cutting wheels are. It is also evident that as the metal increases in heat the cut (or product) decreases. It is seldom that the end of a ¾-inch by ½-inch cast-iron bar is much reddened by the grinding of a free-cutting wheel, and the edges of the bar are generally clean-cut. Under the same conditions wrought iron gets red-hot for a considerable distance, and flattens out and bends over at the edges.

Many years ago an experimental test machine was built in which the metal was forced against the wheel by a continuous screw feed. As the bar elongated with heat, the pressure increased, and with increased pressure increased heat was generated. Under these conditions the bar became intensely hot and red, and the wheel almost ceased to cut.

Complicated with these questions of heat is the subject of contact area and clearance. The ideal conditions of grinding are those in which wheel and work come in contact on a narrow line. A thin edge of saw steel will be ground rapidly and effectively if pressed against the face of a wheel, while a large flat surface shows little product if pressed against the side. While this is partially due to the vastly greater pressure per square inch in the case of the thin edge, it is also due to the lower heat which results from proper clearance. In the case of the thin edge all debris of wheel and metal fly instantly away, each grain removing its quota of heat. In the case of two large flat surfaces rubbing together the debris is retained (with its included heat) and is bruised into the interstices of the wheel, interfering with its cut. For this reason it is a radical mistake to fit wheel and work in such way that large surfaces are in contact. Cone wheels exactly fitted to corresponding interior metal surfaces (axle surfaces, for instance) are a mistake. So would be large curved grinding blocks, if applied like brakeshoes to the curved face of a carwheel.

The tread of car wheels has long been ground in a practical way with an ordinary disk-shaped emery wheel, the curved exteriors merely touching on a narrow line and affording excellent clearance for wheel and metal debris. For this process, some years ago, was substituted a grinder, in which cup-shaped wheels were used. When the writer of this paper saw that machine in operation, a keg of grain emery stood close at hand, and the operator from time to time dropped some of it between the car wheel and the emery wheel. Questions and further examination brought out the fact that flecks of metal adhered periodically to the emery wheel, and that no proper work could be done until these were removed by the use of the loose grain emery. It was stated that the formation of a single fleck could be heard at the most distant corner of the shop, and this proved true. It was also stated that, when the rims or cutting edges of these wheels were pretty well worn down, such rims were removed entirely, and the wheels transformed into ordinary disk wheels. In this altered form, when the convex exterior of the grinding matter was used instead of its flat side, the wheels did good work and no metal adhered to them.

In the absence of verified data as to the relative cutting capacity of small and large wheels, it is well to point out the manner in which circumference and mass modify the effects of frictional heat. The circumference of a 6-inch wheel is about 19 inches; that of a 36-inch wheel about 113 inches. A wheel 6 inches by 1 inch contains about 28 cubic inches; a wheel 36 inches by 4 inches about 4,000 cubic inches. The standard speed of a 6-inch wheel is 3,600 revolutions per minute; that of a 36-inch wheel 611 revolutions. If a bar ¾ inch by ½ inch is ground on these wheels the heat problem will be different in each case. At the first moment, when bar and wheel come in contact at heavy pressure, intense heat will be developed. In the 6-inch wheel this spot (each and every point of contact) will be heated 3,600 times in a minute, while in the 36-inch wheel it will be heated only 611 times. Though both wheels travel at the same surface speed, the circumference of the 36-inch wheel is so much greater

that it has about six times greater ability to cool. The greater area of its surface causes greater radiation and loss of heat, while that which remains has about 1,000 cubic inches of matter to diffuse itself through, instead of the 28 inches allotted to the 6-inch wheel. If, therefore, frictional heat is an undesirable thing, the advantage of large wheels becomes evident.

There is *apparently* one clear deduction from these facts, and this is that water should be used to prevent the injurious effects of heat. Nothing can be more erroneous than this deduction, and nothing has done more to retard the proper development of grinding processes. The use of water on solid emery wheels is a survival of the old Sheffield methods, in which huge grindstones are run in a stream of water, in which the workman straddles a board that presses his work against the stone, in which the heaviest man is the best grinder.

The use of water has been urged indiscriminately as an excuse for an increased variety of grinding machines, and, in times past, as a method of using emery wheels too weak and poor to be used dry. It is not an uncommon thing to read, in commercial literature, that certain wheels can be used equally well wet or dry. In justice to the getters-up of such vague assertions, it is assumed here that they are not intended to imply equal products by the wet and dry processes. It is to be feared, however, that the long-continued and oft-repeated assertion of this generality has created a false impression.

In opposition to any such view, it should be stated in the strongest way that water is a lubricant. Exact data on this subject seem to be almost entirely lacking, but the only ones known to the writer (and procured under his supervision) are now given. Seven different makes were tried under conditions identical except as to the fact that in one series the wheels were used dry and in the other series wet. Sixteen consecutive, intermittent cuts were made by each wheel in each series of trials, the speed being about one mile per minute, the pressure about 112 pounds per square inch, and the material ground cast iron. The total product of five of these wheels under the dry process was 186 12-16 ounces, while under the wet it fell off to 24 13-16 ounces. Two (out of the seven) wheels gave a larger product under the wet process than under the dry, but this result confirms the facts previously adduced as to over-hard wheels and the lessened product due to metallic adhesion. In 32 minutes these two wheels ground off, under the dry process, 2 2-16 ounces, and, under the wet process, 10 2-16 ounces. It seems evident that in this case the use of water lessened the metallic adhesion.

The fact is that water is only necessary to protect metal from the effects of heat. Where there is danger of warping in some article held while cold under the stress of undue tension, or where some desired temper is altered, water can be advantageously employed, but its indiscriminate use (on tools, for instance) encourages careless methods. The dry process carries on a steady educational work, the grinder acquiring increased delicacy of touch and greater knowledge as to the contraction, expansion, density, stress, and temper of metals.

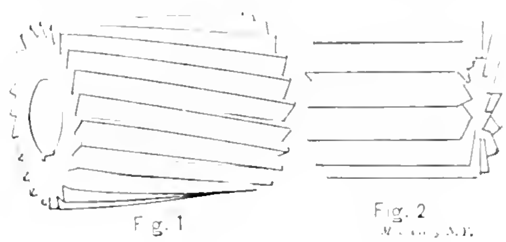
It is a too common assumption that tools cannot be properly sharpened on a dry wheel, yet experienced operators can produce any desired temper by the skilful use of the dry process. The tempering furnace has been (in at least one instance) abandoned for a tempering wheel, and saws have been given an increased durability by the special hardness due to careful use of a dry wheel.

The advantages of intermittent pressure, as affecting the heat problem, are very evident, and the disadvantages of grinding with a flat surface have been pointed out. The facts that high-speed is connected with a free cut, and that a free cut generates the least heat, are well understood. It will, therefore, be readily perceived that if a knife edge is ground on the flat surface of a wheel at half speed, under an unyielding screw feed, all the elements of temper destruction are present. Nevertheless, a 2-foot planer-knife, with bevel 13-16-inch wide, has been successfully ground on an automatic knife-grinding machine with a dry wheel, under the disadvantageous conditions just stated. The record states that such grinding did not blue the knife, which remained cool enough to handle. If a machine can do this, what will not the sensitive and delicate hand of a skilled workman accomplish?

THE SHAPING, GRINDING AND HARDENING OF MILLING CUTTERS.

Zeitschrift fur Werkzeugmaschinen und Werkzeuge, May 5, 1904, p. 316.

The milling cutter plays a most important part in the modern workshop and a great deal of attention has been devoted during the past twenty years to its development. In the care of these tools the methods have grown from the use of the file for dressing and shaping to the almost universal employment of the emery wheel for that purpose. These cutters may be divided, according to the work that they are intended to perform, into two main groups; the axial cutter, as shown in Fig.



Axial and Radial Cutters

1, and the radial miller of Fig. 2. The first works on a plane parallel to its axis, and the latter on one at right angles to the same. The form of the teeth in the two also differs. For example, we make the cutting angle, B, of Fig. 3, and the clearance angle, c, the same as that of a flat chisel for use on the same metal, while the angle of rake for cast iron runs from 0 to 2 degrees, and that for wrought iron about 5 degrees. The clearance angle had best be the same for all cutters, and for both metals from 5 to 8 degrees. In the matter of the form of the clearance surface, R, there should be a difference between the two kinds of cutters. Ordinarily a tooth of triangular section is used; though, for form cutters, the trapezoidal as in Fig. 3, is also found. It is well known that the face of the tooth s is the place where the grinding is done in the case of the tooth that is to be maintained in constant shape, and the angle of rake must then be kept equal to 0 degrees. The teeth of ordinary cutters on the other hand are sharpened on the back. It is, therefore, easily seen that, in the first method of sharpening it is necessary to remove much more metal than in the latter

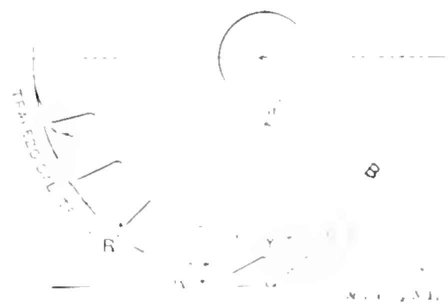


Fig. 3 Illustrating the Shapes and Angles of Teeth

with the result that much more is wasted. This is shown graphically by the hatched portions at the cutting edges of the ordinary and trapezoidal teeth shown in Figs. 4 and 5.

In the cutter with teeth of the ordinary form, the angle of rake a is fixed. It is, however, by no means a matter of indifference as to the form of cutter that shall be used in shaping the teeth. Figs. 6, 7 and 8 show the three forms of cutters that may be used in shaping the teeth on a cylindrical surface. In the forms shown in Figs. 6 and 7 one of the cutting surfaces lies at right angles to the axis of the cutter. In this it is of importance that the end cutting section a should work upon the face of the tooth as in Fig. 6. On the other hand, it is a great disadvantage that the points of the teeth should be so exposed that they cut a more or less jagged surface on the face of the cutter. A better arrangement is that shown in Fig. 7, where the cutters for the front of the tooth run parallel to the

same. A better piece of work can be done with a cutter shaped like that shown in Fig. 8, where both surfaces are worked out by cutters running parallel to them. The adjustmeut of such a cutter can best be made by means of a sheet metal templet like that shown in Fig. 9. It should be provided with a hub, *N*, whose hole will fit over a mandrel or stud run through the center of the cutter to be milled. The angle *a* for cutters intended for use on cast iron had best be made of from 3 to 6 degrees, according to the rake that is desired. The number of teeth, their pitch and depth are, for the most part, left optional, with the result that even in large and well-built machines there is a great deal of chattering.

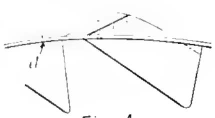

Fig. 4

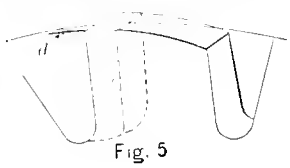

Fig. 5

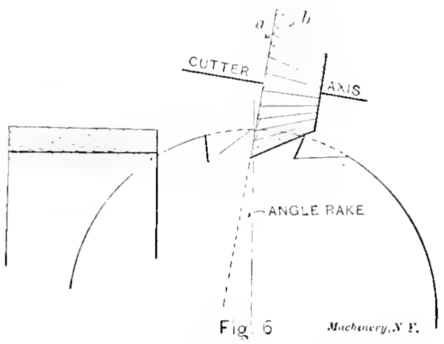

Fig. 6

Relative amount of Metal Removed in Sharpening—One Form of Cutter used for Shaping Teeth.

No hard and fast rule can be laid down for this work, and existing practice is quite varied in its details. In his own practice the writer has taken quite a simple course: The diameter, *D*, of the cutter is first obtained; this depends upon the work to be done and should be as small as possible. The thickness of teeth, *t*, should then be determined from the following formula that has been derived from practical experience:

$$t = \frac{D}{10} + c$$

For cutters up to			2	inches diameter	$c = \frac{3}{16}$ inch.
" "	from 2	inches to	4	" "	$c = \frac{5}{32}$ "
" "	" 4	" "	$4\frac{3}{4}$	" "	$c = \frac{1}{8}$ "
" "	" $4\frac{3}{4}$	" "	6	" "	$c = \frac{1}{16}$ "
" "	" 6	" "	$7\frac{1}{4}$	" "	$c = \frac{1}{32}$ "
" "	" $7\frac{1}{4}$	" "	8	" "	$c = 0$ "

In order to determine the number of teeth, the nearest whole number to the quotient of $\frac{3.1416\ D}{t}$ should be taken. Thus for a cutter of 4 inches diameter we would have 24 teeth and this would cause a modification of the calculated thickness of the tooth from .55625 inch to .5027 inch.

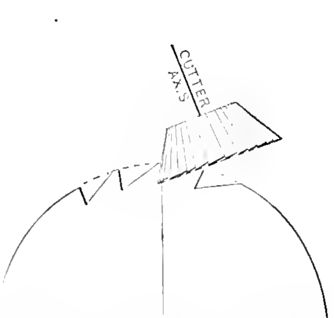

Fig. 7.

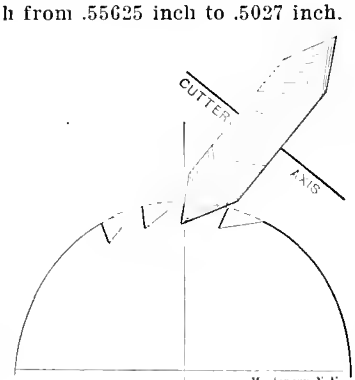

Fig. 8

The exact clearance angle, *c*, Fig. 3, should be given to the tooth by grinding. The grinding of the ordinary milling cutter is done in three ways, each of which has its advocates. In the first and oldest methods it is done at the back on the face of the clearance angle, as shown in Fig. 10, with a small emery wheel, which should, however, have as large a diameter as possible, so that the surface may not be ground hollow. This concavity of surface is the principal objection to this method of grinding, but on the other hand the defect can be readily obviated if the axis of the emery wheel in the horizontal plane is made to stand at a slight angle with the axis of the cutter, as in Fig. 10, instead of parallel to the same, and especially if the cutting face is turned in a direction opposite to that of the inclination of the cutting edge. A special difficulty is to be found in this as well as the other methods of grinding in so adjusting the wheel that the proper clearance angle, *c*, will be given to the tooth. In fact one is dependent entirely upon an inspection or test and the experience of the workman. If the teeth are of the ordinary form, and do not vary essentially from that called for in the rule given above, the clearance angle can best be tested by means of a straightedge laid over two teeth, as shown in Fig. 11, in which the clearance surface of tooth *l* should coincide with the face of the straightedge. If the teeth are pitched closer together than the rule calls for, the angle should be sharper than that of the straightedge. It is also important that the guide, *s*, Fig. 10, by which the tooth being ground is held in place and which governs the position of the tooth relatively to the emery wheel, should be brought to bear against each and every tooth and not against every second tooth, as is the case in common practice. For the sake of convenience this precaution is frequently neglected, with the result that the grinding is not the same on all of the teeth.

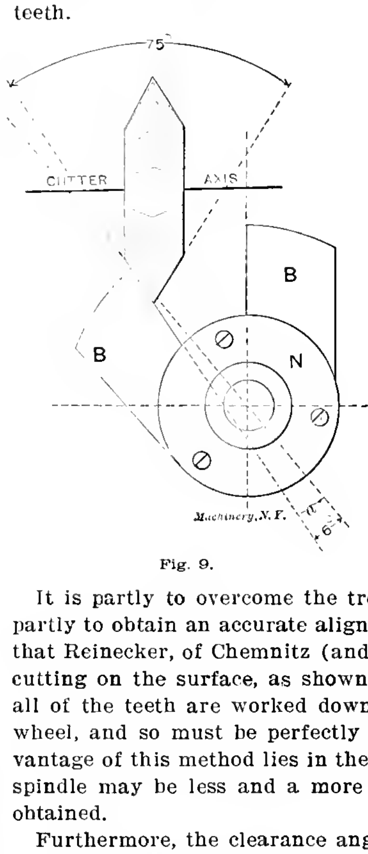

Fig. 9.

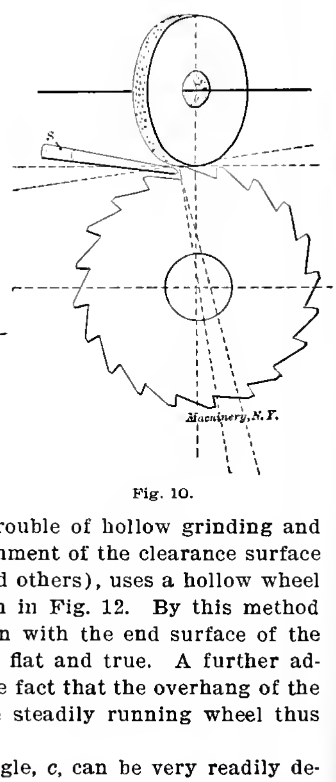

Fig. 10.

It is partly to overcome the trouble of hollow grinding and partly to obtain an accurate alignment of the clearance surface that Reinecker, of Chemnitz (and others), uses a hollow wheel cutting on the surface, as shown in Fig. 12. By this method all of the teeth are worked down with the end surface of the wheel, and so must be perfectly flat and true. A further advantage of this method lies in the fact that the overhang of the spindle may be less and a more steadily running wheel thus obtained.

Furthermore, the clearance angle, *c*, can be very readily determined by an examination so that it may be regulated by a fine adjustment of the guide, *s*, against the tooth that is being ground. The greater surface of wheel in contact with the tooth, however, increases the danger of heating, and for that reason the use of the hollow wheel is sometimes specifically forbidden.

The third method consists in the grinding of the tooth on the front and back at the same time. It is done in exactly the same way as the work of cutting the tooth in the first place, except that, instead of the milling cutters used, as in Figs. 7 and 8, an emery wheel is used, as in Fig. 13. Special automatic machines are built for this purpose and the advantages claimed are that the height of the tooth is not decreased, because of the fact that the wheel is at work on two surfaces so that the cutter does not have to be reheated and rehardened after a short period of wear. This advantage disappears, however, because it has been ascertained that the deepening of the tooth

by grinding requires the removal of so much metal that a great deal of time is required, if, indeed, the whole center is not thrown out of shape by the heating that results from such a grinding. So that the consensus of opinion is that one of the first two methods of grinding on the clearance edge is that to be preferred.

It is of the utmost importance that this grinding should be done on a well-built and reliable machine, for no machine having to do with milling can so easily get out of adjustment and do bad work as an emery grinder; and then, when bad

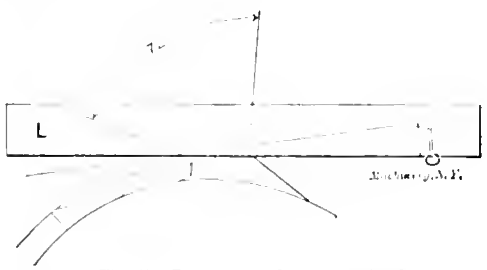

Fig. 11. Testing the Clearance Angle.

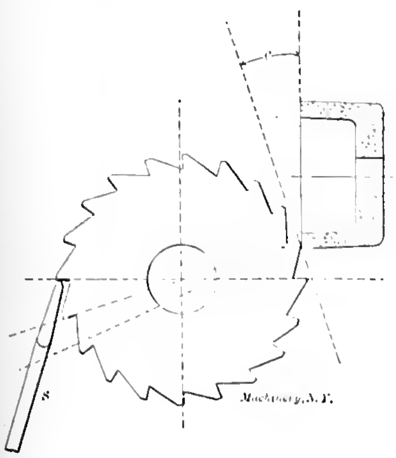
work has been done, it is usually first detected when a job has been spoiled in shaping. Good emery grinders and skillful operators of the same are, therefore, quite as important as the milling machines and cutters themselves. It is, then, not only necessary that the cutting and clearance surfaces should be ground to the proper angles but that the grinding should be so carefully done that the edges of the teeth shall not be heated. If, during the grinding with an emery wheel, the teeth of the cutter are heated to such an extent that they turn blue, the grinder can easily obliterate all traces of his carelessness, by simply passing the wheel once gently over the surface, and then it will not be detected until some defective piece of work is turned out, when the workman and foreman will be more apt to attribute it to the faulty hardening of the cutter than to the man who ground it. For these reasons it is not well to grind the face of the tooth, because overheating is at once visible and the workman has a chance to cover the mistake. The simplest means of avoiding heating in grinding is to use a wet wheel—a method that is most feasible with the Gould & Eberhardt machine where a strong stream of water may be directed against the work, and not one drop be thrown out. It has also been frequently observed that of all things connected with the careless handling of the grinding machine, the overheating of the stock is the most common. An efficient wet-



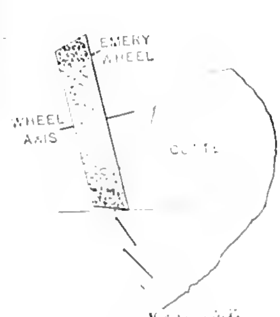


Fig. 12. Fig. 13

grinding machine for working on all sorts of ordinary milling cutters, does not seem to have been brought out as yet and therefore the field is open to some skillful designer to fill the gap.

By careful watchfulness over the grinding machine, faulty grinding can frequently be avoided. If, for example (it may be remarked in passing), a strong stream of sparks is produced in the sharpening of a cutter, it is safe to conclude that too much metal is being removed at a time, and that the cutter will be heated and left out of round. Again, if, when at a short distance from it, the emery wheel is heard to work with a series of dull blows, it will be found that it is not cutting, but is merely sliding over the teeth of the cutter and heating them. A noisy emery wheel is either dirty or glazed over and must be turned down, else it is hard and fine grained. A properly working emery wheel produces a steady ringing tone, which is recognized at once as evidence that it is cutting. In short, wide-open eyes and sharp ears are the most efficient assistants to the careful grinder.

For a long time, now, milling cutters of large diameter have not been made of a single piece, but with a number of inserted teeth. The fastening of these teeth in the cutter head is accomplished by means of screws, keys or by casting them in. Experience with certain forms of these inserted teeth has been that with the ordinary forms of axial and radial cutters, the pitch must be made greater, and the teeth stronger. Hence the shape shown in Fig. 14 has been developed, which differs slightly from that shown in Fig. 3, in that the clearance surfaces are made broader and the curve at the root of the tooth sharper. The difference from the form of Fig. 3 is really very slight; for, in place of the curved clearance surface, *R*, it is straight. Teeth of this form are made in the same way as those of Fig. 3, with the exception of the clearance surface, which is first cut with a miller and then, after hardening, is ground with a hollow wheel, as shown in the second method, Fig. 12. Milling

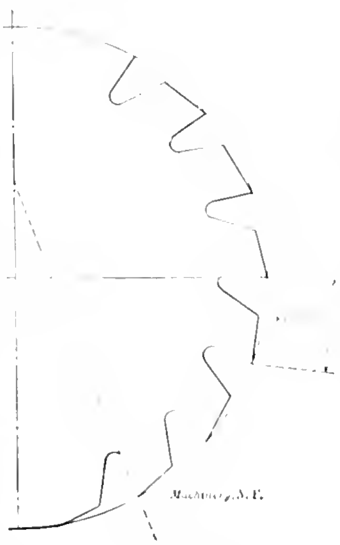

Fig. 14 Fig. 15.

cutters of this kind when run upon strong, well-built machines are capable of taking a very heavy cut with a comparatively small expenditure of power.

A few words should also be said regarding the screw shape or longitudinal pitch of the teeth. The twist of the teeth is a necessity, to insure that the whole of the work shall not, at any instant, be thrown entirely upon one tooth, and that the cut shall be a drawing one so as to clear itself well. A diamond-shaped cutting edge is a necessity. In ordinary cylindrical milling cutters the cutting edge of the tooth usually stands at an angle of from 15 to 20 degrees with the center line; and it is, furthermore, immaterial whether it leads to the right or the left. In vertical- and side-cutting millers, such as bar cutters used for profiling, that twist, on the other hand, should be from left to right when looked at from above, if the cutter is to be used in a hole; since a left-handed twist would tend to carry the chip downward, and also force the piece being operated upon down against the table or platen. Bar cutters, which also work at the ends, as well as the regular end mills, must have teeth leading to the right, and it is especially necessary that the rake or cutting angle of these end cutters should be quite blunt. For bar cutters working on the sides only, the inclination of the cutting edge to the axis of the cutter may be made larger, and rise to from 30 to 40 degrees; which, especially on wrought iron, gives a marked advantage in cutting. In the case of end cutters this angle should not be more than 20 degrees, else the teeth at the end will be made too sharp, as in Fig. 15, and thus be too easily broken; whence the twist angle of the cutting edge which becomes the rake angle of the end teeth should be limited to 20 degrees at the highest, instead of the 30 degrees previously recommended.

It remains, now, to say a few words regarding the hardening of milling cutters, a subject which has already been frequently

discussed. For the machinist in small shops, where a special hardening plant is not provided and where the milling cutters must be hardened in the shop smithy, a few practical suggestions will not be out of place. It is, of course, self-evident to the veriest tyro of a machinist that only the very best of steel should be used for milling cutters. This necessitates a very careful manipulation in itself, aside from the dangers to which the steel is subjected by the many forms into which it may be put. In order to avoid internal stresses of the metal, milling cutters ought, under all circumstances, after being formed and before hardening, to be heated once to a red heat. This heating can be done in an oven, or, in the absence of this, in a plate metal box or piece of pipe in which it is packed in charcoal. The whole may then be raised to the hardening temperature of from 1,600 to 1,900 degrees F. in an open fire and afterward left to cool either in the oven or box. The heating for hardening can also be done in a closed box when no lead bath or muffle-furnace is available. In order to prevent the slightest particle of oxidation it will be well to coat the cutter, before heating with a layer about 1-16 inch thick of heavy soft soap. The temperature of the hardening water should under no circumstances be less than 70 degrees F. A mixture of 3 pounds of soft soap and 1 quart of muriatic acid in 25 gallons of hard water, will materially assist in the hardening, especially by delaying the cooling of the sharp edges of the teeth somewhat and thus lessening the internal tension, without acting in any way prejudicially to the hardening.

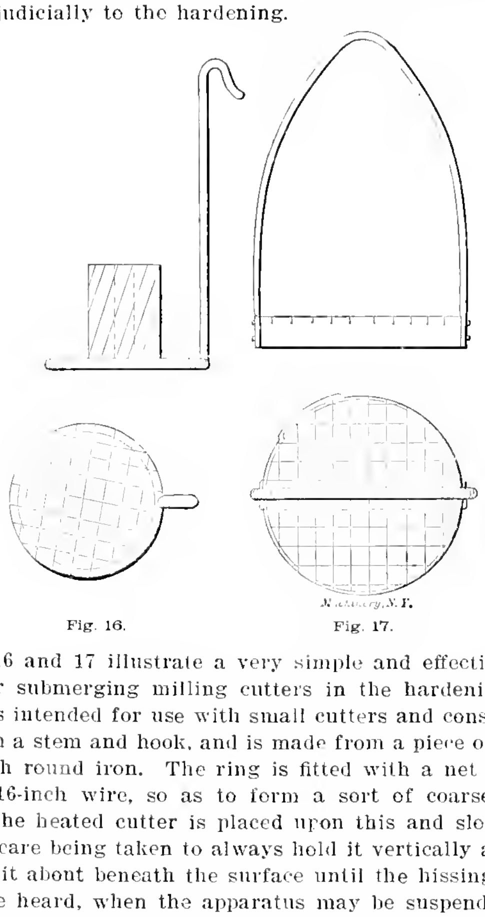

Fig. 16. Fig. 17.

Figs. 16 and 17 illustrate a very simple and effective apparatus for submerging milling cutters in the hardening bath. Fig. 16 is intended for use with small cutters and consists of a ring with a stem and hook, and is made from a piece of ½-inch or ⅝-inch round iron. The ring is fitted with a net made of about 1-16-inch wire, so as to form a sort of coarse-meshed sieve. The heated cutter is placed upon this and slowly submerged, care being taken to always hold it vertically and then to move it about beneath the surface until the hissing can no longer be heard, when the apparatus may be suspended from its hook and left until the piece is thoroughly cooled. The wire mesh gives the water access to the bore in the piece as well as to all portions of the teeth. End millers should be placed upon the netting with the teeth uppermost, so that the thin portions may be cooled last and be fixed. Otherwise there will be danger of cracking. Fig. 17 is a similar arrangement for large and heavy cutters, which a man could not readily handle alone. The ring may be made of band iron from ⅛ inch to 3-16 inch thick and about 2 inches wide, with holes for the fastenings of the wires. The handle made of round iron is fastened to the ring with two rivets on each side. For submerging heavy cutters a bar may be passed through the handle and the whole manipulated by a man at each end. While the hardening is being done, the room should be free from drafts, and glaring daylight or bright sunshine should be deadened by painting the windows or covering them with curtains.

A milling cutter, in unskillful hands, can be ruined in a few minutes by a workman who does not understand that everything depends upon deliberation and care. Proper manipulation on the machine is therefore as essential as the proper shape and preparation. A whole chapter could well be written regarding the use of cutters in the milling machine, but the limitations of space forbid and we will confine ourselves to a few words. The speed of cutting, the feed and the depth of the cut must be governed by the material, the character of the cutter, and especially the character of the work and the shape of the piece. The speed of the cutter is alone dependent on the type of cutter, the feed and the depth of the cut. It is customary in cases of doubt to run the cutter at a certain given speed and then crowd the feed until the limits of heating are reached, or up to the strength of the machine and the resistance of the material.

The following speeds, however, will be found to be very satisfactory:

For cast iron: roughing, 35 feet per minute; finishing, 45 feet. For wrought iron with water cooling: roughing, 40 feet; finishing, 65 feet. For cast steel with water cooling: roughing, 45 feet; finishing, 60 feet. For bronze bearings: roughing, 75 feet; finishing, 100 feet.

With star-shaped cutters whose sharp edges are easily broken, somewhat lower speeds than these must be used, and the rate of feed per revolution must be reduced also. G. L. F.

THE TRANSITION PERIOD IN MACHINERY.

Extract from Address by Mr John R. Freeman at the Case School of Applied Science, May 11, 1904.

This is a transition period, and never was there such opportunity for the trained engineer. Mechanical production must supply the natural increase due to the growth in population, and replace machines worn out by service, and even new machines by something newer. Here in Cleveland your horse cars were not worn out when the cable car replaced them, your cable railways were not worn out when the electric car came in. Not only the equipment, but the shop that makes it, must largely go into scrap. Two or three years ago one of the leading engine builders of the world began on new shops in a city on the Great Lakes, the largest of their kind, designed for building engines of the most massive type. Hundreds of thousands of dollars were expended on these shops and their heavy machine tools, but before these shops were occupied, customers were inquiring, not for engines but for steam turbines. The leading pump builder of America began two years ago on new shops near New York, these also to be the largest in the world; the plans had been matured by years of study for building pumping engines of the ordinary reciprocating type. Before these shops are ready for occupancy the old and simple and inefficient type of centrifugal pump is suddenly so improved as to threaten a revolution which may profoundly change the type of shop equipment demanded. A maker of valves and fittings, a concern which has kept steadily up-to-date for more than a quarter of a century, started, about two years ago, to supply its expanding trade by a factory on the shores of Long Island Sound, designed to employ at first 2,000 and later 4,000 men. The plans were matured with rare care and judgment. First, their man of greatest skill in shop methods plans for his various machines and lays out his floor space. Next, the skilled mill engineer makes plans to house that floor space in. Next, an architect, of national reputation for his inborn sense of beautiful form and graceful line, models the outlines of exterior wall and windows and roof. Machine tools of latest design had been purchased, apparently everything had been provided for, when, just as the roofs are on, the successful demonstration of a new kind of tool steel, which permits of far deeper and more rapid cuts, calls a halt and requires a radical change.

* * *

The 15,000-ton battleship, *New Jersey*, was launched from the Fore River shipyard at Quincy, Mass., November 10. The *New Jersey* is one of five similar vessels which were authorized by act of Congress in 1899 and 1900, and has one feature of design in common with the *Kearsarge* and *Kentucky*, four of her 8-inch guns being in superimposed turrets. She will be propelled by two four-cylinder triple-expansion engines of 19,000 indicated horse power at a speed of nineteen knots.

ON THE SHAPE OF ROLLS FOR CYLINDER CAMS.

R. E. FLANDERS.

The grooves and rolls for cylindrical cams are made in various ways, more or less suitable for the work to be done. The writer had occasion, a short time ago, to give a little thought to this matter, with the following results:

Fig. 1 shows a straight roll and groove, Fig. 2 a roll with a rounded surface in a straight sided groove, and Fig. 3 a beveled roll and groove. In Fig. 1 the action of the roll is faulty, because of the varying surface speed of the cam at the top and bottom of the groove, due to its varying radial distance from the center line. This causes excessive wear and friction, especially in a quick running cam with steep pitches. For such cases, if the duty is light, the arrangement shown in Fig. 2 is better, as the roll has but a very small bearing sur-

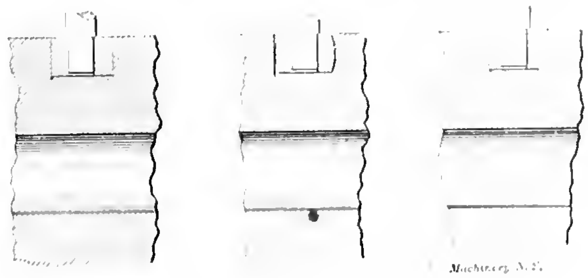

Fig. 1. Fig. 2. Fig. 3.

face, and is thus unaffected by a varying radial distance. For heavy work, however, the small bearing area is quickly worn down, and the roll presses a groove into the side of the cam as well, destroying the accuracy of the movement, and allowing a great amount of backlash.

In Fig. 3 the conical shape is given to the roll with the idea of giving it a true rolling action in the groove. In most cases which the writer has noticed, the lines of the sides of the roll appear to converge on the center line of the cam, as shown in the figure. If the groove were a plain circumferential one, it would give a perfect action, like that of the pitch cones of two bevel gears rolling on each other. If the motion were in a line with the axis of the cam, without any circular movement, conditions would be perfect in Fig. 1. It is evident that in intermediate conditions, the groove must be given a shape intermediate between the two. In many cams of this variety the heavy duty comes on a section of the cam which is of nearly even pitch and of considerable length. In such a case it is best to proportion the shape of the roll to work correctly during the important part of the cycle, letting it go as it will at other times.

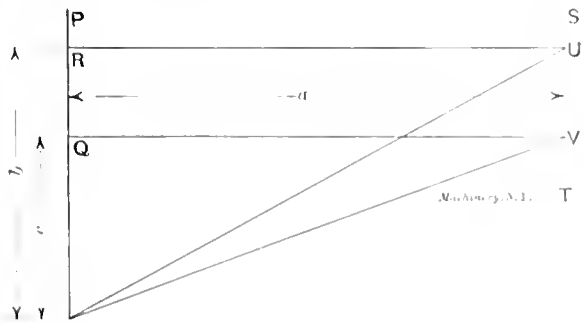

Fig. 4. Diagram showing Method of Finding the Shape of Cam Rolls.

In Fig. 4, b is the circumferential distance on the surface of the cam, which includes the movement we desire to fit the roll to. The throw of the cam for this circumferential movement is a. Line OU will then be a development of the movement of the cam roll during the given part of the cycle, and c is the movement corresponding to b, but on a circle whose diameter is that of the cam at the bottom of the groove. With the same throw a as before, the line OV will be a development of the cam at the bottom of the groove. OU then is the length of the helix traveled by the top of the roll, while OV is the amount of travel at the bottom of the groove. If then the top width and the bottom width of the groove be made proportional to OU and OV, the shape will be suitable to give the result we are seeking.

RALPH E. FLANDERS was born at Barnet, Vermont, September 28, 1880. His education includes four years in high school, and he served his apprenticeship in the works of Brown & Sharpe Mfg. Co., Providence, R. I. He has since worked for the Taft-Peirce Mfg. Co., Flather & Co., and the International Paper Box Machine Co. Mr. Flanders has worked as apprentice, journeyman, draftsman and designer of tools and methods of manufacture. His specialty is the design of automatic machinery for light and medium weight manufacture.

A SYSTEM OF DRILL JIGS FOR ROUGH CASTINGS.

H J BACHMANN

H J Bachmann

The recent contributions to MACHINERY in reference to drill jigs are interesting, but there is one type of jig that has not been described. It is an old idea in a new form and it has proven itself immensely profitable wherever employed.

Herewith are given a few sketches and a description of two jigs for drilling castings that have not been previously machined, *i. e.*, are just as they come from the foundry. It is not very difficult to design a jig when there is some part of the casting finished to size, but when there is practically nothing to start from, it becomes quite a serious matter. If we are to judge from the number of discarded jigs in the shops it seems that quite a few toolmakers have "fallen down" on this problem.

The principal feature of these jigs is, of course, the screw bushings, two of which are shown enlarged in Figs. 3 and 4. By screwing down on the bushing the casting is clamped between the screw bushing and the plain bushing shown in the bottom of the jigs. Thus it will be seen that they perform the double function of locating the hole and also holding the casting securely in its proper position in the jig. When only one end of the boss is accessible the plain bushing cannot be used, and other means must be devised to back up the thrust of the screw bushing.

Being movable they will take care of any reasonable variation in the size of the castings and also insure that the hole shall be drilled in the center of the boss. This latter condition is very desirable in work of this kind, for the sake of appearance and strength. In this form they are rendered applicable to all forms of castings having any kind of a circular projection or boss over which the bushings may be fitted, as shown in the cuts.

When headless bushings are necessary (as on both ends of the larger jig, Figs. 5, 6 and 7) they are tightened down with a spanner, whereas a plain drill rod pin is sufficient for the other. When both ends of the boss are held by bushings the holes to receive these bushings must be in line and when they are so aligned it is impossible for the hole to come out of center on either end of the boss. The simplest and safest way to align these holes is to run a single-pointed boring bar through the screw bushing into the bottom of the jig after the screw bushing has been fitted to the jig, the shank of the boring bar, of course, to be a good fit in the hole of the screw bushing which has been previously lapped to size.

On the larger sizes of bushings it has been found advantageous to use a good quality of machine steel, case-hardened and having a smaller tool steel bushing inserted in the center. When made of all tool steel the distortion caused by hardening is too great to allow a good fit, which is essential on the threaded portion.

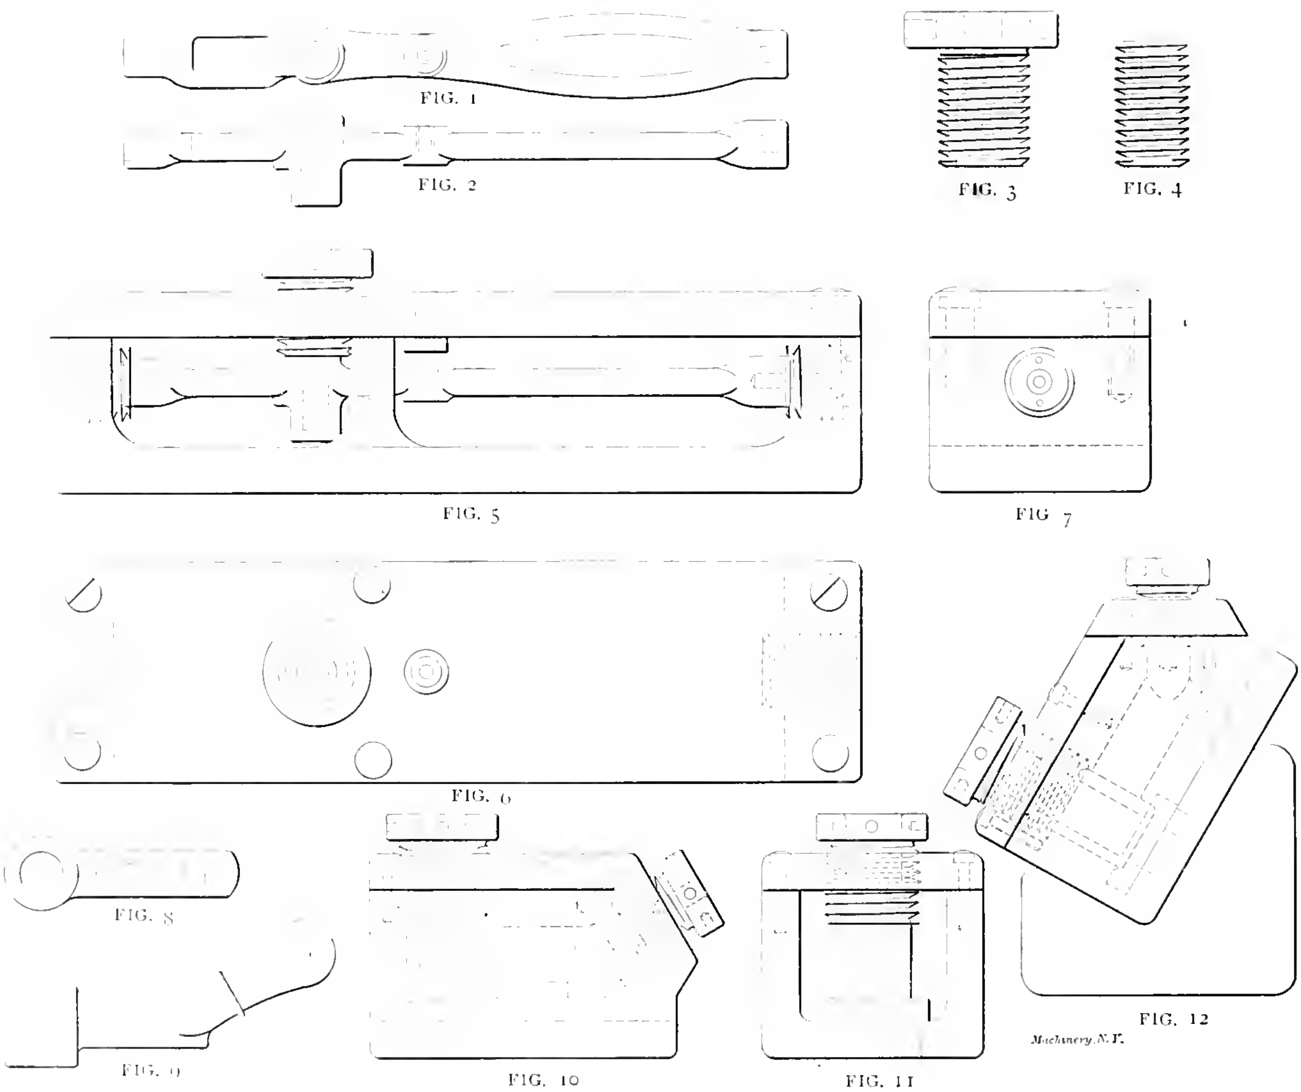
The bodies of the jigs are made of cast iron, cradle shaped and cut out where possible to facilitate cleaning. The covers which hold the screw bushings are of machine steel, held in place by means of fillister head screws and dowels.

HENRY J. BACHMANN was born in Birsthal Baden, Germany, March 28, 1880. He took a course in Pratt's Institute, Brooklyn and served an apprenticeship with the Brass Goods Mfg. Co. of that city. He has since worked for the Neptune Meter Co., General Incandescent Arc Light Co., F. A. Errington and the Cutler-Hammer Mfg. Co. He is a toolmaker and his specialty is tools for brass working. Mr. Bachmann has been an occasional contributor to MACHINERY for a number of years.

The larger jig, Figs. 5, 6 and 7, was designed for drilling the breast drill frame shown in Figs. 1 and 2. The casting is clamped by the large bushing first and then the smaller bushings on the end are brought up just tight enough to obviate any spring in the casting. There are two holes in this frame which must be reamed square with each other. After trying unsuccessfully to ream the holes by hand after drilling in the jig the holes were reamed in the jig as follows: The hole in the bushing was made the exact size of the hole to be reamed in the casting. A drill of this size was used to spot the hole, following with a reamer drill and lastly the rose reamer, making in every respect a satisfactory job.

The smaller jig, Figs. 10, 11 and 12, designed for the simple lever shown in Figs. 8 and 9, presents no difficulties beyond the drilling and tapping of the hole for the wooden handle at an angle of 30 degrees, and the adjustable stud screwed into the bottom of the jig to resist the pressure of the bushing. In this jig it is also necessary to clamp the larger boss first, so that when the smaller bushing is tightened there will be no tendency to displace the casting. The same procedure was followed in the case of the tapped hole as in the case of the reamed hole, namely: full size drill to spot, tap drill and then the tap itself. This latter was operated by means of a tapping attachment with friction chuck. The advantage over tapping by hand was evident because every handle fitted the lever just as shown in the sketch, adding greatly to the appearance of the finished article. The method of tilting the jig by means of the 60-degree angle block, Fig. 12, is open to criticism, but inasmuch as it was the simplest way, it was adopted. It is hardly necessary to say that these jigs are most profitably employed in connection with a multiple-spindle drill press, but even with a single spindle press they will show a saving over some ancient devices.

There is one thing that is generally overlooked in the construction of jigs and that reminds the writer of a very conspicuous sign in a large patternmaking shop—"Round all edges and fillet all corners"—should apply to the toolmaker as well as the patternmaker, for if he does not take the trouble to finish his work the boys in the shop will finish it for him in a way he won't like.



System of Drill Jigs for Rough Castings.

NOTES ON TOOLMAKING.

FRANK E. SHAILOR.

A good rule to follow when planing work is: "Plane the widest surface first." For instance, a die block is to be planed all over. The wide side is done first, next one edge, the block being positioned by the wide side just planed, bearing against the solid jaw of vise; then the block is inverted and the other edge planed, it being still positioned by the planed wide side against the solid jaw. We now have three planed surfaces to position the block for the last wide side. If the edges are planed first, as is customary with a great many machinists, it is obvious that the edges were positioned by unplaned, and therefore untrue, surfaces, hence they will not be parallel with each other. Moreover, the edges do not furnish ample bearing to properly position the block for planing the wide side at right angles.

When planing any work where absolute parallelism is required, never depend on the vise or bed of the machine unless the bed has been very recently trued up. A very good way to accurately machine work and to overcome the necessity of truing the bed, is to machine the piece all over to within a few hundredths of size, and then grip a piece of scrap steel or cast iron in the vise, or on the bed of the planer (or surface grinder) and carefully machine the surface. We now have a surface true with the crosshead of the planer or emery wheel spindle of the grinder. The piece to be finished is in

turn waxed to said true surface and with a keen cutting tool or emery wheel the piece can be accurately brought to size.

A wax suitable for this purpose is composed of 7 parts beeswax, 2 parts rosin, and 1 part shoemaker's wax melted together and thoroughly mixed. Just before the wax is cold, form into conveniently shaped sticks. The wax is applied around the edges of the work with a warm soldering iron, but care must be taken that no grit or wax gets under the piece to be machined. The wax does not become brittle so it can easily be removed with a copper scraper and used over and over. It is

Fig. 1 Diamond lap

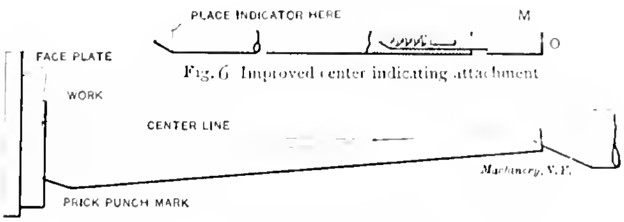

Fig. 6 Improved center indicating attachment

Fig. 7 Showing how location of prick punch mark is changed, when using solid bar

Notes on Toolmaking.

understood, of course, that "cut-meter" speeds cannot be employed when using wax for holding work. Light chips must be taken, especially on the surface grinder, as heavy chips would warm the work and cause the wax to melt. The holding qualities of this wax are such that the bed of a No. 2, B. & S. surface grinder can be moved back and forth by means of a piece of steel 3 inches square waxed to the bed. For holding thin work that must be straight when finished, the

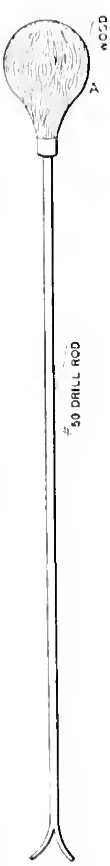

Fig. 2.

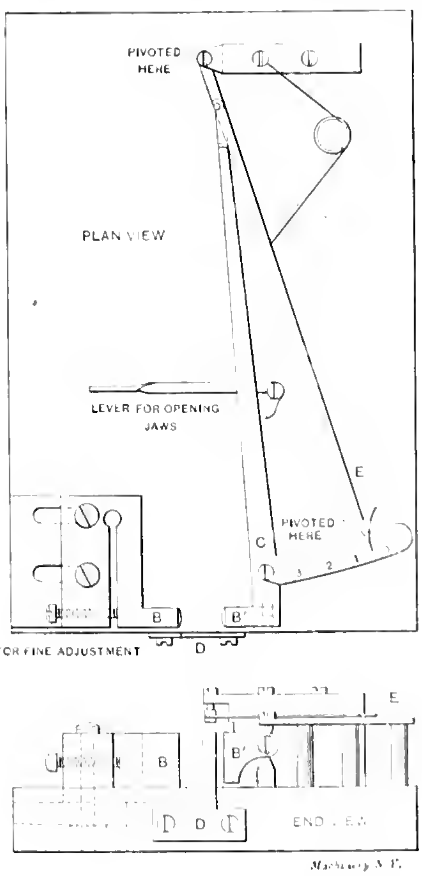

Fig. 3

wax will be found superior to the magnetic chuck, for the chuck exerts such a tremendous pull that if a piece of work is slightly sprung it will straighten against the magnetic face and after the piece has been ground and removed from the chuck, it will be found to have assumed its original curved form.

Grinding with Diamond Dust.

Diamond dust of all grades is an indispensable article in the up-to-date toolroom. To cite the many uses to which diamond dust can be profitably applied would require considerable space, and so only a few will be mentioned. It is extremely valuable in grinding small spring chucks having holes, say 0.060 inch in diameter. It is impossible to use an emery wheel in a hole of such diameter and unless the hole is ground the chuck will not, as a rule, run true. By charging the lap, Fig. 1, uniformly with diamond dust, a very small hole can be ground as nicely as though it were a 2-inch hole ground by an emery wheel. The lap is charged with diamond dust by rolling it between two hardened surfaces, but the dust should never be *pounded* into the lap. To obtain the best results the lap must run true and cut all around, but this is not possible if the dust is pounded in the lap, for the hammer blows produce minute flat spots, so that only the corners or high spots touch the work. Diamond dust does not spark and it is an easy matter to crowd the lap and strip some of the dust. To overcome this possibility the "harker" shown in Fig. 2 is brought into play. The forked end is placed against

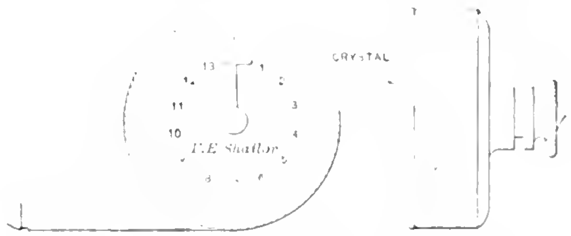

Fig. 4 Indicator for general work, assembled. Multiplies [illegible] times.

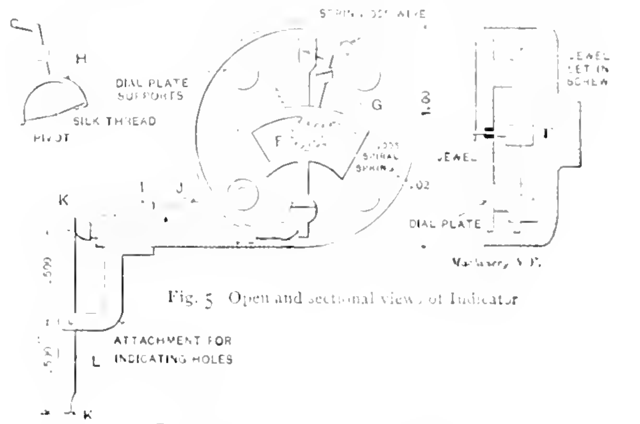

Fig. 5 Open and sectional views of Indicator

Sensitive Indicator for General Work

some stationary part of the grinder spindle, and end, A, placed in the ear. The movement when the lap touches the work is readily noted as the slightest sound magnified many times vibrates along the rod. The harker is nothing new, for our fathers were content to use an ordinary file in place of the more elaborate tool shown at Fig. 2.

One thing that must be closely watched when using diamond dust for grinding is that the lap does not become dry, but is kept moistened with a thin lubricant. Kerosene is excellent for this purpose. Soft work should never be ground with diamond dust as the dust will leave the lap and charge the work. The writer has often made small gages, both plug and ring, by roughly grinding first with No. 1 diamond, and then substituting for the lap one containing No. 5 or No. 6 diamond (which is very fine), lapping the gage to size at the same setting.

In grinding a plug gage much difficulty is experienced when calipering to find if the gage is perfectly straight. No matter how skillful a mechanic may be in using the micrometer, he is sure to apply uneven tension on work when measuring, and as 0.0001 inch one way or the other ruins a plug gage for accuracy, the simple little tool shown in Fig. 3 will be found of exceptional value in determining the straightness of a gage, though not the size unless it is set with a standard. The gage here shown multiplies errors 200 times. The jaws, *B*, *B'*, are hardened, ground and lapped. Jaw *B* is adjustable, while the other jaw is movable and connected to indicator point, *C*. An adjustable stop, *D*, is provided for the work to rest on, so that the jaws will be squarely in contact with the work. If three gages are to be made, as is customary, the indicating instrument will be found valuable in making them exactly the same size. When one is finished satisfactorily,

set the gage between the jaws of the indicator and note the graduation recorded by pointer, E. Since the indicator reading is 200 times greater than the actual error, it will now be easy to make the other two gages as nearly alike as it is possible to get them. It has often occurred to me that this style of instrument would make an excellent universal gage for pieces of work ordinarily measured with a snap gage, having a limit of 0.0001 inch or 0.0002 inch. All that would be necessary to make one indicator cover a large field of work, would be to retain a standard of each piece to be gaged, and set one indicator to said standard. An indicator of this denecessary to make one indicator cover a large field of work, each year for the reason that 0.0001 and often 0.00001 inch prevents a piece entering the ordinary snap or ring gage and it is thrown out. On the other hand a piece enters the gage and is accepted, but said piece is often as much below size as the piece thrown away was above. With the inspector it is a matter of go in or not go in. If it goes in it is "all right," if it does not go in, it is "scrap."

Fig. 4 shows another style of indicator that I designed and built for my own use. The dimensions are given here for the benefit of those who are occasionally inclined to do "Government work." This indicator is very sensitive and can be used on locomotive building, thus covering the entire field. The objection to most indicators now on the market is that they are not sensitive enough for small work, such as watch or instrument pivots, and will cause said pivot to "spring" before sufficient pressure is applied to make the indicator needle register. The indicator shown at Fig. 4 can be made either with the pinion, F, and segment of gear, G, or as shown at H. The lever, H, contains a silk cord wound once around the pivot upon which the pointer is fastened. If the silk thread is used it should be soaked in melted beeswax to prevent the fuzz or fringe fraying out under constant use. In Fig. 5 is shown an attachment for indicating holes. I represents a sleeve having a tapered hole which fits the taper, J. The contact points, K K, are equidistant from center, L.

Fig. 6 shows an improved centering attachment, the improvement being the spring end, M. If the bar were solid and the pointed end were placed in the prick punch mark of the work on the faceplate, with the tail center placed in end, O, it is obvious that the prick punch mark would be distorted and its position changed when knocking the work to bring the prick punch mark central with the spindle. By use of the spring end on the bar in sketch, this difficulty is overcome since the spring compresses before the point of the bar distorts the prick punch mark. The reader probably knows that it is a disagreeable, uncertain job to indicate work with the old-fashioned so-called "wiggler." The vibration of the shop causes the needle point to constantly tremble, it is difficult to ascertain the "high point" of the needle when rotating the faceplate, and the "wiggler" seldom multiplies over 15 times. When using an indicator in connection with the bar shown at Fig. 6 for indicating a prick punch mark or hole, all that is necessary is to note how many graduations the needle has traversed and knock the work so that the needle will go back one-half that amount, and there you are almost at the first rap. In my opinion it is poor policy to use a prick punch mark for determining the exact center of a piece of work. To grind a button to some given size, fasten it the proper distance from the edges of the work, and then to indicate the button is a much more accurate way, for we have no assurance that the prick punch was driven in exactly where it should have been. True it may be very close, but the day of "somewhere near" has passed.

* * *

TABLE OF SPUR GEAR TEETH GIVING DIAMETRAL PITCH.

L. S. BURBANK.

There are plenty of good formulas giving the shape of gear teeth, size of blanks, etc., but I have often wished that there was a table of gear teeth giving the proper diametral pitch and face of teeth under various conditions so one might have it before him to see at a glance whether or not the ratio of teeth desired would admit of sufficient tooth-strength. Figuring the strength of gear teeth is, in many instances, somewhat unsatisfactory because the bother of choosing and applying one of the many varied and more or less complicated formulas does not justify the time spent, especially as the size of teeth is so often and so largely modified by the velocity ratio that to keep within a safe strength is often the main object. But to guess at it pure and simple is going altogether too much in the dark, although I have no doubt that more gear teeth are guessed at, *as to strength*, than are figured, if the truth could be known.

Why not have a table giving the diametral pitch directly for all gear teeth working within certain practical limits? Then all that need be done is to ascertain the tooth speed and the force or horse power, under which it works, and, from the table, read at once the allowable diametral pitch for an assumed proportional tooth-face, provided for in the table; the result, together with the velocity ratio already known, gives all the data necessary to make a drawing or sketch. Let us see what can be had for a table:

In Kent's Mechanical Engineer's Pocketbook under the heading of "Gearing" may be found an interesting comparison of some gear tooth formulas by various authors, made for the purpose of showing the variation in results, but favors, with good reasons, an empirical formula by Mr. Wilfred Lewis. This formula gives $W = s\ p\ f\ y$, where W is the load, in pounds, transmitted by the teeth; s, the safe working stress of the material; p, the circular pitch; f, the face of tooth, in inches; and y, is a factor depending upon the form, and number of teeth, and whose value for different cases is given in a table. The value for this factor, y, for a cycloidal tooth or a 15-degree involute tooth, which latter is the one most commonly in use, is given as ranging from 0.067, for a pinion of 12 teeth, to 0.124, for a rack. The working stress, s, for different speeds of cast iron teeth, is given as ranging from 8,000 pounds for a tooth speed of 100 feet or less per minute, to 1,700 pounds for a tooth speed of 2,400 feet. The gradation is given by a table as follows:

Speed.	100 feet or less.	200	300	600	900	1200	1800	2400
s	8000 lbs.	6000	4800	4000	3000	2400	2000	1700

If, in the above formula, the variable quantities could be reduced to two in number and the circular pitch expressed as diametral pitch, a very convenient table, such as I have mentioned, could be arranged: Suppose we let p_1 = the diametral pitch then $p = \frac{\pi}{p_1}$. Suppose also we assume the width of face, f, to be 8 divided by the diametral pitch; or $f = \frac{8}{p_1}$. This gives a very good proportion for the face and one easily determined afterward from the table.

$$\text{Then } p\,f = \frac{\pi}{p_1} \times \frac{8}{p_1} = \frac{8\,\pi}{p_1^2}$$

Substituting this value in the original formula we get

$$W = \frac{s\,y\,8\,\pi}{p_1^2}$$

from which

$$p_1 = \sqrt{\frac{s\,y\,8\,\pi}{W}}$$

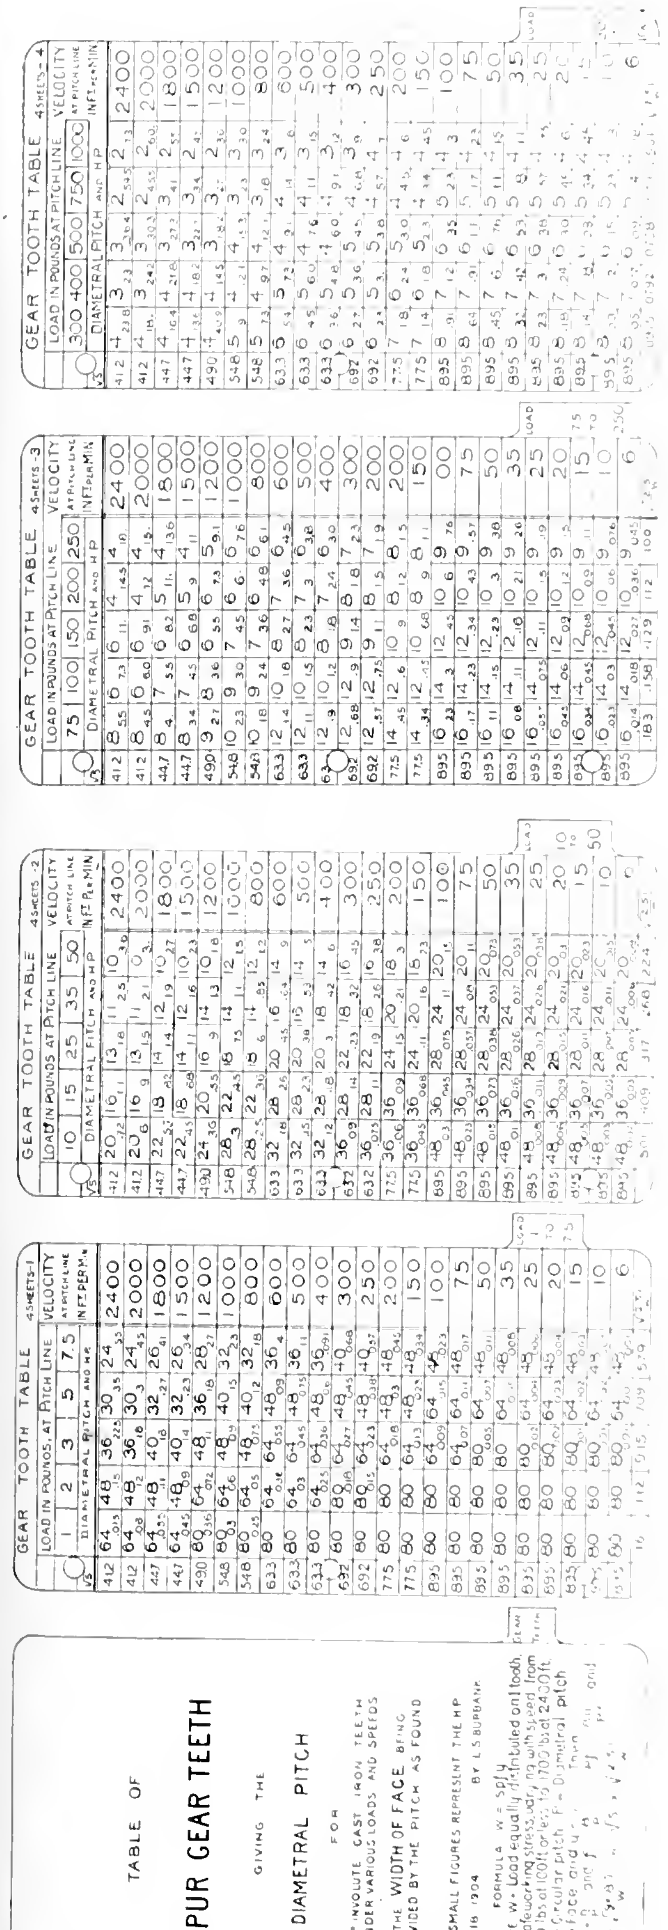
Suppose now, as the original formula can be only approximately correct, that we strike an average for the factor, y, as between 0.067 and 0.124, and call it 0.1. Then our formula stands

$$p_1 = \sqrt{\frac{s\,8\ \pi}{W}}$$

which we can separate into two factors and express it

$$p_1 = \sqrt{s} \times \sqrt{\frac{2.51}{W}}$$

In this formula the factor $\sqrt{s}$ contains the working stress



These Tables are Reproduced in their Original Form as presenting a good Example of Compilation of Engineering Data in Convenient Shape for Ready Reference

for tooth speeds and the factor $\sqrt{\frac{2.51}{W}}$ contains the load on the tooth.

Now we can easily arrange a vertical column from the ... preceding table, containing a series of values for $\sqrt{s}$ covering a convenient range of tooth speeds—say, from 6 to 2400 feet per minute—and likewise a horizontal row containing a series of values for $\sqrt{\frac{2.51}{W}}$ covering a convenient range of loads say, from 1 to 1,000 pounds.

Then from the products of these two sets of figures we can compile the desired table of diametral pitches. As these factors are preliminary, they need not necessarily appear in a working table. As the products of $\sqrt{s}$ and $\sqrt{\frac{2.51}{W}}$ (the loads and velocities) divided by 33,000 give the horse powers, I have included these (in the small figures) because of their addition to the value and convenience of the table. Some of these H. P. values are pretty small, to be sure, but none the less instructive.

Let us now take an example: Suppose we were designing a machine in which a belt wheel, running at 200 R. P. M., is to drive a pinion shaft whose pinion meshes with a gear running at 25 R. P. M., and we know, either by calculation or experiment, that the force, or load, on one of these gear teeth is 300 pounds. What are the proper dimensions of the gear blanks and what size pulley should we use, the distance between shafts being 18 inches?

The velocity ratio is 200 to 25 or 8 to 1. The sum of these ratio terms is 9. The diameter of the gear, on the pitch line would be $2 \times \frac{8}{9} \times 18 = 32$ inches. Its tooth velocity would be

$$\frac{32 \times 3.14 \times 200}{12} = 1{,}675, \text{ say } 1{,}500 \text{ feet per minute.}$$

The load we already know to be 300 pounds. Now, from the table we read at once the diametral pitch to be 4, and incidentally we see the horse power to be 13.6, say 14. The width of face is $8 \div 4 = 2$ inches and the outside diameter of the blank, by the well known rule, is $32 + 2/4 = 32\frac{1}{2}$ inches. The pinion blank is $4\frac{1}{2}$ inches diameter by 2-inch, say $2\frac{1}{4}$-inch face. The number of teeth in the gears are, of course, readily calculated, knowing the diameters and the diametral pitch. For the dimensions of the pulley we have given in the table the H. P. and we have simply to apply some belt formula such as H. P. $= \frac{DRW}{2750}$ and, if we choose a 6-inch belt, our pulley is 32 inches diameter. The horse power, as given is equally convenient in calculating sizes of the shafts, that is to say, the bores of the gears.

The table will be found convenient also in modifying the original tooth face in cases where it is desirable to use a different pitch from that given in the table. Where the pitch is chosen in the same horizontal line in which the original is found, it is simply necessary to multiply the tooth face, derived from the original pitch, by the ratio of horse powers corresponding to the two pitches; the original horse power being the numerator. The resulting tooth-face gives a strength equal to the original tooth.

For instance, suppose, in the above 32-inch wheel, that it were desirable to use a 5 pitch instead of the 4 pitch called for; the original tooth-face is $\frac{8}{4} = 2$ inches, as above, the horse power corresponding to the original pitch 4, is 13.6 and that corresponding to 5 (in the same line) is 9, the required tooth-face, therefore, is $2 \times \frac{13.6}{9} = 3.02$ inches, say 3 inches.

Where the desired pitch occurs several times in the same line, the average horse power may be taken.

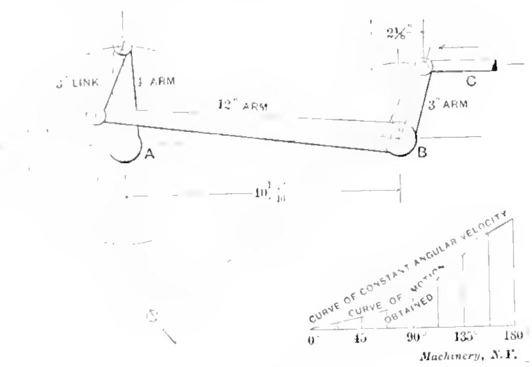
I trust that the above table will prove to be of practical value in many places.

LETTERS UPON PRACTICAL SUBJECTS.

LINK MOTION FOR ROTATING A SHAFT 180 DEGREES.

Editor MACHINERY:

We had a little problem which consisted of driving the shaft *A* through an arc of 180 degrees, or slightly over, without the use of gears, the movement to be reversible and without backlash. The driving shaft is not shown, but it operated by means of a crank, the rod *C*, shown in the sketch.



Link Motion for Rotating a Shaft 180 Degrees.

We accomplished our results as follows: A 4-inch lever arm was keyed to the end of the shaft *A*. A 3-inch link connected this lever to a 12-inch lever arm at *B*, whose center of oscillation was on the line bisecting the 180-degree arc and at a point 10 13-16 inches from *A*. The 12-inch arm is operated by a rod working on a 3-inch arm lever mounted on same shaft. The sketch shows the relative positions of the various parts after moving through the 180 degrees. The angular velocity of *A*, however, is far from constant, as may be seen from the accompanying diagram, in which the ordinates are proportional to the distance traveled by the rod *C* at the driving end. The straight line above the curve would indicate the curve for a constant angular velocity. J. D. ADAMS.

Phoenix, Ariz.

GRAPHICAL SOLUTION FOR BEAMS.

Editor MACHINERY:

In finding the modulus required in a beam to carry a given load over a certain span, the accompanying diagram has been found to be of value. To the left of the diagram will be found a column of spans in inches. Reading across the sheet we find the oblique lines for the various loads, from the intersection of which with the span line we read above or below, as the case may be, until we intercept the oblique line of the fiber stress to be employed. From the intersection thus found we read again to the right and find on that side of

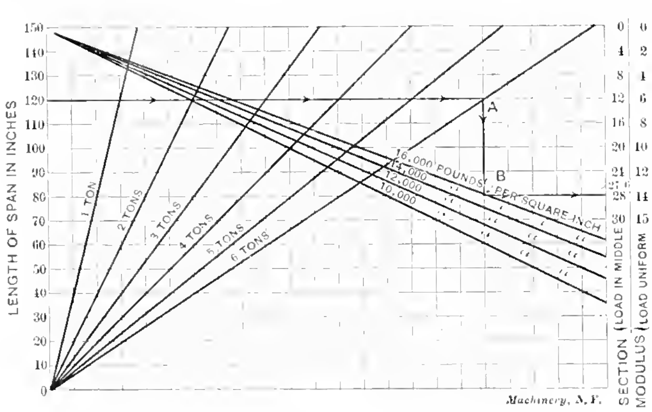


Chart for Graphical Solution of Section Modulus of Beams.

the sheet the correct section modulus to be employed for the different cases of loading as indicated. For example: What section modulus is required for a beam having a span of 120 inches and carrying a load in the center of 12,000 pounds when the fiber stress is limited to 16,000 pounds per square inch? The horizontal from 120 intersects the 6-ton or 12,000-pound diagonal at *A*; thence the vertical intersects the 16,000-pound fiber stress diagonal at *B*; and thence the horizontal gives the reading 27.6 in the first column at the right. It can readily be seen that in like manner a column of section moduli for the cantilever may also be added.

WALTER RAUTENSTRAUCH.

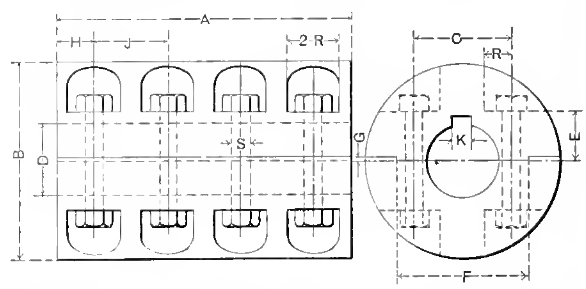
Sibley College, Ithaca, N. Y.

THE ADVANTAGE OF THE CLAMP COUPLING IN CEMENT MILLS.

Editor MACHINERY:

In mills where dusty or gritty products are handled machinery wears out rapidly and has to be replaced very frequently. In replacing such machinery it is very often desirable to do it with machinery of a later and improved pattern. This necessitates a continual taking down and putting up of shafting for the purpose of shifting or removing pulleys, gears and clutches. With the usual form of flange coupling this is quite a job as the couplings are hard to remove from the shafts and after they have been replaced and keyed on, the shaft has to be put in a lathe and the coupling squared up.

In our mill we frequently ran from one week's end to another with scarcely a stop, so the time left for repairs was very limited. We found the style of coupling shown with



D	A	B	C	E	F	G	H	J	K	R	S	WEIGHT LBS.
1 7/16	6	4 1/4	2 1/2	1 1/8	3 5/8	1/8	1 1/2		5/16	15/16	5/8	19.89

Machinery, N.Y.

Clamp Coupling Dimensions.

table gave excellent satisfaction. The smallest size of shafting used anywhere about the mill is 2 15-16 inches diameter and not a great deal of this size is used, but I have calculated the other sizes so as to have the table complete.

We always kept a number of extra bearings on hand and the millwright who looked after the line shafting used to mark the bearings that showed signs of wear. When for any reason it became necessary to shut down the engine for half an hour or so he would pull out the old bearings and slip in the new ones. The old ones were then babbitted at his leisure and were then ready for a new place.

Rutland, Mass. H. A. HOUGHTON.

TO TRUE UNIVERSAL CHUCK JAWS.

Editor MACHINERY:

The following is a description of a method which I have used and found very effective for truing the jaws of lathe chucks which have been strained or worn out of true to such an extent that they would not hold the work firmly. In most chucks there is quite a thickness of metal in the faceplate between the back of the jaws and the recess which is threaded to screw onto the spindle. If this has been drilled through to allow a rod of stock to be put through the hollow spindle of

the lathe, open the jaws far enough to clear, and true this hole up by taking a light smooth cut with a boring tool. Next take a piece of stock about 6 inches long, of sufficient diameter to leave a small shoulder and turn the end to a size that will be a nice running fit in the hole already trued in the chuck faceplate. Then turn the large diameter true for a distance slightly more than the length of the jaws, letting it taper about three or four thousandths inch, the large diameter being at the shoulder already turned. After oiling well, place the end turned down in the hole in the chuck and hold the other end in the tailstock chuck, if there is one belonging to the lathe; if not bring the tail center up, after first placing a dog on the lap, and adjust it so as there will be just sufficient end play to allow the spindle to revolve freely. You are now ready to begin lapping the chuck jaws true.

Place some emery and oil on the lap and close the jaws of the chuck until the longest one touches the lap; start the lathe on the high speed, holding the lap from revolving by means of the dog. Adjust the jaws from time to time until all of them are found to have a bearing on the lap their whole length. The advantage of this method is that if the jaws of the chuck are loose, when you screw them down on the lap they take the same position they would when tightened on a piece of work in the chuck, and when the job is finished if carefully done they will be found to have a parallel grip on a straight piece of work.

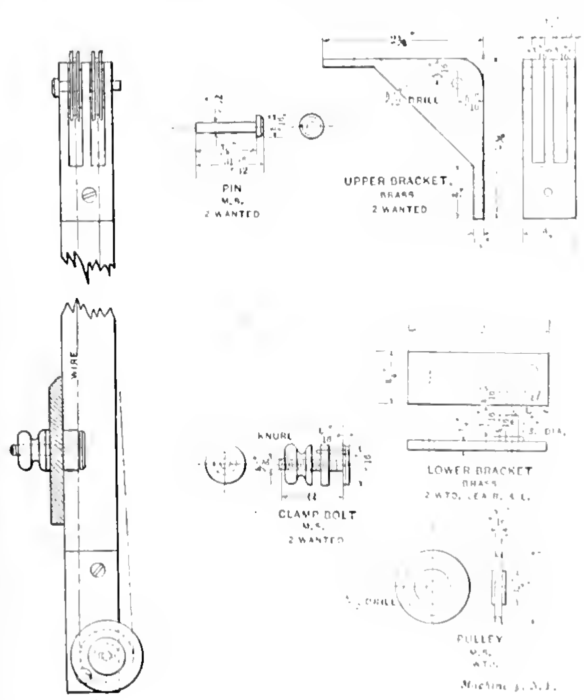
This method can also be used in truing up large chucks by placing the lap on the centers, being careful to keep the live center well supplied with oil. If, after truing the inside you wish to true the outside of the jaws you simply tighten the chuck on a perfectly round piece of stock and grind the outside with a grinding attachment. J. E. MANIFRRE.

New York.

PARALLEL MOTION FOR DRAWING BOARD.

Editor MACHINERY:

Seeing the description of parallel motion for drafting boards by V. A. H. in the August issue, I decided to send details of fixtures that I have on my drafting board. I have used this motion a good deal and consider it far ahead of any T-square



Parallel Motion for Drawing Boards

as it will stay where it is put, is of easy action and it needs no care to draw a line the full length of the board, as one end of straightedge is as firm as the other.

The wire (for I use music wire No. 2 instead of cord) is crossed on the edge of board away from the draftsman and passed over pulleys on each end. The ends of the wire are connected by a small spiral spring of sufficient stiffness to keep the wire under tension. An end of the board is shown at *A*, with straightedge fastened to wire. The straightedge can be slotted where clamping bolt passes through, which will allow it to be set at an angle if wanted. The upper corners of the board are cut away at an angle of 45 degrees to allow the upper bracket to set up to the board; the brackets are fastened to the board by common wood screws. The pins for the upper bracket are a snug fit in same and pulleys must have hole large enough to allow them to turn freely. A pin is forced into the lower bracket and a small hole drilled at *A* for a pin, not shown in detail, which is used to keep the pulley in place.

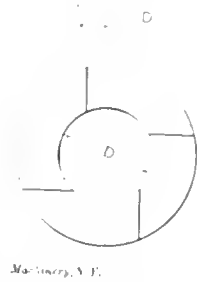
The board proper in my drafting table being but $\frac{5}{8}$ inch thick I have the brackets made $\frac{3}{4}$ inch wide, but they can be made any width, the idea being to have the upper wire on ends as nearly parallel with top of board as possible. I put a small pin through the head of the clamping bolt and its washer, to prevent it turning when tightening same. The dimensions of washer and dimension *a* are not given, as these depend upon the distance from upper wire to under side of straightedge and the thickness of the straightedge.

Athol, Mass. H. M. B.

REGARDING THE TEETH OF HOLLOW MILLS.

Editor MACHINERY:

I have read with interest Mr. Markham's articles in MACHINERY, and consider that they, in a general way, fittingly typify the art of toolmaking as it applies to the modern toolmaker and toolroom practice. While the articles in question are no doubt written for the beginners in their line of work, they can, I believe, be read with profit by the experienced workman as well. When it comes to the cutting of teeth in hollow mills, however, I take exception; from a careful reading of the article relating to this class of tools and reference to the illustrations, I come to the conclusion that he sets the face of the teeth in mills on a line with the center, or radially, which is different from what I have been in the habit of doing when making these tools for the machining of steel or cast iron.



Hollow Mill with Tangent Cutting Faces

While working in from fifteen to twenty shops I have had frequent occasion to observe the action of these tools, principally, for the rapid reducing of bar stock in the turning or screw machine work, and, from these observations I have been led to believe that the most noteworthy point to take into consideration is the proper cutting of the teeth sufficiently in advance of the center to insure a keen cutting edge and give somewhat of a side rake which is not possible to develop when the teeth are in line with the center. For brass, I always cut the teeth straight and on the center; for cast iron and steel, more especially the latter, we cut them spiral or straight, and for general practice ahead of the center. The rule I adopt when cutting the teeth is to set the side of the milling cutter from 5-16 to $\frac{3}{8}$ of the diameter of the hole in the hollow mill in advance of the center; the sketch gives an idea how it looks when finished. Clearance is given the mills in same manner as Mr. Markham describes, either by taper reaming from the back or by grinding internally; also we bevel the teeth when possible at the cutting end so that the tool may center itself and last longer. C. H. ROWE.

Worcester, Mass.

JIG FOR SPACING AND DRILLING HOLES AT A GIVEN ANGLE.

Editor MACHINERY:

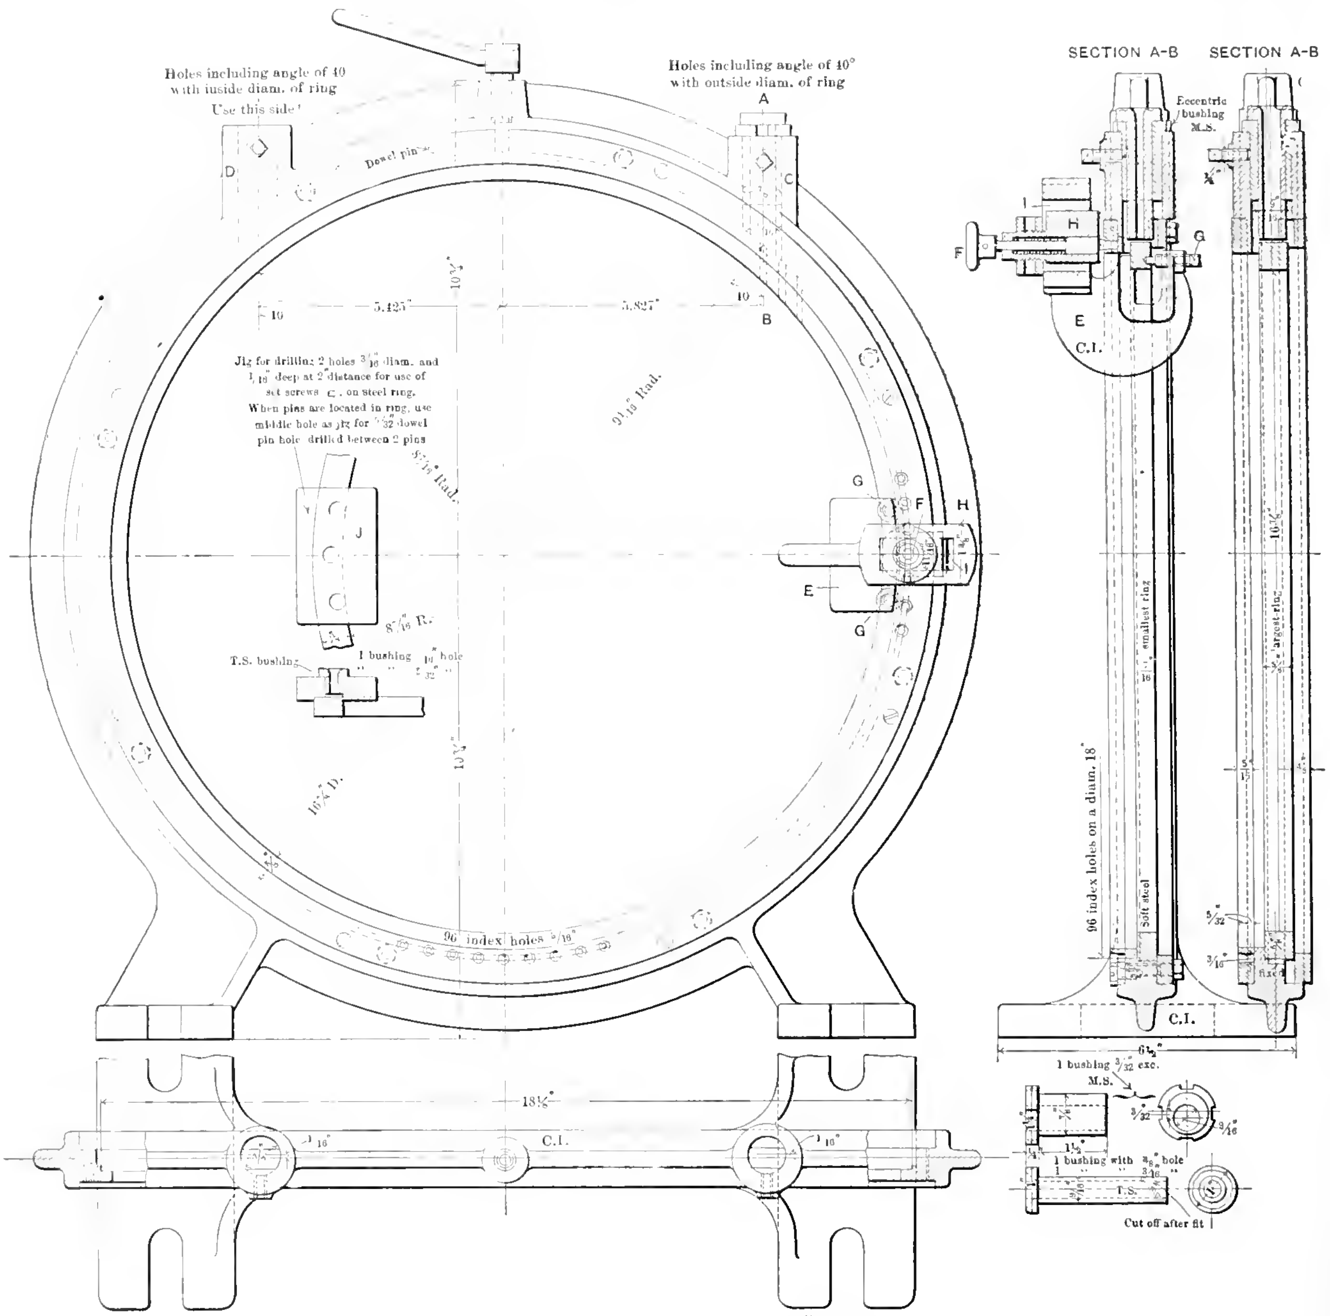
One of the most interesting jobs I have had to deal with recently, was drilling properly-spaced holes in soft steel rings at a given angle to the diameter, and a brief description of the operation, together with a drawing of the jig which was used, will I think, be of interest to your readers.

The rings to be drilled, in this instance, were $18\frac{1}{2}$ inches outside diameter, $16\frac{7}{8}$ inches inside diameter, by 7-16 to $\frac{5}{8}$ inch wide. The rings 7-16 inch wide, having 96 holes 3-16 inch in diameter, and those $\frac{5}{8}$ inch wide, 48 holes $\frac{3}{8}$ inch in

diameter, drilled, in both cases, at an angle of 40 degrees to the outside diameter of the rings. The jig body consists of a single casting, bored to receive the ring to be drilled, allowing it to rotate freely, and counterbored at either side for the indexing ring and the retaining, or cover ring, which is removed when the work is finished and a fresh ring is to be inserted. Referring to the drawing, it will be seen that the two bosses, *C* and *D*, which take the drill bushings, are not equidistant from the center line. This difference is necessary to compensate for the thickness of the ring (5/8 inch) and gives at *C*, the same angle to the outside diameter, as that which is obtained at *D*, to the inside diameter of the work, viz.: 40 degrees. To bring the drill central for different width rings, there is an eccentric bushing bored to receive the drill bushings, and made a wringing fit in the hole in the boss. A setscrew binds this bushing after it has been swung to the desired position by means of a spanner-wrench. This method of centering the drill changes the angle somewhat, but as all of the holes in one piece of work have the same angle, the result is satisfactory.

The indexing, or spacing of the holes is, really, the novel feature of this jig. This is accomplished by means of the separate fixture *E*, which is fastened on to the work much after the manner of a C-clamp. The two setscrews *G*, engage the two holes spotted on the face of the ring to receive them, and the taper end of the spring-pawl, *F*, engages the taper holes in the index ring. The block *H*, carrying the pawl may be adjusted in the slot *I*, to suit an index circle of different pitch diameter. The small jig *J* is for locating the holes for the setscrews in the indexing fixture, and the central hole in this jig is for drilling the dowel-pin hole in the work after it is finished and ready for assembling. JULIUS LENHART.

Philadelphia, Pa.



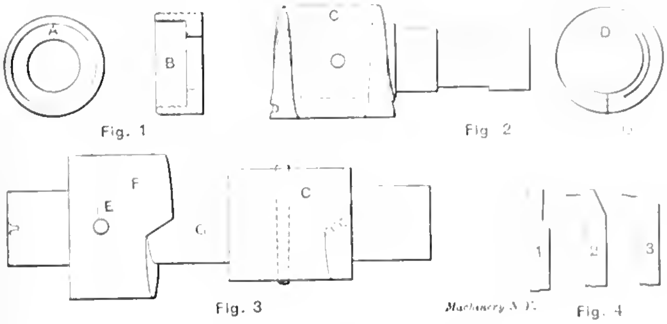
Jig for Spacing and Drilling Holes at a Given Angle.

MAKING FORMED CUTTERS ON THE LATHE.

Editor MACHINERY:

I send you some sketches of a rounding tool, which, although it is not new, may interest some of the readers of MACHINERY. The tool was made to round the outer rim of a cup-shaped piece, Fig. 1. The sectional view, *B*, shows the rounding of the outer rim. The material being cast iron and fairly thin, they come hard as a rule, and a mushet tool had previously been used for the rounding. The grinding and keeping in shape of the mushet tool was generally unsatisfactory, and it was decided to make the tool shown in Fig. 2, in two views, *C* and *D*. The tool consists of a hollow shell fitted to a shank for a turret holder. The shell, it will be seen, is a double-ender, so when one end has been used up it can be reversed and the other end used, thereby making two tools in one. The shaping groove is slightly

flared out so as not to leave a square shoulder as the cup is finished all over. A tool of the above description is somewhat out of the ordinary line, requiring some special fixtures for its shaping, but it is, nevertheless, not hard to make, and for the benefit of some of the readers I will give a brief description of how the one in question was made.



Making Formed Cutters on the Lathe.

A cast iron piece somewhat larger in diameter than the forming tool was bored out the same size as the other and fastened to a soft steel arbor, made for that purpose with a setscrew, *E*, Fig. 3. This was placed in a universal milling machine and a cam cut out on the end of the cast iron piece with a lead of ⅝ inch to one turn; the short part of the cam was dressed off with a file to the proper shape. The blank cutter was then placed on the same arbor and secured with a taper pin. With the work mounted as shown in Fig. 3, the arbor was placed on the centers of the latho and driven with a dog in the usual manner. A piece of 1-inch square iron, *H*, Fig. 5, was drilled for a bolt in the middle and a ⅝-inch pin at the end and at right angles to the bolt hole. This piece was bolted to the outer edges of the toolpost saddle. Another piece, *L*, of the same section but somewhat longer was drilled a loose fit for the pin, *M*, and a smaller pin, *N*, was put through the piece, *L*, and the ⅝-inch pin, *M*, to form a hinge on which the piece *L* might swing. The other end of the piece, *L*, was turned down to receive a roller, *K*. The roller was made crowning with a radius equal to the distance from the center of the roller to the pin *N*. A feed screw, *J*, was tapped through the end of the piece *L* and the point was sunk into the piece *H* for support. A rope, *P*, was fastened to the carriage and run under the headstock and over an idler sheave fastened to the gear bracket. A weight, *W*, was fastened to the rope to keep the roller, *K*, against the cam; the apron of the carriage, of course, was disconnected.

The first operation was to trace the outline of the cam on the cutter blank with the tool No. 1, Fig. 4. The blank was then taken off and where the short rise of the cam takes place a few holes were drilled, indicated by the dotted circles in Fig. 3, and the rest of the stock was taken out with a file. This was necessary in order to relieve the tool of the scraping action when being forced out by the cam. The outline of the cutter was then cut by feeding in the cross-slide carrying the tool No. 1, several cuts being necessary. The roughing tool No. 2 was next used, the relative position of this tool and the finishing tool No. 3 with the roller *K* in starting the cut, being shown in Fig. 5. These tools are sunk into the blank by placing a wrench on the feed screw *J* and giving it a slight turn to the left for every turn of the cam. In order to relieve the tools Nos. 2 and 3 of the top scraping out, at the rise of the cam, a hole is drilled at the end of the groove, as shown at *O*, Fig. 2.

One end of the forming tool being completed, the taper pin was removed and the blank reversed. The short incline of the cutter is left until after the hardening, when it is ground for cutting.

CHARLES THIEL

Lawrence, Mass.

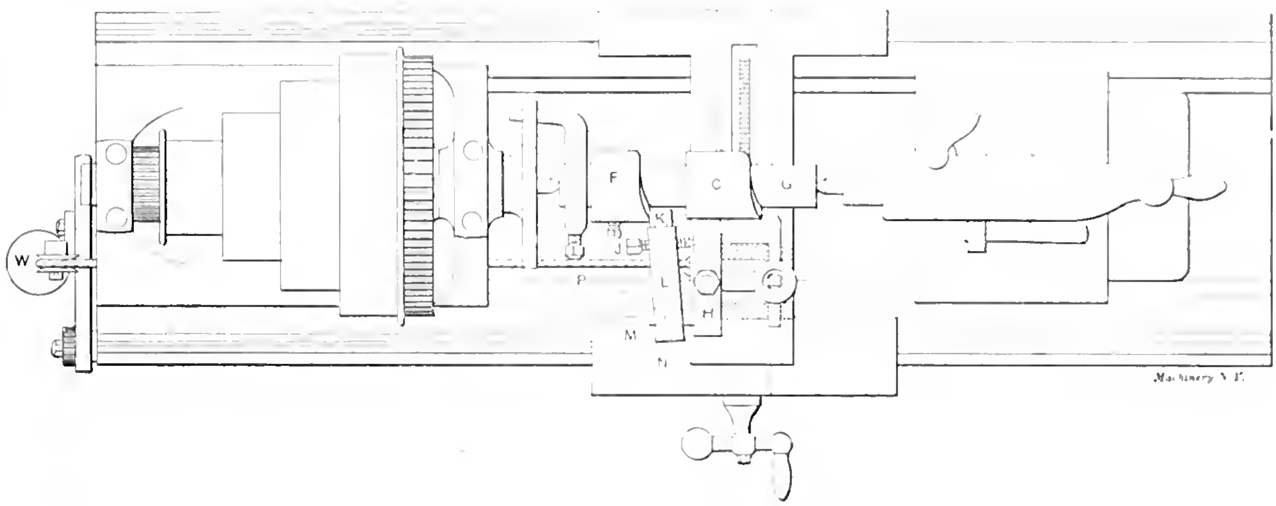


Fig. 5 Lathe "Set-up" for Making Formed Cutters.

LATHE RIG FOR TURNING MACHINE HANDLES

Editor MACHINERY:

I had the pleasure of rigging up an old engine lathe some time ago for the purpose of turning machine handles used in the construction of various machines, and it seemed to me it was a very neat and cheap way of obtaining the required shape, as well as finish necessary to make a good machine handle, although this method may have been employed for the same purpose before.

Fig. 2 shows sample of machine handle to be finished—swung between centers and driven by dog, *K*; the taper attachment is used with the taper bar, *T*, Fig. 3, clamped so as to be in a parallel position with spindle of machine and planed out so as to allow plate *B*, Fig. 1, to be screwed and doweled upon its surface. The former plate is laid out from the outline of the handle *A*, and the curve is generated by using, in this case, a one-inch roll. Fig. 3 shows tapped holes with eyebolts *L* inserted in the toolpost slide *E*, and also in carriage *F*.

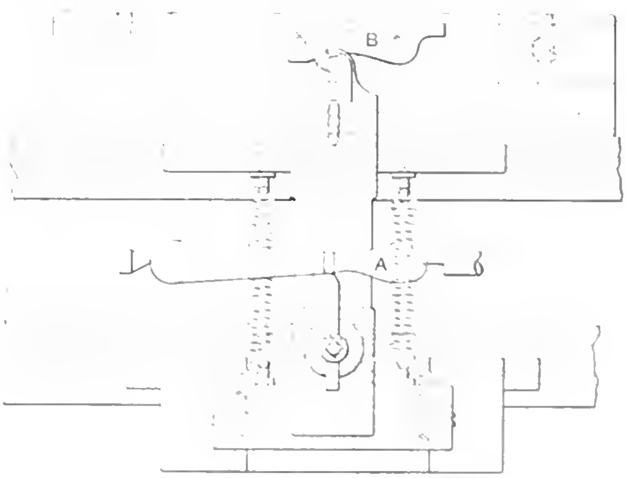

Fig. 1 Lathe Rig for Turning Machine Handles

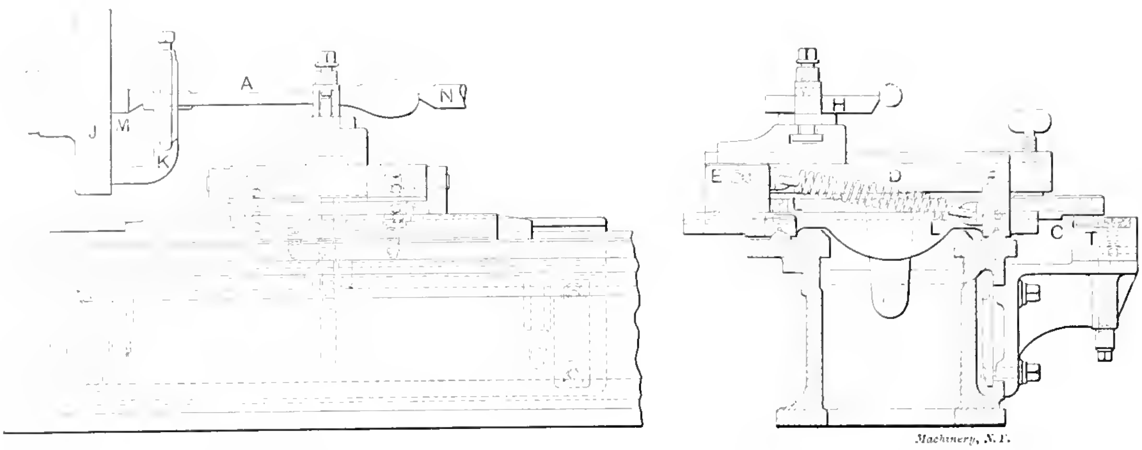
With these two points connected with coil springs, *D*, which

hold the roll C in contact with the face of the former plate B, Fig. 1, tool H with the proper feed applied through lead-screw, follows the outline of the former, thus giving the required shape of handle. With a former plate for each size handle, the outfit is complete.



Figs 2 and 3. Side and End Elevation of Lathe Rig for Turning Machine Handles.

Of course this method is not limited to this class of work alone. It may be used for many kinds of forming work, where a large enough quantity is required to make it pay to make former plates. DRAFTSMAN.

HOW THE PILLOW-BLOCK SEAT OF A LARGE ENGINE WAS PLANED OUT WITH A SMALL PLANER.

Editor MACHINERY:

E. J. Buchet.

The accompanying photographs, Figs. 1 and 2, show how we had to do a heavy job of planing in a shop equipped with small tools. The job in question is an engine bed weighing 12 tons, which had to have a seat planed out at right angles for the pillow-block. As no planer in the shop was large enough to carry the job, the alternative was adopted of making one of the planers act as a shaper, but the first thing to do was to get the casting into position. No cranes being available, the casting was mounted on rollers like those used for house moving. The chain was made fast to one end of the bed and a long rope fastened to it, was wound round the table of a 10-foot boring mill. Then the boring mill table was started up,

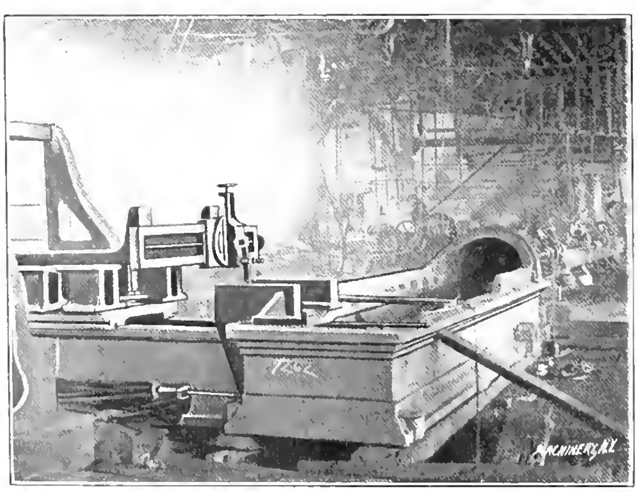


Fig 1. Planing Pillow Block Seat with Small Planer.

and the engine bed pulled into position behind the biggest planer in the shop. Here it was lined and leveled crossways to the travel of the planer platen, and a short distance below it. The cross-rail was taken off another planer and bolted to the back of the planer platen by means of angle irons. The cut was taken on the backward stroke of the planer platen. A very good job was done in this manner and in a reasonable length of time. E. J. BUCHET.

Dubuque, Iowa.

ERNEST J. BUCHET was born at Dubuque, Iowa, June 2, 1870. His early education was limited to common schools. He served a four years' apprenticeship with the Novelty Iron Works, and besides this concern he has worked for the Iowa Iron Works, the Chicago, Milwaukee, and St. Paul Railroad, etc.

"FRICTION OF SLIDING KEYWAYS."

Editor MACHINERY:

Your very instructive article, "Friction of Sliding Keyways," in MACHINERY for November reminds me of serious trouble I had many years ago. I encountered the defects of splined driving shafts in their most serious form, viz.: in heavy tapping machines for pipe threads. In those days tapping six-inch pipe threads was something to boast about; and it really was—when you tried to get a splined shaft to follow such a tap. Generally, when the tap took hold, the wheel on

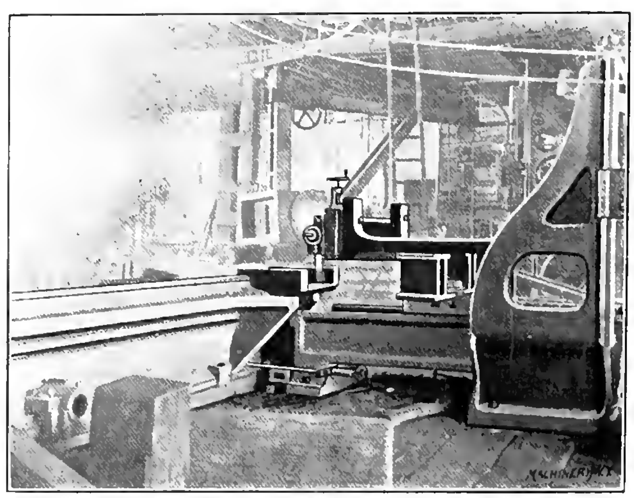

Fig. 2. Planing Pillow Block Seat with Small Planer.

the main spindle did just the same thing; then as the tap led into the work it was either torn out of the chuck or the whole table of the machine was lifted. Twenty-one years ago I had reached the point of building machines for my own use and met the difficulty as follows:

In Fig. 1 (next page) a portion of a heavy tapping machine is shown, enough to show the spindle action. In the great wheel A, a key like N, having radial sides, is driven in fast, but is a sliding fit for the spindle C, which has the keyway cut full length. Wheel A has a clamp hub, and this along with the clamp collar D, permits the spindle C to be set to any height suitable to the work on hand. When set, wheel A and clamp collar D are practically solid parts of spindle C, and grasp the square rack B, in which the spindle rotates. This rack B is actuated by a pinion in rear of bearing J, giving feed as per L.

As the spindle C is fed down to its work the wheel A goes along, traveling on the long pinion E, which is the driver. Pinion E receives power through bevel gear F, from back

gearing. So A, B, C, D and G move as one piece, balanced by wire ropes, M M, passing over pulleys. Solid black represents section through bearings in machine frame; section O being in another plane to take the pinion E behind the great wheel. This also allows cross beam G, which is fastened to the top end of the rack B, to pass over wheel F, till it strikes top of bearing J, as indicated by feed distance L. This combination follows an eight-inch tap without any noticeable drag. Apparently it is because the teeth of E and A are in constant motion on each other and, therefore, the downward motion of A on E is only compounding the movement of translation. Fundamentally, however, it is caused by the fact that the pressure on the teeth of A and that on the key in its hub, vary inversely as their distances from the center. That is, this method of driving reduces the drag of the spindle as much as C is smaller in radius than A. In these machines the great wheels are about eight times the radius of their spindles, but the advantage is greater than this for, since the key is fast in the wheel A, the spindle C would be driven by *less* than its radius, so that the ratio between dragging the spindle C over the key, or allowing A to travel on the long pinion E would be at least ten to one in favor of the system as described above.

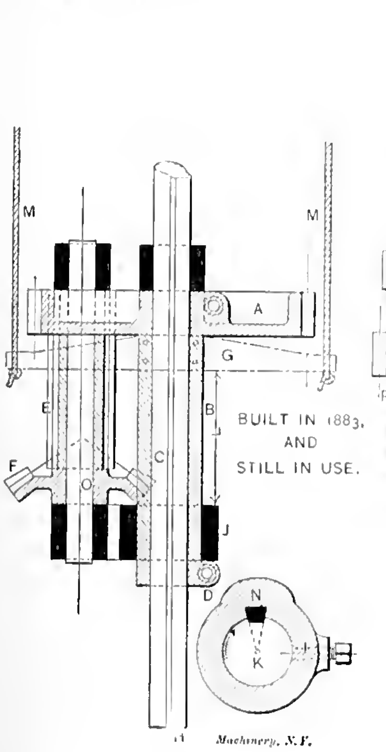

Fig. 1.

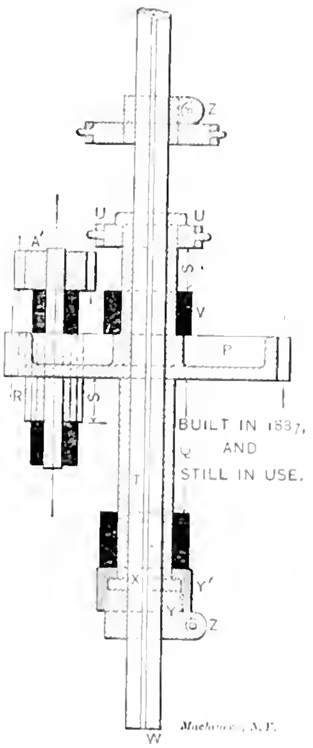

Fig 2

All chucks and taps are fastened to the spindle at H, by sockets, as shown at N I, the flat pointed setscrew at I serving merely to keep the piece from dropping off, since all the driving is done by the radial side key N. The absence of any socket, screw, or hole in the end of the spindle at H is just the very thing which makes it universal. This system by which the great wheel moves *along* the driving pinion E, combined with a spindle having a plain end H, I have been unable to improve to this day. All taps above three inches have this hub and dovetailed key N as part of the tap, so that the spindle of the machine becomes the stem of the tap. Those interested in this "reverse-stem" method of holding taps are referred to photograph of our taps in MACHINERY of January, 1900.

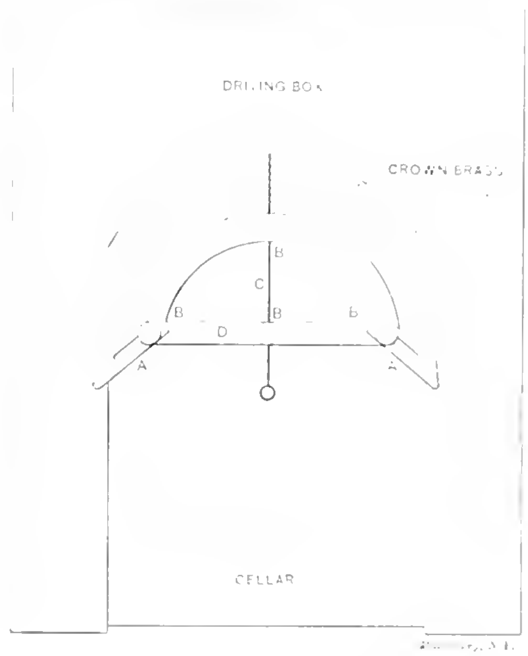
Most of this description also applies to a later machine of 1887, shown in Fig. 2. In this case the great wheel P has a long hub, as shown, and is a sliding fit on spindle T, and is a little overbalanced by a forked lever, the ends of which are shown at U U. Hence it normally remains up against bearing V, as shown; but when the tap takes hold it "bites" the spindle T, and travels with it, through the short spaces S, S which are more than long enough for a pipe thread tap. The instant the tap lets go, the great wheel P, automatically moves up to the position shown in sketch. So unobtrusive and quiet is this action that the average operative in using the machine does not even know of its existence. In moving the spindle over the range of the feed as per distance Q, no downward motion of P takes place, *unless we put work on at* W, when instantly P becomes practically a part of spindle T, and moves along with it. Rack Q in this machine is circular and has a flange on the lower end at X. The pieces Y, Y' may be considered as a solid piece. Spindle T is very long and is balanced by a forked lever as shown, and by shifting clamps, Z, Z, it may be let down to do work lying on the floor. Power comes through the spur gear A', from vertical back gearing. This machine, in action, is just the same as the machine shown in Fig. 1, but the gearing is more compact. The older machine has the advantage in that its great wheel will follow the whole range of the feed, and will therefore take a greater range of work outside of tapping pipe threads.

JAMES ARTHUR,
New York. President The Arthur Co.

TOOL FOR LAYING OUT CROWN BRASSES.

Editor MACHINERY:

Having been helped at different times by short articles and descriptions of tools appearing in your journal, I submit to you a brief description of a tool I both saw and used in one of the shops of the N. Y. Central. To a railroad machinist the drawing will almost explain itself, but to those not of that "fraternity" I give a description which I hope may suggest some other use to which this tool may be put.



Tool for Laying Out Crown Brasses

The tool consists of eight pieces, as follows: Two blades A A, four thumbscrews, B B B B, a scriber C and the body D. The cut shows plainly how it looks when assembled. The work it is designed to do is common in railroad shops in fitting a crown brass to a driving box. To use the tool proceed as follows: Place the two blades A A so that they fit against the flange as shown in the drawing, see that they set at the same angle, then clamp in position; now move the scriber C until it touches the box as shown. This finishes the measuring of the box proper. To transfer the measurement to the crown brass we proceed to lay a scale along the outside of the brass, place the scriber so that it just touches the scale, then scribe along the outside edge of blades A A and the brass is ready for the machine. This saves a good deal of time over the old method in vogue in many shops.

R. G. D.

* * *

The so-called indelible or aniline pencil is said to be effective for numbering or marking negatives, being used for this purpose on the undeveloped plates. A Stamford photographer says that he has found Dixon's "Eterno" to be the best for this purpose, as its writing is unaffected by the developing or fixing baths.

SHOP KINKS.

A DEPARTMENT OF PRACTICAL IDEAS FOR THE SHOP.

Contributions of kinks, devices and methods of doing work are solicited for this column. Write on one side of the paper only and send sketches when necessary.

HOW A TRIPLE WORM WAS CUT.

Some time ago I was required to make a worm which was to be used on a wire-measuring machine, and as the method used in cutting the worm was a little out of the common it will perhaps be of interest to the readers of MACHINERY. It was made of bronze with a triple V-thread 3½ threads per inch, or 3-10 lead. While calculating the gears to be used in cutting the worm, I found, as there were 3 1-3 threads in one inch, that this trebled would be 10 threads in one inch, and it occurred to me that all other threads could be cut at once using a 10-thread chasing tool, which I did, making a very neat accurate job and saving a great deal of time. The lathe used was a Reed lathe with 5-thread leadscrew. The nut was released at will and all the cuts taken without stopping the lathe. R. B. CASEY.

Schenectady, N. Y.

TEST GAGE FOR MAINTAINING STANDARD TAPERS.

In steam injector work the requirements for accurately ground reamers of unusual tapers are severe, and the gage shown in the sketch was designed to maintain the prevailing standard. It consists of a graduated bar 1 inch square, with the slot F, Fig. 1, running its entire length. The stationary head, A, is secured in position flush with the end of the bar, and the sliding head, B, is fitted with a tongue which guides it in the slot. This head may be secured in any desired position by means of the knurled thumb nut. The bushings, D

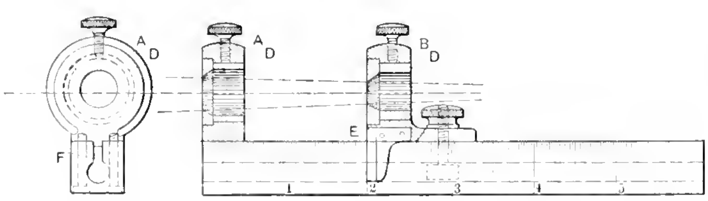


Fig. 1. Fig. 2.

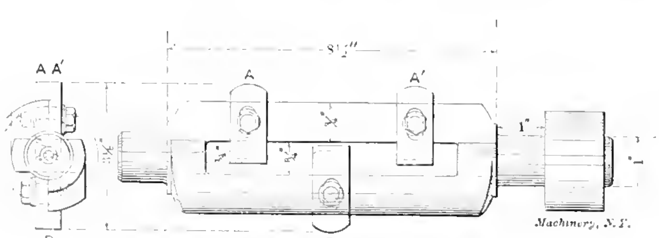
and D' are made of tool steel, hardened and ground to a knife edge on the inside, flush with the face. All bushings are made interchangeable as to outside diameter.

The head, B, is fitted with an indicating edge, E, which is set flush with the knife edge of the bushing. The reading indicates to .01 inch, the distance the bushings are from each other, and the difference in their diameter being known, it is easy to compute the taper. With this gage it is possible to maintain the standard tapers to a fine degree, each reamer being marked with the reading as shown by the scale. I. B. NIEMAND.

WIRE STRAIGHTENER.

In answer to a request from one who signs himself "Connecticut," asking for information in regard to a wire-straightening machine, I would say that we are using a device which is giving satisfaction. The sketch sent herewith, showing some of the dimensions, which may be varied to suit condi-

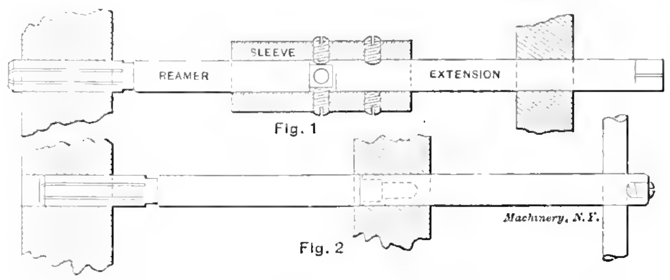


tions, gives a general idea of what it is. We can straighten any size wire in this machine up to ¼ inch in diameter. The lugs A, A' and B are movable and A, A' should be set at about the center line of the machine. The lug B, should be set in past the central line about ¼ inch making a short bend in the wire. Now, by placing the wire to be straightened through the central hole in the journals, grasping it with a pair of pliers and starting the machine, which should run at about 1,000 revolutions per minute, the wire with a slight pull will come perfectly straight from the machine. The lugs A, A' and B, should be concaved or rounded out on the ends where the wire bears, and should be hardened. E. B. KINGSLEY.

East Syracuse, N. Y.

TWO REAMER EXTENSIONS.

How many times have I wanted a specially long reamer to reach through two holes which were a distance apart! As I was walking through the shop a few days ago I saw a man using a simple extension which filled the long-felt want, and it is so simple and easy to make that I considered it worthy of the attention of your readers. The sketch, Fig. 1, will speak for itself. One screw is sunk slightly into the extension shank to prevent slipping while four screws form a

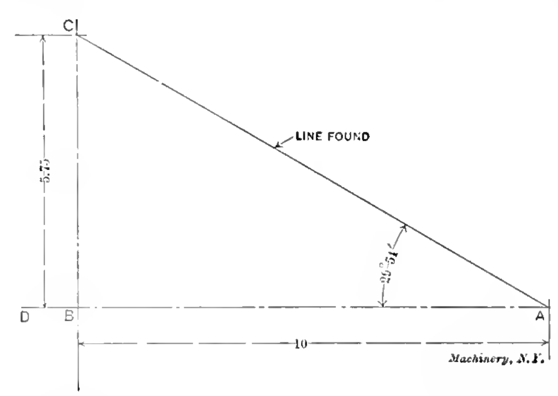


square place in the sleeve to take the square end of the reamer. The sleeve may be made from any kind of a piece of scrap iron, by simply drilling a hole through it the size of the reamer shank. The extension is merely a piece of shafting the same size as the reamer shank. Any ordinary tap or reamer wrench may be used on the square end of the extension. Fig. 2 shows another tap and reamer extension which will suggest to many machinists a good, practical tool for every-day use especially on the general run of jobbing work.

Pearl River, N. Y. H. E. WOOD.

TO LAY OUT ANGLES FROM A TABLE OF TANGENTS.

The diagram illustrates an accurate way to draw without a protractor lines at any angle wanted. Suppose we wish to draw a line at a certain angle with another and take for example 29 deg. 54 min.: First we draw a straight line, A D, of indefinite length and measure off 10 inches on the line from A to B; then find in a table of tangents, etc., the tangent of 29 deg. 54 min., which is .57503 for a radius of 1. For 10



inches it would be $.57503 \times 10 = 5.7503$ or 5¾ inches. Measure 5¾ inches from B to C at right angles to line, A B, draw a line from A to C, and we have the angle 29 deg. 54 min. This gives results more accurate than many of the protractors. ARTHUR W. MCALPINE.

Auburn, N. Y.

[Conversely, the angularity of two lines may be found by measuring the tangent and finding in the table what angle it corresponds to.—EDITOR.]

A NEAT SCREW DRIVER.

I send herewith a sketch of as neat a screw driver, for all-around shop use, as I have seen yet. This was first introduced in the shop by one of the tool makers. A, Fig. 1, rep-

resents a handle made of cold-rolled stock, is made hollow to lighten it. The knurling gives the hand a good grip. It will not split or become soaked with oil as the ordinary wood handle does. In finishing the hole *B*, if we use ¼-inch, 5-16-inch, or any standard hand reamer, it always gives a taper of about .005 inch at the front end, which makes it convenient

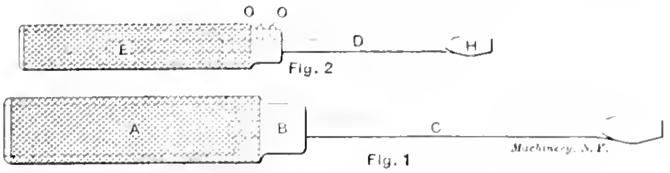


Fig. 2

Fig. 1

for a driving fit for *C*, that is, if the reamer is only run in flush with the end of the hole. The smaller screw driver, Fig. 2, is also a convenient tool. The blade, *D*, can be made to fit different-sized screws by making end *H* stronger and larger than *E*. *D* may be reversed by loosening the screws *GG*. PATRICK J. KING.

South Boston, Mass.

MILLING SQUARE JAW CLUTCH TEETH.

By using an odd number of teeth in designing the square jaw clutch it can be milled with only one setting of the cutter and one revolution of the index head.

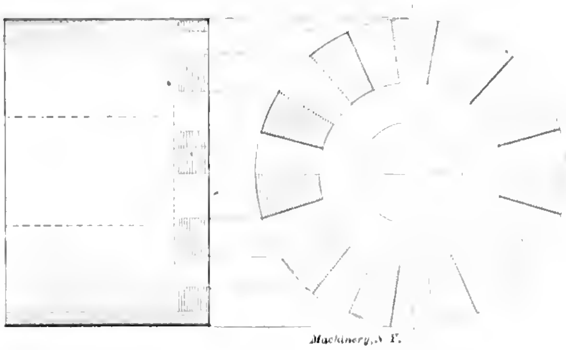

Fig. 1.

Fig. 1 shows one-half of a clutch with an odd number of teeth and Fig. 2 the method of cutting them. Bring the side of the cutter to the center line and cut space, *a* and *a'*, index and cut space, *b*, and *b'*, and so on; when half way round the cutter will only have the corners, *c*, to cut (shown dotted).

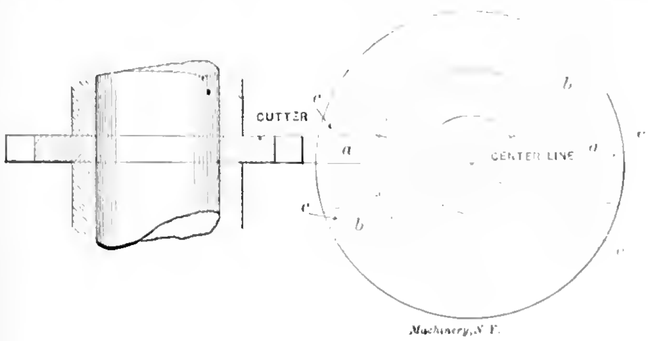

Fig. 2.

The cutter must be small enough to pass through the narrowest part of the space, but need not necessarily be that size. By moving the cutter 0.002 inch across the center line, the clearance between the teeth will be 0.004 inch.

Cleveland, O. DRAFTSMAN.

SIMPLE DRILLING JIGS FOR SHAFTS—WINDING SPRINGS—CUTTING OFF STOCK IN ENGINE LATHES.

The following kinks are some that I have found useful in the shop and I trust that they will likewise be of value to some of the readers of MACHINERY. The first is a jig for drilling shafting which requires two or more holes in a certain fixed relation to one another a considerable distance apart. This scheme requires as many blocks, *A*, Fig. 1, as there are holes to be drilled in the shaft. They are plain rectangular blocks, drilled and tapped on the sides for setscrews and bored for the shafts and drill bushings, as indicated in the cut. These blocks are slipped over the shaft to their proper locations and allowed to adjust themselves by setting on a surface plate or planer table, where they all take their positions automatically. The setscrews are then tightened and the holes drilled. Should it be required to counterbore the holes, the drill bushings may be made removable, and with their outside diameters slightly larger than that of the counterbore.

The second kink is for winding springs in the lathe. A forked holder is made for the toolpost, and is provided with two rollers of the general shapes shown at *A* and *B*. Roller

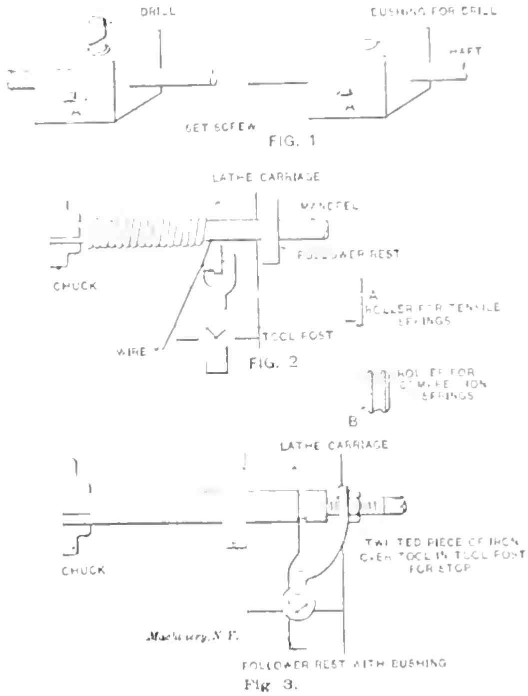

FIG. 1

FIG. 2

Fig. 3.

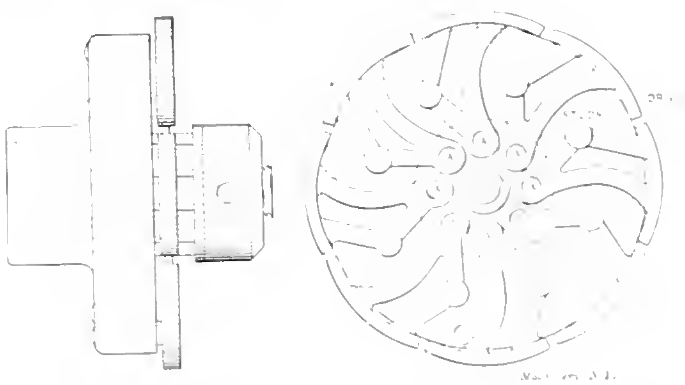
A is used for winding tensile springs, the carriage being moved along by the winding of the spring on the mandrel as indicated in the cut, Fig. 2. For winding compression springs, the carriage is fed by the screw cutting gear set to the proper pitch, and the roller, *B*, is used in the forked holder. A roller with a V-groove does not work as well as the half-round groove shown at *B*.

Fig. 3 shows how stock can be cut off in an engine lathe fully as quickly as in a screw machine. The cut shows the method so clearly that I think it requires no further description. HERMAN JOHNSON.

New York.

FACING SEGMENT GEARS.

We had a large number of drop-forged segment gears to finish. The drilling, reaming and facing of hubs were done first; next they were driven on an arbor, and the sides of rim faced. We used a straddle tool with inserted cutters on this

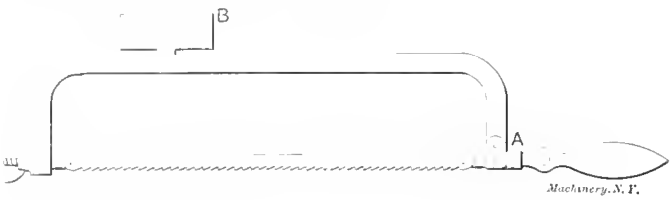


job, facing both sides at once. To watch this tool standing idle for about three-quarters of the revolution was aggravating, and in order to avoid this loss of time I devised a fixture like the accompanying sketch. The segments are slipped on the studs, *A*, and against the driver pins, the large nut holds them firm. By using a gear cutter that cuts the teeth to length at the same time they are shaped, the turning of the outside of the segments was made unnecessary. H. G.

Cleveland, O.

USING A HACKSAW AS A PARTING TOOL IN THE LATHE.

Having a number of pieces to saw in a hurry, I placed one in the power hacksaw and started it going and then fitted up a common hacksaw so that it was used in the lathe with great success on another piece. A ½-inch hole was drilled through the handle at *A* and a small weight was put on at *B*. A ½-inch arbor was clamped in the tool post parallel with the ways, and the hacksaw mounted on it by slipping it through the hole *A*. The work was caught in the chuck, and as it



rotated under the saw the cross-slide was moved across slowly as the sawing proceeded. I have since used this scheme more than once with good results, especially on any piece that has a hole through it. The saw does not work so well on solid stock as it is liable to break as it nears the center. I cut small gears or pulleys in halves in this way in a fraction of the time required with a parting tool, and with very little loss of stock. The weight required is small, being not over 8 or 9 ounces. ROBERT B. OTIS.

Orange, Mass.

* * *

HOW AND WHY.

A DEPARTMENT INTENDED TO CONTAIN CORRECT ANSWERS TO PRACTICAL QUESTIONS OF GENERAL INTEREST.

Give all details and name and address. The latter are for our own convenience and will not be published.

The following questions are referred to the readers for answers:

15. S. H.—Can you inform me of some solution for cleaning highly polished iron or steel?

16. L. M.—What is a good preparation to put upon zinc or tin sheets so as to make a good and permanent black or dead flat surface for templet work?

17. E. H.—What are the best methods, tools, etc., to use in turning off granite rolls of about 8 inches diameter by 10 inches long, having a 1½ inch hole through them, and properly affixed to a permanent shaft?

18. T. T. V.—We have experienced much difficulty with the thick, hard scale left on crucible cast steel after the annealing process. The acids we have tried, though they remove the scale nicely from forgings and cast iron, leave thick, hard patches on the crucible steel apparently untouched. These patches are of course very destructive to the cutting tools. Can you perhaps inform us of a process that will entirely remove the scale?

19. M. M.—I have tested the solution for which a formula was given in this department in the September number, for a non-corrosive soldering fluid, and find that it does excellent work. The expense of the preparation is an objection in my case, however, and I would like to inquire of your readers if there is any other less expensive compound for the purpose. Could the grain alcohol be diluted or some other ingredient be used in its place?

Answer to Question No. 3.

In the September number was an inquiry by H. J. N. regarding the use of aluminum for gas or gasoline engine castings. He wished to know whether an aluminum mixture could be used for the bedplate or other castings. This is replied to by R. M. W., who says: "I have found the best composition of aluminum for bedplates, etc., to be McAdamite, made by the McAdamite Co., New Brighton, S. I. It is much stronger than any other aluminum alloy I have had anything to do with. It has the same ring as steel and when broken the fracture has the same appearance. I hardly think it would be suitable for cylinders as its melting point is about 1,000 degrees, the same as that of pure aluminum. The composition is a secret, but H. J. N. could probably get fuller information by writing direct to the firm."

20. Subscriber.—Is it considered good practice to run steel gears at 1,200 to 1,300 feet per minute when used in machine tool construction? Should both gears be of the same or different material, and if both are of steel should both be hardened?

A.—We referred this question to the Boston Gear Works who replied: "We should consider the speed mentioned by your subscriber as the extreme limit for durability. We would suggest that gears running at this speed would probably give better results by having them casehardened. We should not consider cast iron suitable for the purpose, as the gears would probably wear rapidly. Neither should we consider that steel gears would wear well if of soft steel not hardened. It would be better still to have the larger gear of hard brass, and the smaller one of a good quality of steel not hardened. If well lubricated, we believe that good results could be obtained at the speed mentioned."

21. C. G. R.—Can you tell me where I can get information about the transmission of power by frictional gearing, like the Evans friction cone and similar devices? Is there any book published on this subject?

A.—There is no single book treating on this subject, but reference will be found to transmission by frictional gearing in works on machine design, notably Unwin's and Reuleaux's. The best information that we have, however, is to be found in a contribution upon "Paper Friction Wheels," by W. F. M. Goss, in the transactions of the A. S. M. E. for 1897. Prof. Goss conducted a series of experiments by means of two pulleys held in frictional contact, one an iron pulley, and the other of compressed strawboard. In accordance with the usual practice of selecting the yielding material for the driver, the strawboard wheel was made the driver and the iron wheel the follower. The driver was on a shaft with a belt pulley from which it received its power, and the follower was connected with a band brake for measuring the power transmitted. As a result of the experiments he gave a formula for H. P. transmitted, which is reproduced below. Let d = diameter friction wheel in inches; w = width of face in inches; N = revolutions per minute. A coefficient of friction of 0.2 is assumed, and a pressure of 150 pounds per inch width of face at the contact surface. Then,

$$\text{H. P.} = \frac{150 \times 0.2 \times \frac{1}{2}\pi d \times w \times N}{33{,}000} = .000238\, d\, w\, N.$$

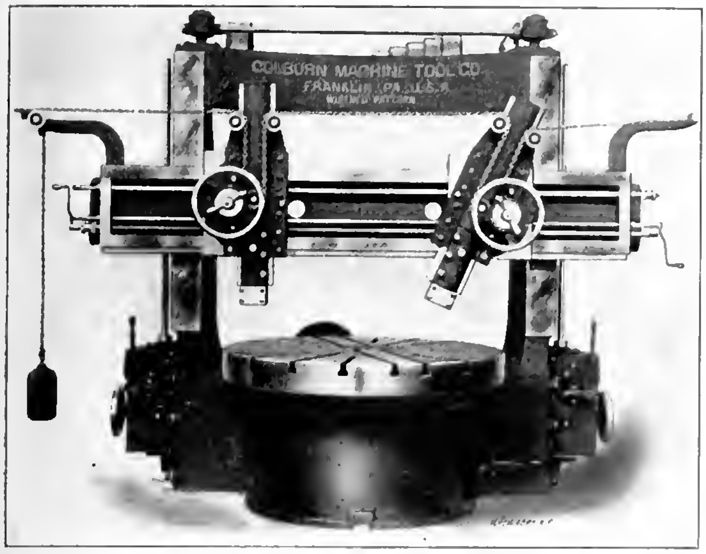
The uncertain quantities in the above formula are the pressure allowed at the points of contact of the two pulleys, and the coefficient of friction. The values used are based on the following considerations: The coefficient of friction was found to be constant, nearly, for all pressures of contact up to a limit which lies between 150 and 200 pounds per inch width of wheel face, beyond which limit its value apparently decreases. It also varies with the diameter of wheel. Paper wheels of 8, 12 and 16 inches diameter gave nearly the same coefficient, but one of 6 inches showed a 10 per cent decrease in the coefficient. The formula as given, therefore, does not apply to pulleys less than 8 inches in diameter. The coefficient is not affected by variations in peripheral speeds between 400 and 2,800 feet per minute. It shows the greatest increase with the per cent increase in the slip between the friction surfaces. A slip of 1 per cent. gave a coefficient of 0.14; a slip of 2 per cent. a coefficient of 0.2; and a slight rise above 2 per cent slip gave a rapid rise of the coefficient to 0.3, after which with an increase of the slip above 3 per cent the coefficient of friction drops rapidly and the wheels are unable to carry the load. From the foregoing, therefore, it is evident that pressures should not go beyond 200 pounds per inch width of face, and that the load should not be great enough to increase the slip beyond 3 per cent at the outside. The coefficient of friction of 0.2 can be used for leather in lieu of any better value as well as for paper. It is generally assumed in the transmission of power by leather belting that the coefficient lies between 0.25 and 0.3, so that 0.2 is evidently a safe value.

NEW TOOLS OF THE MONTH.

A RECORD OF NEW TOOLS AND APPLIANCES FOR MACHINE SHOP USE.

THE COLBURN WIDENED BORING MILL.

The accompanying half-tone shows the 72-inch boring mill brought out by the Colburn Machine Tool Co., Franklin, Pa. They have applied the widening principle to this tool, so that by widening the bed casting and substituting a new cross rail and top brace the mill has an actual swing of 74 inches. Apart from these changes, and cone pulleys with wider faces for a 4-inch belt, this mill is built entirely like their regular 60-inch pattern. The tool is particularly useful for shops occasionally having large pieces to turn and bore out but not enough work to warrant the purchase of a heavy type 72-inch mill, also for work of large diameter but comparatively light or medium character. It is heavy enough for the use of high-speed steels on all cast-iron work but not for rapid turning on such work as locomotive steel tires.



Colburn Widened Boring Mill.

There are 10 changes of speed for the main spindle, arranged in geometrical progression. The main driving mechanism is contained in a separate headstock placed between the housings at the rear. This headstock can be removed, should it be necessary to take the machine apart. The main drive on the table is by spur gear and pinion.

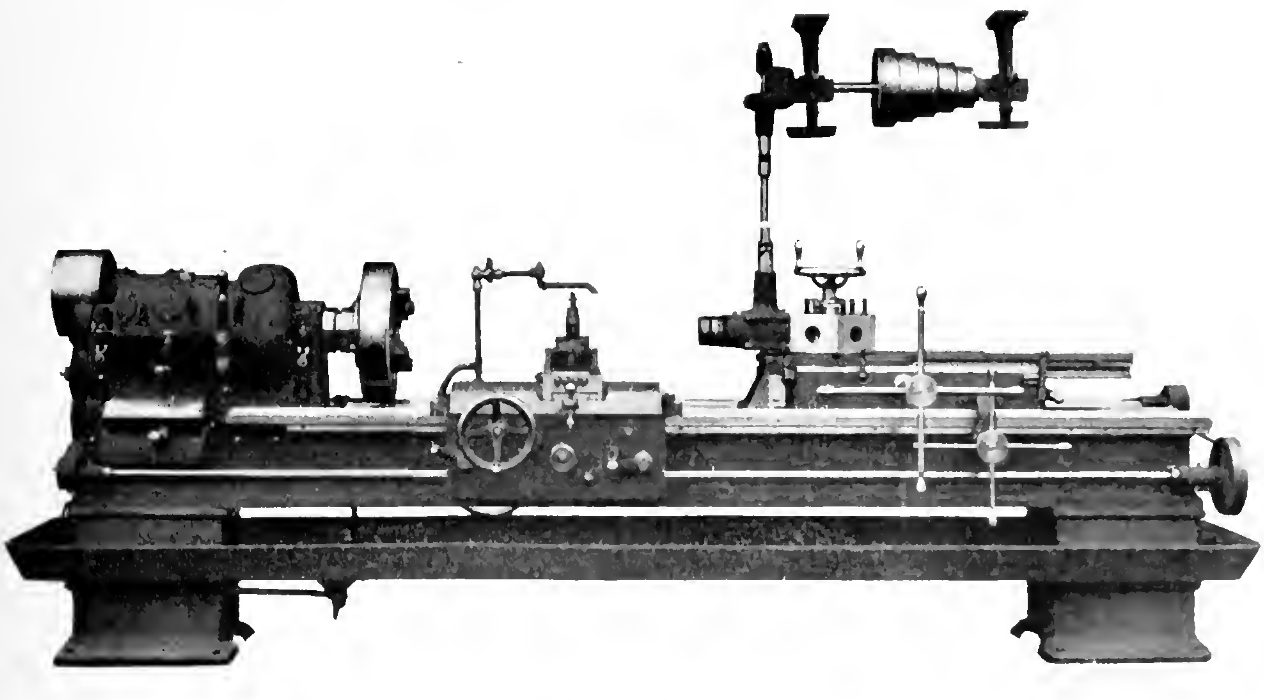
The heads are entirely independent in their movements and can be set to any angle. There are 10 positive feeds for each head, ranging from .025 to .500 inch horizontally and from .020 to .400 inch vertically. The feed boxes on each side are conveniently located for the operator. Turning the handwheel one revolution gives five changes of speed, and a multiplying lever in front changes the gear ratio, so that five more changes can be had by turning the handwheel a second time.

The hand lever near the top of the feed box is for reversing the feed or stopping it. All these feed changes are secured without stopping the machine. A friction brake, operated by a foot treadle within easy reach, eliminates all shock and jar and will stop the table instantly in any desired position.

A thread-cutting attachment, which can be applied at any time to the right or left-hand head, is supplied with this mill and will cut from 1 to 13, including 11½, threads per inch The principal dimensions are: Swing, 74 inches; maximum distance under cross rail, 47 inches; table diameter, 58 inches; travel of rams, 26 inches; length of cross rail, 9 feet 6 inches, floor space required, 12 feet by 7 feet 10 inches; weight, 22,500 pounds.

AMERICAN TWENTY-TWO-INCH LATHE.

The illustration herewith shows a 22-inch "American" lathe with patent all-geared head, turret, oil pump, pan and special boring device. The entire screw-cutting mechanism has been omitted on this machine, inasmuch as the lathe is primarily intended for roughing and boring; and the feeding mechanism, while of the same principle as that on the regular "American" lathes, is of a special nature. There are seven carriage feeds, ranging from .2 to .015.



American Tool Works Company's Twenty-two-inch Lathe

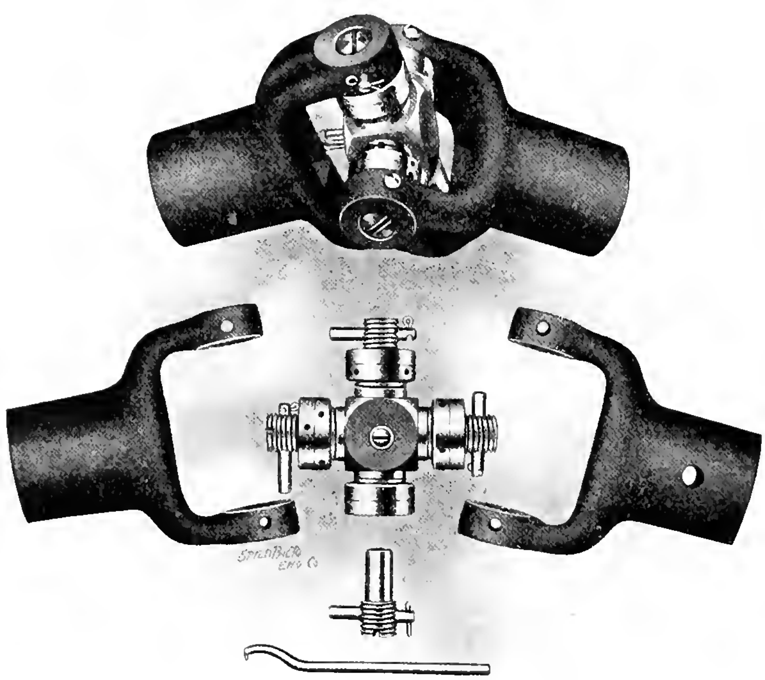
The geared head is simple, powerful and efficient. Only six gears are required to obtain four speeds through the levers shown on the front. The four speeds obtainable through the head, in connection with a triple friction countershaft, supply twelve distinct speeds to the spindle, ranging from 5 to 322 revolutions per minute.

The carriage is fitted with a plain block rest, which is provided with a calipering attachment, consisting of a set

of four adjusting screws, attached to the plain block rest after the manner of eyebolts, each one falling, when desired, over into corresponding slots in the yoke piece over the front carriage dovetail. By adjusting knurled locknuts on any of the four screws and dropping same into the slot, the travel of the cutting tool toward the center, and hence the diameter to be turned, is limited at pleasure. This attachment is very useful in duplicate work, as adjustments can be made for duplicate turning of pieces with four shoulders.

The hexagon automatic turret is of good size, with rapid and easy adjustments. It is provided with power feed, driven by sprocket chain from the feed rod, thus giving fourteen feeds to the turret, ranging from .16 to .007. The worm is dropped out of mesh with the wheel by an improved tripping device. The turret slide has an extra long bearing on the bed; the top slide has a 24-inch movement, controlled by pilot wheel, and is supported on the front end by an improved supporting shoe, which slides on the ways and is firmly bolted to the end of the turret slide directly under the cutting tool. It insures accurate alignment in boring, and has a gibbed bearing both at the top and bottom of the ways, thus preventing all spring in any direction.

The drilling attachment is affixed to one of the faces of the turret, and is very useful in boring operations. It consists of a symmetrical housing carrying miter gears, and



Baush-Bocorselski Universal Joint.

these actuate a spindle with ball-bearing thrust, which carries the boring bar. The spindle revolves from a separate overhead countershaft, as shown, by means of universal joints connected by a telescopic rod, which thus compensates for any movement of the turret slide. The boring spindle revolves in the opposite direction to the main spindle on the head, and has five rates of speed through the cone pulley on the countershaft. If it is desired to use another face of the turret, it may be revolved without disturbing the drilling attachment, owing to the telescopic rod.

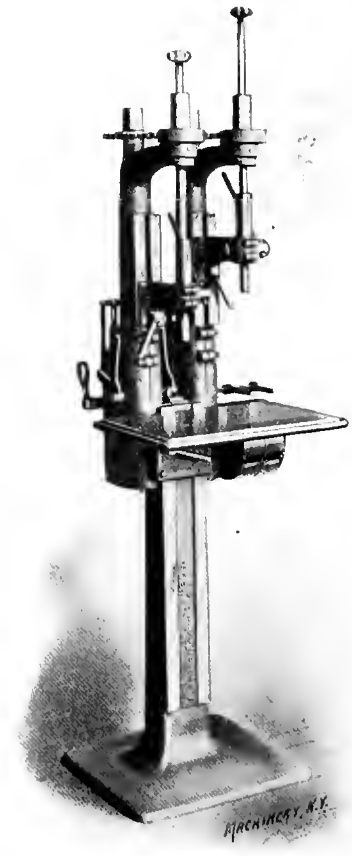
The boring tool is provided with an oil supply which is drawn up by an auxiliary pump through the turret stem and boring bar. The carriage has an oil supply similar to that of the turning tool.

The lathe is very substantial throughout, to adapt it to the very heavy strains which a lathe of this character must undergo. It is built by the American Tool Works Co., Cincinnati, O.

BAUSH-BOCORSELSKI UNIVERSAL JOINT.

The cut herewith represents a new universal joint designed by Frank E. Bocorselski and manufactured by the Baush Machine Tool Co., Springfield, Mass. The joint assembled is shown at the top of the view, in a position of about 15 degrees. It can be run at an angle of 30 degrees. The forks of the joint, shown on the right and left-hand side have a tapped hole to receive a trunnion screw (also shown) with a taper pin passing through it to keep the screw from turning in its fork section. Both the forks and the trunnion screws are of steel.

A novel feature of this joint is the transmission spool or block, shown in the center of the cut. This is of bronze and is bored through from end to end of the projecting arms, to receive the trunnion screw previously mentioned. This also leaves an oil reservoir in the center of the transmission block. The projecting arms have slots in them into which felt is inserted to distribute the oil from the reservoir along the bearing on the trunnion screw and the inner faces of the fork sections. There are two check nuts on each arm, for adjusting the joint to a central position and taking up wear. All the bearing surfaces are steel against bronze. The spanner wrench shown at the bottom of the cut is furnished with each set of joints.



Fenn-Sadler Two-spindle Sensitive Drill.

FENN-SADLER TWO-SPINDLE SENSITIVE DRILL.

The half-tone herewith shows a two-spindle drill press recently brought out by the Fenn-Sadler Mche. Co., Hartford, Conn. This machine was designed especially for manufacturing purposes, although it is handy for tool room work, being very quickly adjusted. The top columns can be swung to different positions, making a very handy feature for jig work, as it is possible to drill two holes without moving the jig and both holes can be drilled at the same time.

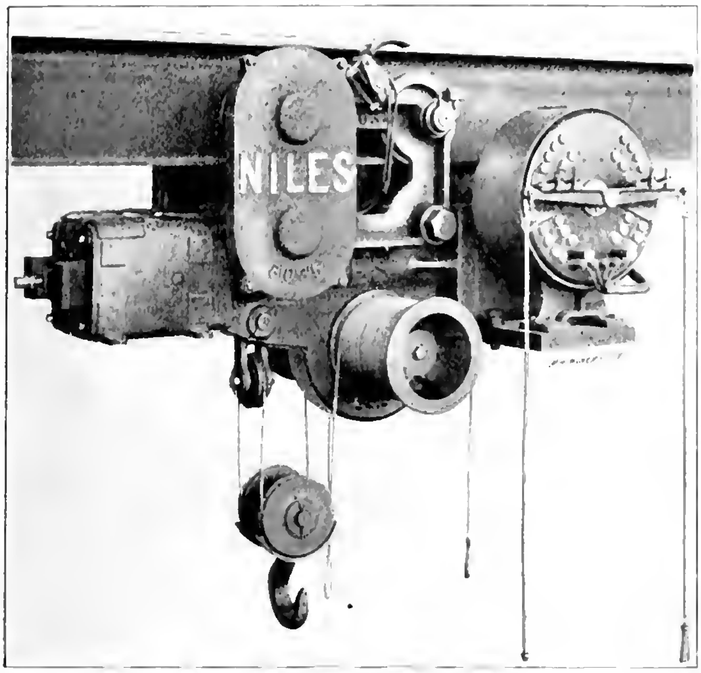
Both spindles have three changes of speed, each one independent of the other. The speed is changed by means of a lever which is operated from the front of the machine. The change of speed is obtained by sliding gears.

The machine is driven by gears. It has but the one belt and is very strong. It is warranted to drill ½-inch holes at the speed that manufacturers desire at the present day.

NILES ELECTRIC TRAVELING HOIST.

The half-tone (next page) shows a new type of hoist built by the Niles-Bement-Pond Co., New York. It is built in capacities of ¾ to 6 tons, and may be used either as a hoist, running on an I-beam track, or for a small capacity crane in which case it is mounted on a traveling bridge. In the latter case it is

arranged to run between two I-beams, or channels, of the bridge, and the controllers for raising or lowering the hook and operating the traversing mechanism may be placed either on the hoist, on the bridge and operated by cords from the floor, or from an operator's cage attached to the bridge. When used on an I-beam the controllers are attached to the hoist and operated by cords from the floor. The hoist will run on straight or curved tracks, and is usually provided with a separate motor for traversing, but if desired hand



Niles Electric Traveling Hoist.

traverse may be furnished, or all the traversing mechanism may be omitted and the trolley moved along the track by pushing on the load. The increased service of the electric traverse, however, more than compensates for the slight additional cost.

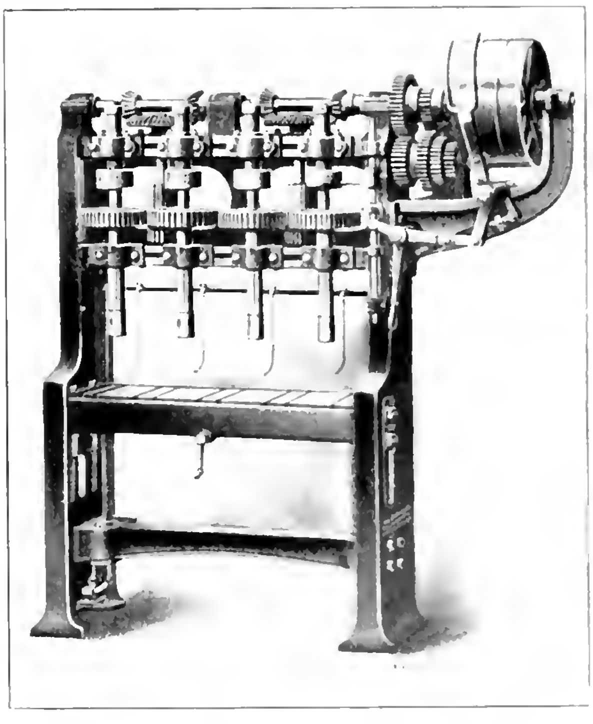
The hoist is self-contained in one heavy cast-iron frame, to which the motors are attached end on, and the power is transmitted directly from the armature shaft to the drum shaft through a train of worm and wheel gears. The traversing mechanism is also driven by worm and wormwheel gears, except that when the trolley is arranged to run on a single I-beam a double set of gears is used to connect the worm gear shaft to the truck wheel shafts. All the mechanism is enclosed in oil- and dust-proof casings. A powerful electric brake is attached to the hoist motor.

NUT TAPPER.

While practically all nuts are tapped by running through them a tap with a long shank on which the nuts are collected, there are a large number of articles which cannot be tapped by this method, since it is necessary in many instances to back out the tap. Any piece which is to be threaded with a taper hole (and this includes nearly all pipe fittings) must have the tap backed out. Also, articles which do not have a hole clear through them must be threaded by first running in the tap and then backing it out. Still other pieces, which are to be tapped only to a certain depth must be threaded by the same process. It is apparent that if a tap is to be reversed it must be provided with a leadscrew of the same pitch as the tap, in order that the tap may not grind around in the hole after it has just cleared the threads. Furthermore, when a positive feed in the shape of a leadscrew is used some kind of a relief is necessary which will yield in case the tap misses the hole and strikes solid metal, as otherwise the machine might be wrecked. Adjustments should be provided for varying the speed, the distance which the taps will move, for cutting threads of different pitches, for running right or left-hand; and means must be provided for quickly and automatically reversing the taps at any desired position.

The National Mchy. Co., Tiffin, O., have brought out a tapper in which the attempt has been made to meet these various requirements. The half-tone shows the general design. Three pulleys—a driving pulley, a reversing pulley and an idler pulley—are carried on the horizontal shaft at the top. Next to the pulleys is a cone of gears by means of which the speed of the tapping spindles may be easily regulated. Below the pulleys and carried on the overhanging arm are a set of levers, by which the machine is automatically reversed at any desired position and then brought to rest with taps in their highest position. Each tap spindle is equipped with a relief device which can be so adjusted that any pressure on the tap—within reasonable limits—will cause it to yield. In addition each spindle carries a sleeve leadscrew, which can be easily removed and replaced by one to suit the pitch of the tap. The tap spindles are made to revolve for either right-hand or left-hand threads, by throwing in either one or the other of the bevel pinions on the top of the machine.

The table is machined on top, and is equipped with T-slots for clamping the jigs which hold the work. It is provided with means for easily adjusting its height. A system of force lubrication is used which not only oils and cools the tap, but also carries away the chips into the movable chip pan. The operation of this tapper is as follows: When the machine is at rest and the taps are in their highest position, the work is secured in the jigs, located on the table; the hand lever is then to the left shifted, throwing the belt on the driving pulley and starting the machine in motion. The taps rotate and descend at the same time, tapping the work, until a definite position is reached at which point they automatically reverse and back out of the holes which they have just threaded; as soon as they reach their highest position, the belt is automatically thrown onto the idler pulley and the machine comes to rest. New work is then secured in the jigs and the operation is repeated.



Four-spindle Nut Tapper

The machine illustrated occupies a floor space of 6 feet 5 inches by 3 feet 3 inches and has a net weight of 3,000 pounds. The manufacturers are prepared to build jigs for holding any class of work which it is desired to tap on this machine.

ELECTRIC HOIST.

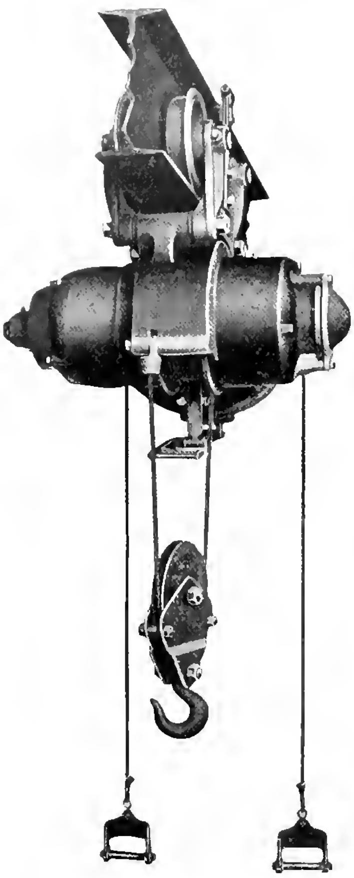
The General Pneumatic Tool Co., Montour Falls, N. Y., have placed on the market an electric hoist known as the Shepard hoist. This apparatus has a number of new features which can be best referred to by taking up the different parts in order.

The motor is fully inclosed but the commutator and brushes are easily accessible and are visible through mica windows.

Two carbon brushes are employed and flexible metallic leads are used to carry the current, to avoid sliding contacts. The armature and field windings may be removed without disturbing other parts of the hoist.

The controller is inclosed in a separate case, independent of the hoist proper, and is arranged for a wide speed control. The segments, while fully protected, are visible at all times. Each contact has an independent magnetic blow-out. The controller is reversible and gives equal speed control in hoisting and lowering. While it is ordinarily mounted on the hoist it may be located elsewhere if desired.

An automatic stop is provided to prevent overwinding. It acts directly on the lower block, and cannot be put out of adjustment by the stretching of the cable. A mechanical brake is provided, to prevent the load from running down when the motor is at rest. It offers no resistance to hoisting but can only be released by reversing the motor and it can be immediately set again should the load descend at a speed slightly greater than that corresponding to the speed of the motor. No current is consumed in loading, aside from the small amount necessary to rotate the motor under no load. The friction surfaces of the brake are submerged in oil. An electrical brake is also applied directly to the armature shaft and is always set at full power unless held off by the current flowing through the armature. The gear consists of a double train of machine-cut and spur gears contained in a sealed case and submerged in oil. This part of the apparatus has been designed like the other parts, so that the gears can be removed without interfering with any other section. Replacing the cover secures the gearing ready for service, and there are no pins, keys or screws to be replaced.

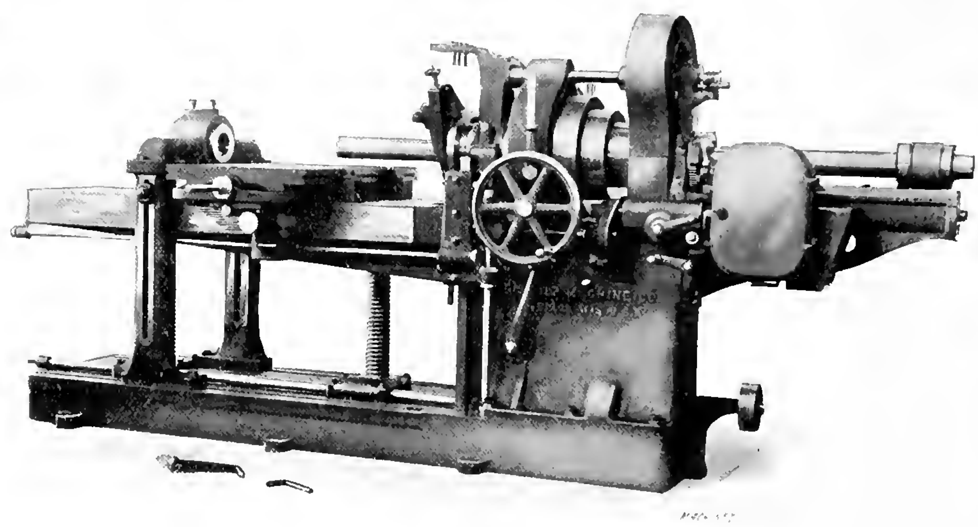


Electric Hoist.

The trolley is made in a variety of forms, one of which is shown in the illustration. It is provided with roller-bearing wheels, having chilled spherical treads, and will be furnished with pendant hand chains or an electric motor, for the traveling movement, if desired. It requires unusually small head room. It is claimed for this hoist that it consumes less power than the worm-driven hoist; that the brakes hold the load positively, without absorbing power while the hoist is operating; and that the accessibility of the various parts, and the wide speed variation, are strong points in its favor.

HORIZONTAL BORING MACHINE.

The horizontal boring machine shown herewith is one of the latest tools produced by the Gisholt Machine Company, Madison, Wis. The headstock is of the friction back-geared type with two sets of back gearing. The boring bar is of hammered crucible steel accurately ground and with taper socket for the insertion of supplementary boring bars. The feed mechanism is of the same type used on the Gisholt lathes, namely, by means of a coarse-pitch screw. The feed is positive and no extra attachment is required for screw cutting. Operating levers are located on both sides of the machine, thus giving absolute control from either side. The table adjustment is a new feature. By the simple movement of one lever convenient to the operator when standing close to his work, the table may be accurately raised or lowered by power and is capable of the finest adjustment. The cross table has a compound movement and is fitted with a power cross feed when desired. Both transverse and longitudinal screws for moving the cross table are fitted with micrometer index dials reading to .0010 inch. The yoke for the table is of the box section form of a very rigid construction and is clamped in the table instead of by use of bolts in T-slots. It carries double bushings for support of the boring bar. This machine is one of several shown by this company at St. Louis.



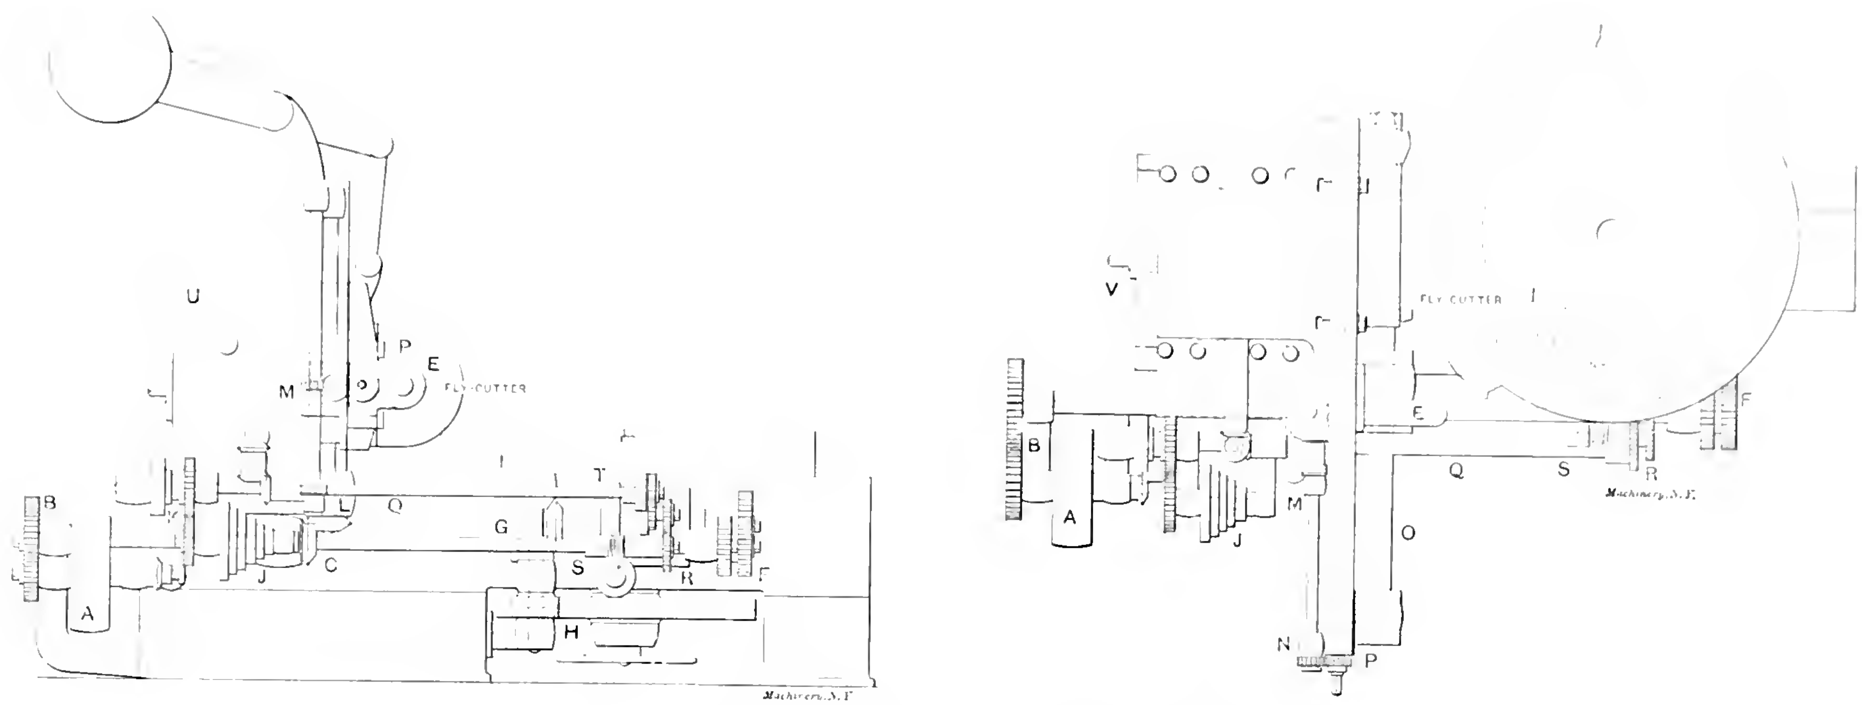
Gisholt Horizontal Boring Machine.

WORMWHEEL GENERATING MACHINE.

The increased demand for a machine to generate accurate wormwheels has led to the design shown herewith. As will be seen, the design is especially rigid; the stiff anvil construction allows of taking very heavy work and heavy cutting without the usual bad strains. The machine is constructed to generate wormwheels either with or without the use of a hob. Although there have been similar machines built for this purpose in Europe, and one in the United States, at the works of Hugo Bilgram, this machine embodies many distinct and original improvements.

The cutter drive and dividing train is driven by the pulley, *A*, thence through the speed-change gears, *B*. The bevel gears, *C*, and worm and wormwheel, *E*, connect with the tool. The horizontal shaft extends to the dividing change-gears, *F*, through the "jack-in-the-box" and gears, *G* and *H*, to the work spindle. The faceplate gears, *I*, are used for driving very heavy work of large diameter, to eliminate all torsion of the work spindle.

The feed-drive and conjugating train are driven from the cone, *J*, thence through the change gears, *K*, worm and wormwheels, *L* and *M*, gears, *N*, to the feedscrew *O*, which gives the slide, *P*, and cutter-spindle the movement or feed tangential to the blank. The shaft, *Q*, connects with the gears, *R*, worm and wormwheels, *S* and *T*, and the "jack-in-the-box," which gives a plus or minus amount to the rotation of the blank. The use of the "jack-in-the-box," or differential gearing, is a very convenient method for giving the blank the same amount of movement along the pitch line, as the tool passes through in feeding endwise, in cutting with the single tool or a taper hob. The two movements, the dividing movement and the conjugating movement, are thus combined, so as to give the blank the effect of both. The conjugating movement alone would give the blank one correct spur notch, gen-



Elevation and Plan of Eberhardt Brothers Company Wormwheel Generating Machine.

erated by the tool. The dividing movement gives the blank the necessary wormwheel rotation, or indexing. Combining these movements through the "jack-in-the-box," the blank is continuously rotated, and at the same time receives the tangential conjugations, so that the result is to produce a perfect generated wormwheel.

In the earlier machines which used the single tool or taper-hob principle, the cutter spindle was supported by a slide underneath it which gave it the required endwise movement or feed. That method of construction required the cutter spindle to be made in a large span between its bearings, and also placed the cutter spindle several inches out from the frame of the machine. In the machine illustrated, the cutter spindle is supported by stationary bearings, and is moved endwise by means of a slide at one end of the spindle. This gives greater rigidity to the cutter spindle, by bringing the bearings closer together, and thus shortening the span of the spindle and placing the spindle close up to the frame.

This machine can accommodate the ordinary cylindrical hob, in which case the tangential feed is stopped by locking the tool slide, *P*. The stanchion, *U*, is then fed forward by means of the screw, *V*, and the hob enters the blank in the usual hobbing manner. The single or fly cutter method is used either to save the expense of a hob, as where only a few wheels of a certain pitch are to be made, or in a case where a particularly accurate gear is required. The fly cutter is the cheapest and yet the most accurate tool for wormwheel generating. It is ground after hardening, thus eliminating the imperfections that develop in hardening hobs. It is simple to make, being merely the shape of a single rack tooth. The standard thread angle $14\frac{1}{2}$ degrees, may be used, but this may be varied to suit special requirements. For instance, where a wheel has a small number of teeth, the angle may be made 20 degrees to avoid under-cutting.

In operation the cutter-spindle is set to the correct center distance by means of a vernier scale on the bed and stanchion. The tool is set out the proper distance from the spindle center (one half the outside diameter of the worm, plus the clearance) and is swiveled to suit the worm thread angle. The tool commences cutting at one side of the blank, and the cutter spindle feeds endwise, tangent to the blank, until the wheel is finished. For commercial purposes, one passing across is sufficient to finish the wheel, but much better results are produced by taking a finishing cut. This method of cutting is not a "nibbling" process; on the contrary, the chips are heavy, and resemble planer chips.

In cutting wormwheels with a fly cutter, it may be valuable to note that considerable time can often be saved by having a "hunting tooth." To illustrate: In cutting a wormwheel of 10 teeth, in which the ratio of wheel to worm is 1 to 1 (a ratio which this machine can easily cut) the wheel would have to be indexed 9 times; whereas, if the wheel could have 11 teeth, to suit a worm of 10 threads, one setting of the fly-cutter would cut the 11 teeth without any further indexing.

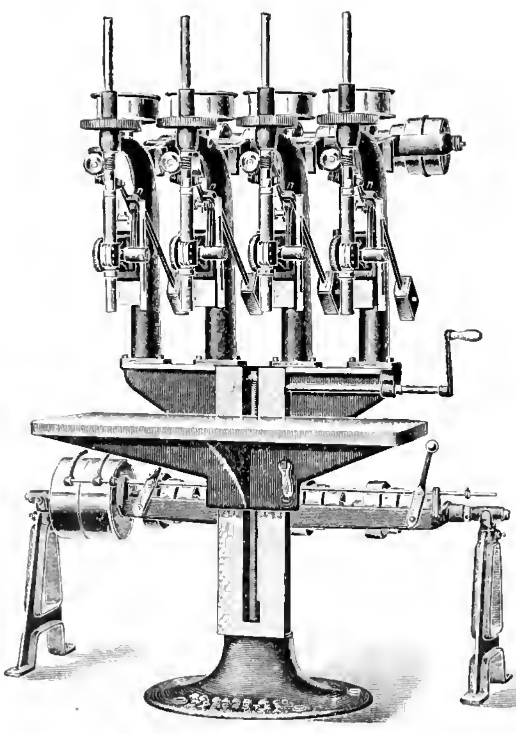
This machine accommodates single or multiple thread worms of any diameter. Right- or left-hand threads are cut by merely setting the tool to the right or left. It is made in two styles: The plain style cuts wormwheels in which the worm is at right angles to the axis of the wormwheel. This style cuts spur gears with the ordinary rotary cutter. The universal style cuts wormwheels to suit worms at any angle to the wheel axis. This style also cuts spiral and spur gears either with the ordinary rotary cutter or with a hob. Six sizes of each style are built, by Eberhardt Brothers Machine Company, of Newark, N. J.

SENSITIVE DRILLING MACHINES.

The use of high-speed drills, together with the modern practice of duplicate jig work, has created a demand for more

powerful machines of the class known as sensitive drilling machines. To meet this demand H. G. Barr, Worcester, Mass., has brought out ten new machines. One of these styles has two, three, four, five and six spindles guaranteed to drill up to ⅝-inch holes in ordinary practice, but not intended for high-speed drills of that size. These have one-inch spindles with ball-bearing thrust collars, the bearings being made of tool steel from the bar. There is a No. 2 Morse taper in the spindles, and three speeds independent to each spindle. The spindles have a traverse of 5 inches. The heads are adjustable and the tables are also adjustable on the columns. The spindles have power feed driven independently from each spindle, also automatic stop and quick return. All the drills have lever feed and power feed, but are furnished without feed, at lower cost, if desired.

Another style is built in five sizes with two, three, four, five and six spindles. It is similar to that described above with the following additional features: The spindle driving pulleys are set on studs back of the spindles and are geared to the spindles with spur gears about 2 to 1, giving sufficient power to drill ¾-inch holes easily with high-speed drills. They will drill holes larger than this but are not warranted to stand continuous use with ⅞-inch drills, or larger, as these sizes are for a heavier class of machines. The tight and loose pulleys on all these machines are 10 inches by 3¾ inches. The manufacturer states that these machines are strong and durable and have been designed with a view to adapting them to up-to-date needs and, added to their regular line, make a very complete line of sensitive drilling machines, there being 36 different machines.



Barr Sensitive Drill.

GRIDLEY AUTOMATIC TURRET LATHE.

The Windsor Machine Co., Windsor, Vt., have for some time been manufacturing an automatic turret machine for bar work that is a distinct departure from other automatic screw machines. They have brought out a machine of entirely new design, embodying the more important features of the earlier machines, but containing a new arrangement of mechanism and tools. In this, as in earlier machines, the tools are fastened to and supported by slides gibbed onto the periphery of the turret which does not move axially, but is mounted to revolve on an axis parallel with the spindle.

In the base of the machine is the horizontal cam shaft containing the drums and disks to which the cam plates or dogs are fastened for actuating the various motions of the machine.

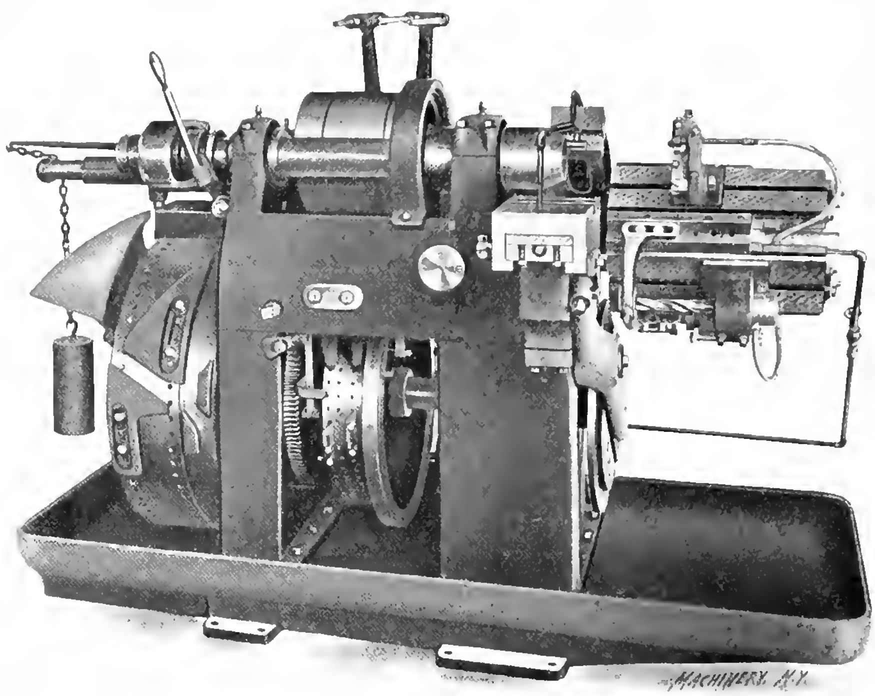


Fig. 1. New Automatic Turret Lathe.

The turret is supported by a hollow spindle running in bearings at each end of the headstock. On this spindle is keyed a wormwheel and an index plate, the latter having four notches corresponding with the four slides of the turret. The wormwheel is driven by a worm on a shaft at right angles to the lathe spindle, and on the rear end of which is the belt pulley which runs continuously. The worm is thrown into or out of action by a clutch mechanism operated by a lever which receives its motion from the drum at the center of the cam shaft. This lever also withdraws a locking pin which fits into the notches in the index plate. The arrangement of the mechanism is such that the pin must be positively withdrawn before the clutch faces come in contact, and also the clutches must be thrown out of contact before the pin can again engage the notches.

The turret slides derive their feed from the large cam plates bolted on the face of the cam wheel at the left of the machine. These plates operate a drew bar extending through the hollow spindle of the turret and engaging a pin attached to the under side of each slide when the slide is brought into position by the rotation of the turret.

The lathe spindle is fitted with a draw chuck operated by cams on the right of the large drum. Inside the sleeve of the draw chuck is a feed tube for feeding the stock through the spindle. This is split at the chuck end of the spindle so as to grip the stock securely enough to feed it forward, but slide over the stock when the chuck is closed on it and the sleeve is drawn backward by the large cam attached to the left-hand side of the large drum. This places the sleeve in position for feeding the stock again under the action of the weight shown in the engraving, after the usual method in such machines.

The cams attached to the face and left-hand side of the small drum at the center of the machine are for shifting the spindle and feed belts. The spindle is back-geared at a ratio of 4 to 1, and is driven by either of two belts—one of which reverses the motion of the spindle when backing out a tap. If automatic dies are provided, however, both belts may run in the same direction, thus making two belt speeds. The disk at the extreme right of the cam shaft carries two sets of cams, one for the cut-off arm and the other for moving the forming

slides, plainly shown in the illustration. Perhaps the chief interest in the machine centers about the novelty of the horizontal turret with its slides, to which are bolted the tools and tool holders. This arrangement enables a great variety of work to be done with comparatively simple tools which are readily adjusted. Much of the work is performed by single-point cutting tools or turners instead of with box tools or forming tools. The turret slides have longitudinal T slots so that the tool holders may be located at any point in the length of

Fig. 2. Turner used on Lathe.

the slide, which fixes their position relatively to the work, while the feed cams determine the time and extent of the movement of the tools.

The half-tone, Fig. 2, shows one of the turners regularly supplied with the machine, which is to be clamped directly to ono of the turret slides. This turner carries its own back rest and uses a single-point cutting tool. The back rests shown in place are of the usual type consisting of blocks clamped in position, but roller back rests, such as shown standing beside the turner in the engraving, have been found to give very satisfactory results and to greatly reduce the friction.

In Fig. 3 are details of a cross slide designed to be clamped to one of the turret slides and to be used in turning, by the aid of a former bolted to the turret. This is designed so that the slide carrying the tool withdraws automatically on the return,

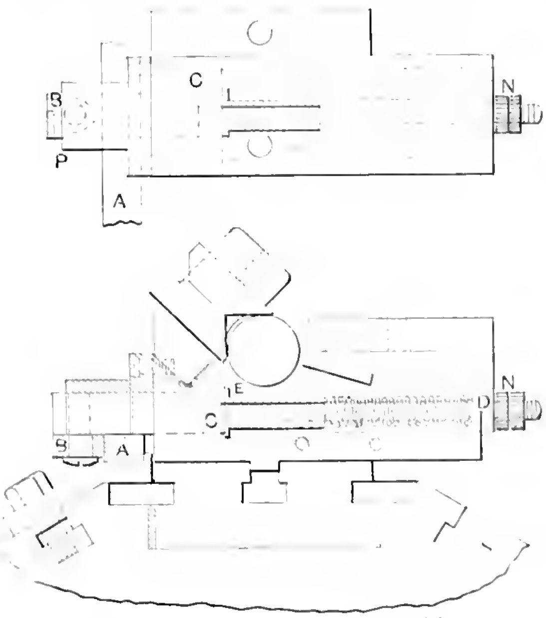

Fig. 3. Tool Slide and Back Rest.

thus preventing the cutting edge from rubbing over the finished work. In the illustration *A* is a guide against which the swivel block *D* pivoted to piece, *C*, bears. Piece *C* extends through the head and is threaded on the end for the nut, *N*. The spring bearing against the slide at *D* and against the bushing at *E*, which at its other end bears against the casting supporting the back rest, tends to continually push the tool away from the work as far as allowed by the position of the nut, *N*, thus taking up all backlash. When the tool begins to cut, the swivel block *B* takes the position shown in the upper view, with the pin, *P*, bearing against one side of the slot. When the tool travels in the other direction, the block swivels slightly until the pin bears against the other side of the slot and allows the spring to force the tool a slight distance away from the surface of the work. Fig. 1 shows a similar device arranged for a fixture containing a boring, turning, and facing tool, and designed primarily for taper work, although the

Fig. 4. Taper Turner

piece shown at *A* is cylindrical. *B* is the former pivoted at *C* to a block attached to the turret. In case taper work were to be done, the outer edge—the upper edge in the engraving—would be the taper surface of the former against which the projecting piece attached to the slide would bear. Against the back or lower side of the former a swivel block, *D*, bears, which is pivoted to the base of the attachment. The purpose of this block is to relieve the tool on the return as in the turner shown in Fig. 3, without in any way affecting the adjustment of the guide bearing against the taper part of the former, which determines the shape of the piece.

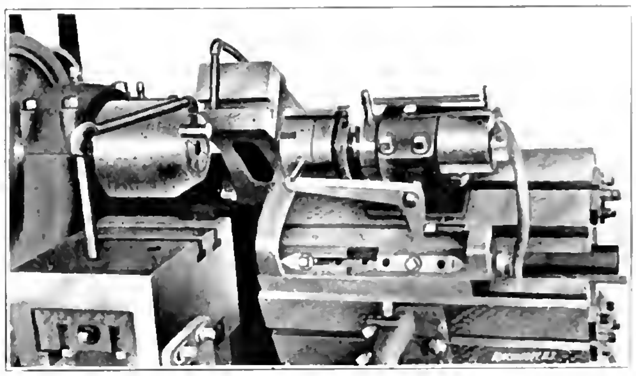

Fig. 5. Geometric Die Fitted to Lathe

The illustration, Fig. 5, and the line drawing, Fig. 6, shows the way in which a geometric self opening die is fitted up for use on the machine. As the die advances upon the work lever *B* comes in contact with the stop, as indicated, and opens the die. Upon the return the arm, *C*, of the bell crank lever hits a stop bolted to the lathe turret which throws up the long arm of the lever, hitting pin *A* of the die and closing it.

In Fig. 7 is the drilling attachment, fitted up with a hollow drill. The guide bushing for the drill is carried by an arm

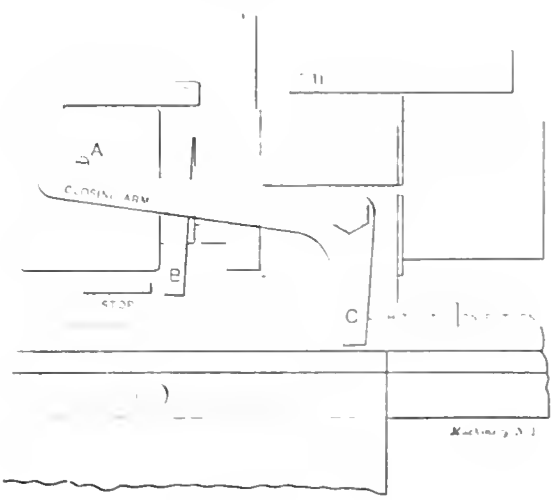

Fig. 6. Details of Die Holder

bolted to the turret while the drill holder is clamped to one of the turret slides. Oil is carried to the drill by flexible tubing, and the arrangement is such that oil is supplied to this and to the other tools only when the slide carrying each tool

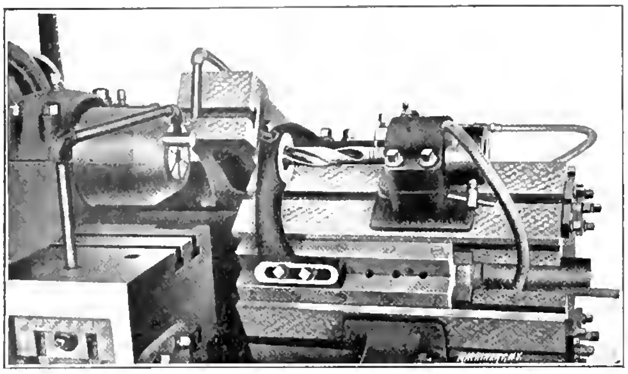

Fig. 7. Drilling Device, Gridley Automatic Turret Lathe.

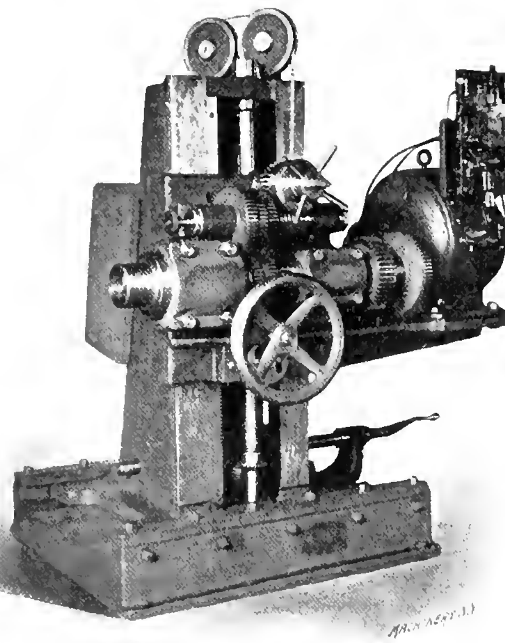
is in a position where oil is required. In every other position the slide automatically shuts off the supply, so that the oil is not flowing over parts of the machine where it is not desired.

SARGENT MILLING MACHINE.

A special milling machine made by W. L. Sargent, Fitchburg, Mass., is shown in the accompanying illustration. The frame consists of a heavy upright made to travel in ways on the base of the machine. The saddle carrying the working spindle travels vertically on the column and is balanced by a casting supported by a cable at the rear of the column. The machine is driven by an electric motor located on the saddle, so that the machine is self-contained and independent of



Sargent Special Milling Machine.

belts and pulleys. It has power feed in a vertical direction. The feed is driven through a cone of gears and a friction clutch. The principal dimensions of the machine are: Vertical movement of saddle, 20 inches; hole in spindle No. 6 Morse taper. Saddle has power down feed with three changes. Spindle driven by constant speed two H. P. motor, arranged to give suitable speeds by change of pinions. Front spindle bearing $4\frac{1}{2}$ by 8 inches. Size of base 33 by 38 inches. Net weight of machine with motor, 4,200 pounds.

* * *

Some brands of high speed steel are very high in price, but perhaps their cost to the user is not disproportionate to their cost to the maker when we consider the high price of many of the constituents used. For instance, vanadium costs, abroad, about $10 per pound; molybdenum, $1.50; tungsten, 65 cents, and nickel, 35 cents.

FRESH FROM THE PRESS.

MECHANICAL APPLIANCES AND NOVELTIES OF CONSTRUCTION. By Gardner D. Hiscox. Published by the Norman W. Henley Publishing Co., 132 Nassau Street, New York. 396 8vo. pages. Illustrated with nearly 1,000 engravings. Price $3.00.

This is a supplementary volume to the one upon mechanical movements by the same author, which has passed through ten editions. Instead of dealing with elementary movements like the earlier volume, it contains illustrations and short descriptions of many combinations of motions and of mechanical devices and appliances found in different lines of machinery. Some of the chapter headings are: Steam Power Appliances; Hydraulic Power Appliances; Road and Vehical Devices; Horological Time Devices; Textile and Manufacturing Devices; Perpetual Motion; etc. While perpetual motion, of course, is a dream and a fallacy, the historical treatment of the subject in this chapter will prove of interest. The other chapters, however, deal with practical devices. The engravings are all made by the wax process (the same that is employed in MACHINERY) and are unusually well executed. The book will appeal to mechanics, inventors and others who wish to familiarize themselves with interesting mechanical devices covering a wide range of work in many fields.

A SECTIONAL DRAWING OF A MODERN BATTLESHIP WITH REFERENCE LIST OF PARTS. Published by the Derry-Collard Co., New York. Price 50 cents.

This is probably the finest sectional engraving of a mechanical subject that has ever been produced. It shows a longitudinal section of a modern United States navy battleship of the *New Jersey* and *Connecticut* type, completely equipped and supplied with the stores necessary for a sea voyage. The section has been drawn in different planes at different points of the ship, so as to show the interior of all the important compartments into which the hull of a vessel is divided, regardless of whether they are located in the central plane of the boat or at front or back of it. By this means practically everything that goes to make up a battleship and its equipment is shown. There are in all 497 items to which reference is made in the list of parts.

The original drawing from which the engraving was produced is a wash drawing in black and white, the preparation of which extended over a period of two years. The reproduction is nearly 3 feet long, and $13\frac{1}{2}$ inches high. It is printed on heavy plate paper, suitable for framing. Reference to certain details will show the care with which every part has been gone into. Of the machinery equipment, besides the engines and boilers all the auxiliary machinery, such as winches, steering gear, blowers, pumps, etc., are shown and the machine shop and laundry are shown fully equipped, and we note that in the machine shop even the handles of the engine lathe are drawn, so carefully has the artist gone into details. We are informed, moreover, that all these parts are in the correct proportions, as the details represented were carefully measured before being placed on the drawing if their sizes were not known. The method of hoisting the ammunition is indicated, the food supply in the refrigerator is shown, as well as other stores, furniture, etc., etc. Underneath the drawing is a scale by which dimensions of any of the parts can easily be determined. The ships semaphore signals are set, the speed cone has been elevated, indicating "full speed ahead," and the flag signals read: "We can defend ourselves." The drawing was approved by naval officers before the engraving was made.

MANUFACTURERS' NOTES.

THE NEW ENGLAND ROLLER GRATE CO., Springfield, Mass., have decided to open up a store for the sale of machinery, new and secondhand, and shop and foundry supplies, at 218 Worthington St., on the first of December.

THE NORTHERN ELECTRICAL MFG. CO., Madison, Wis., were recently awarded the order of the Cutler Hammer Mfg. Co. for the electric equipment for their works, consisting of a 75 K. W. and a 37.5 K. W. generator

THE BLANCHARD MCHE. CO., Boston, Mass., report that on Nov. 11 their office at No. 11 Harcourt Street, was burned out, there being considerable damage. This, however, will give them an opportunity to secure larger quarters so long needed.

THE CROCKER-WHEELER CO., Ampere, N. J., are distributing a postal card stating that they are supplying the electric light and power plant for the U. S. S. *Connecticut*, which consists of 8 Crocker-Wheeler generators direct-connected to Forbes marine-type engines.

THE BAY STATE EMERY WHEEL CO., Worcester, Mass., have purchased the real and personal properties owned by the National Emery Wheel Co. and will continue the manufacture of corundum and emery wheels by the same processes, and under the supervision of Superintendent H. F. Sanderson.

HENRY E. EBERHARDT, who was identified with Gould & Eberhardt, Newark, N. J., for more than 35 years, as a member of the firm, chief designer and inventor, has resigned from the above company, and is now associated with his sons in the Eberhardt Bros. Machine Co., Newark, N. J

THE NORTHERN ELECTRICAL MFG. CO., Madison, Wis., are equipping the new plant of the 23d Regiment Armory, Brooklyn, with two 75 K. W. "Northern" generators direct-connected to a Harrisburg engine, and with a 35 K. W. "Northern" generator belted to a Nash gas engine.

J. G. BLOUNT CO., Everett, Mass., manufacturers of lathes and grinding machines, have just completed a new storehouse next to their shop, which will give them additional facilities for carrying a larger stock than they have heretofore been able to, so as to fill all orders for their tools on receipt.

THE VITRIFIED WHEEL CO., Westfield, Mass., have recently moved into their new plant. The plant is well lighted and built after approved modern methods. This company manufacture pure corundum wheels for grinding purposes; also vitrified wheels, made of a new crystal corundum.

The McCullough-Dalzell Crucible Co., Pittsburg, Pa., have just completed a new dry house, comprising a series of deep pits, flanked by large furnaces. The drying process is an important factor in crucible making. Natural gas is the fuel used for heat and power. The company report an encouraging growth of new business during the year.

THE BURKE ELECTRIC CO., Erie, Pa., is a new company incorporated under the laws of New Jersey with a capital of $150,000. They have absorbed the Keystone Electric Co. of Erie, Pa., whose plant they will occupy, and are to manufacture dynamos and motors under the patents of James Burke, president of the company. Herbert B. Coho is vice-president and Gustave Faure manager and superintendent.

We have received a letter from the Coes Wrench Co., Worcester, Mass., saying that they have recently been visited by four engineers from Vienna, Austria, who are securing information from American plants, and from conversation with them the Coes Wrench Co., is led to believe that they are attempting to secure points about the manufacture of American hardware, which will be detrimental to the interests of firms selling abroad, where the competition of foreign manufacturers of hardware is very keen.

The National Electric Co., Milwaukee, Wis., have entered into an important arrangement with Robert Lundell and Robert T. Lozier, by which the National Company will manufacture and market the new motors and generators and systems of operation and control that are covered by the latest inventions of Robert Lundell; the commercial direction of the undertaking being placed in the hands of Robert Lozier, who will also act as general manager of the Electrical Sales Department of the National Company. Mr. Lundell assumes the direct supervision of the engineering involved under the license that he grants the National Company, and which covers all of Mr. Lundell's inventions not already under license to other companies, and all inventions that he may hereafter make during the life of this license.

NEW TRADE LITERATURE.

Manufacturers and others sending catalogues for notice are requested to address them to the Editor of MACHINERY, so that they can be kept separate from catalogues sent us for other purposes

James McCrea & Co., Washington St., Chicago, Ill. 1904 catalogue of steam specialties.

The Whitman & Barnes Mfg. Co., Chicago, Ill. Illustrated catalogue of haying tools and supplies.

Zeh & Hahnemann, 213-219 Chestnut St., Newark, N. J. Circular of this company's inclinable power presses.

The Western Electric Co., Chicago, Ill. Bulletin 6010 of knife switches. The various styles of these are here shown and described.

The Cook Mfg. Co., Albion, Mich. Catalogue of gas and gasoline engines. The Cook engine is here described and illustrated in detail.

The Dean-Waterman Co., Covington, Ky. Catalogue of the "Dean" gas and gasoline engines, built in sizes from 2 to 50 horse power.

The Crowe Metal Mfg. Co., Chicago, Ill. Illustrated catalogue of metal name plates.

The Henry Walke Co., Norfolk, Va. Catalogue H of portable sawmill machinery and similar specialties, as manufactured by the Curtis & Co. Mfg. Co.

The Emerson Electric Co., St. Louis, Mo. Bulletins Nos. 3060 and 3061 showing bipolar enclosed motors, and friction and bench drills driven by Emerson motors.

The Mechanical Appliance Co., Milwaukee, Wis. Booklet illustrating the "Watson" multipolar motors and generators and their application to various types of machinery.

The Wellman-Seaver-Morgan Co., Cleveland, Ohio. Pamphlet descriptive of the Akron Chilian mill designed and built for the wet grinding of metalliferous rock. This is described in detail.

Greene, Tweed & Co., 17 Murray St., New York. Illustrated catalogue of belt studs, belt couplings, piston and sheet packings, the "Rochester" automatic lubricators, wrenches, the "Colvin" interchangeable hammer, etc.

The Norton Emery Wheel Co., Worcester, Mass. Leaflet relative to India oil stones. These are regularly made in 34 shapes covering ordinary demands of the trade, but anything special in this line will be made to order.

The Gem Mfg. Co., Pittsburg, Pa. Illustrated catalogue of oilers, torches, flexible shafting, boiler-tube cleaners, loose-pulley lubricators, etc. Also circular of the Nos. 1 and 2 impulse water-tube boiler cleaners.

The Manhattan Electrical Supply Co., 32 Cortlandt St., New York. Circular of the Hubbell shade holder which, it is stated, is simple in design, strong, durable and holds the shade rigidly without chance of its loosening.

The Charles E. Wright Co., New Orange, N. J. Catalogues of saw machinery. Catalogue "A" takes up band and circular saws; another, wood and metal band sawing machinery and a third takes up cold metal cutting.

The Falls Rivet & Machine Co., Cuyahoga Falls, Ohio. Illustrated catalogue of the Wadsworth improved core machine, making 24 sizes of round cores from 3/8 to 6 inches; also, square, hexagon and irregular shapes.

The C. W. Hunt Co., West New Brighton, N. Y. Catalogues Nos. 046 and 047. The first treats of electric hoists, winches, capstans, the different styles of which are here shown; the second describes coal-handling machinery.

The Fritz & Goeldel Mfg. Co., Grand Rapids, Mich. Illustrated catalogue of drafting room and office furniture, including several styles of drafting tables, drawing boards, blueprint frames, office desks and typewriter desks, railroad filing cases, etc.

The Coburn Trolley Track Mfg. Co., Holyoke, Mass. Booklet calling attention to the Coburn trolley track for carrying materials on an overhead track and saving time and labor. Their No. 20 catalogue gives complete details and will be sent on request.

The Vilter Mfg. Co., Milwaukee, Wis. Catalogues of refrigerating and ice-making machinery; of horizontal Corliss engines; of steam boilers; of buildings for breweries, bottling and ice-making plants (Catalogue C); and of bottlers' machinery and supplies.

The Ingersoll-Sergeant Drill Co., New York. Form 341, "Driving the New York Subway, a short history of this great enterprise, mentioning incidentally the part played by this company's rock drills and air compressors in the construction of the subway.

J. M. Carpenter Tap & Die Co., Pawtucket, R. I. New catalogue, No. 16, and price list of taps, dies, hobs reamers, screw plates, pipe stocks and dies, tap wrenches, etc. They call attention to their very complete list of their round die sets to be here found.

The Ingersoll-Sergeant Drill Co., New York. Pamphlet, "The Storage Air Brake System of the St. Louis Transit Co.," containing a short sketch of this system and referring to the tests of the system made by the Railway Test Commission at the St. Louis Fair.

The Colburn Machine Tool Co., Franklin, Pa. Catalogue "A" of the Colburn universal saw table. This was described in Machinery, July, 1903; also illustrated pamphlet relative to their 72-inch widened pattern vertical boring mill, described elsewhere in this issue.

The American Steam Pump Co., Battle Creek, Mich. Illustrated catalogue No. 12 of the Marsh steam pumps. Boiler feed pumps, plunger pumps, marine pumps, yacht pumps, tank pumps, vacuum pumps are shown. Also air compressors, deep well pumping engines, etc.

The American Blower Co., Detroit, Mich. Bulletin No. 171, descriptive of a new product the "A B C" type vertical, enclosed, self-oiling engine. The oiling system is fully described and the engine is illustrated by a number of half tones showing the different types and details.

The Bayldon Machine & Tool Co., Jersey City, N. J. Advertising card in the shape of an emery disk, calling attention to the company's disk grinders and showing their No. 20 disk grinder, which they state is a reliable machine and furnished at a very low price for a good disk grinder.

The Sprague Electric Co., New York. Bulletin No. 218 showing some of the applications of the Sprague electric motors. These are shown driving radial drills, planers, die presses, various styles of pumps and other machinery. The Sprague [illegible] and spur geared, and an electric winch also appear.

The Chandler Planer Co., Ayer, Mass. Illustrated [illegible] containing description of the Chandler planer which, with the [illegible] high-speed steels, runs at a cutting speed of 60 feet per minute [illegible] at 200 feet per minute. A complete description of this [illegible] published in Machinery, July, 1904, number.

The Evans Friction Cone Co., Newton Center, Mass. 1904 catalogue of the Evans friction cone. Hanging patterns Nos. 5, 6 and 8 are shown and standing pattern No. 9, the first for driving machinery from overhead and the other from the floor. The rest of the booklet is devoted to a very large list of users of this style of drive.

The Joseph Dixon Crucible Co., Jersey City, N. J. Twenty-four page booklet on the subject of graphite for lubricating automobiles and motor boats. The lubricants here described are just for this special class of machinery and the booklet will prove useful to those interested in motor cars and motor boats, to whom a copy will be sent free.

The Columbus Machine Co., Columbus, O. Special catalogue, 1904 of gas and gasoline engines. In addition to their regular line, shown in their previous catalogue, they here illustrate a geared pumping engine and a hoisting engine, recently put on the market. Also a traction engine for agricultural purposes. A list of sizes is also to be found.

The Garvin Machine Co., New York. Booklet descriptive of the solid extended knee which is a prominent feature of the Garvin milling machines. There are no openings either in top or sides, which adds to its stiffness and solidity and makes its use specially desirable for heavy work, obviating chattering. The knee is here fully described.

The Monarch Engineering & Mfg. Co., Baltimore, Md. Pamphlet describing the Steele-Harvey metal melting and refining furnace. It consists of an outer steel shell, lined with a double row of firebrick into which fits the crucible. The furnace can be tilted at any angle and the crucible being always within the furnace loses no heat in cooling off.

The Carborundum Co., Niagara Falls, N. Y. "This Land of Ours," an attractive pamphlet giving interesting historical matter relative to this country generally and in particular about the plant of the above company where carborundum is made. The many and various uses to which carborundum may be put, are here enumerated and illustrations shown.

The Sawyer Tool Mfg. Co., Fitchburg, Mass. Circular showing the company's new line of friction joint calipers (patent applied for). These are outside and inside calipers, and hermaphrodite calipers whose joints have pockets for holding the beeswax for an indefinite period. The joints are adjustable for any desired tension. Complete catalogue furnished free.

The Turner, Vaughn & Taylor Co., Cuyahoga Falls, Ohio. Loose-leaf catalogue of the company's products. These include core machines; steel and cast-iron tub beaters and rubber washers for removing sand, etc.; roll pointers; wire-drawing machines; the Chaser clay mills, double-acting steam press; chain link cutters and winders; oil and gas-burning furnaces, etc.

The Alcolm Co., 200 Broadway, New York. Initial edition of the New York Business Telephone Directory, a copy of which is delivered for every telephone in Manhattan and the Bronx. This enables one to find promptly business addresses and those of professional men, lawyers, doctors, etc. Private addresses are entirely eliminated and the addresses given are classified according to the business or profession. The book will be published twice a year.

The Abendroth & Root Mfg. Co., Newburg, N. Y. Catalogue (with discount sheet) of pipe, spiral riveted, straight seam and punched; and of formed sheets for making up at destination. Different samples of this pipe are shown and quite a number of views of its installation, with testimonials of its efficiency and durability. A number of tables appear and the new style of Root exhaust head is shown. The company also manufacture the Root water-tube boilers, elevators, bilge pumps, flumes, etc.

The Norton Emery Wheel Co., Worcester, Mass. Catalogue of emery and corundum goods and grinding machinery. This book contains 167 pages and appears to be very complete; emery cylinder chucks, bench grinding machinery, floor grinding machinery, the Norton bench tool grinders, countershafts, a lathe grinding attachment, etc., are described. The Norton Co. no longer manufacture or sell the Walker universal tool and cutter grinder but are prepared to furnish a universal tool and cutter grinder, in two sizes, which they can recommend to the trade.

The John M. Rogers Boat, Gage & Drill Works, Gloucester City, N. J. Catalogue No. 7, of small tools. These include fixed caliper and internal and external cylindrical gages and limit gages; measuring machines; corrective gage standards (disks for correcting fixed gages, for setting calipers), etc.; reamers, in many varieties: taper, shell, pipe, inserted blade, spiral fluted, adjustable bladed, etc.; rose reamers, hand reamers, and chucking reamers; and a special adjustable milling tool for milling, facing and centering work in one operation. A number of useful tables also appear.

The A. S. Cameron Steam Pump Works, New York City. Miniature catalogue of steam pumps, a reproduction in part of their complete catalogue. This neat little pamphlet presents a few designs of the Cameron pumps, viz., steam pump for regular service; boiler feed pump; automatic feed pump and receiver; light service pump, with removable bushing; single compound; air pump and condenser; plunger pump; mining pump; sinking pump, etc. The advantages claimed for this pump are simplicity, due to the small number of working parts, and durability, the steam mechanism consisting of four stout pieces only.

The Standard Welding Co., Cleveland, Ohio. "Welding [illegible]" — booklet telling what this company does in the matter of [illegible] welding. Mention is made of some apparently impossible [illegible] have been successfully done by this method. As an example [illegible] steel boiler flues 4 inches in diameter have been welded together to make 30-foot tubes; a pile of bands 14 inches wide 10 feet long at 1-16 inch thick are welded into a continuous belt; a [illegible] sprocket shaft is welded to a steel casting, for use as a brake drum on an automobile, etc. The company state that by their [illegible] of electric welding work is done with far less expense [illegible] effectiveness. The book is sent free upon request.

The Norman W. Henley Publishing Co., 132 Nassau St., New York. Catalogue 9 x 12 of technical books. This is a list of up-to-date works on the following subjects: [illegible] making and interchangeable manufacturing; gas engines; dies; [illegible] steel; compressed air; machine shop tools; patternmaking; perspective drawing; saw filing; liquid air; automobiles; the steam engine; the locomotive; etc. Among them we note as nearly ready "Gas Engines and Producer Gas Plants, by R. F. Mathot, covering the subject of the gas engine; and "American Lathe Practice," by W. H. Vandervoort, covering the latest practice in lathe and boring mill operations. Each book mentioned is the work of a man experienced on the subject of which he writes, and is therefore reliable and valuable. A good description of the works appears in this catalogue, to serve as a guide.

in the selection of them. This catalogue, and their 114-page catalogue of practical books, will be furnished upon request.

CHARLES H. BESLY & CO., 15-21 South Clinton Street, Chicago, Ill. Illustrated catalogue, 1904, of the Gardner grinders, spiral groove disk wheels, Besly band grinders, etc., also of band polishing machines, Helmet cement, Helmet oil, Badger oil cups, and other specialties. The principle of the Gardner grinder and the spiral-groove disk wheel (an essential feature of this tool) are here described, and full directions given as to the methods of operating same. Nine new machines are shown and also two styles of motor-driven Gardner disk grinders, on which can be used any of the well-known makes of motors. A number of pages are devoted to illustrations of the various operations that can be rapidly performed with this tool, such as: Finishing malleable iron wrenches on a No. 6 grinder at the rate of 75 wrenches per hour; grinding a casting (a case for a toothed steering quadrant for automobile) in 90 seconds; grinding 8-inch forgings both sides in 15 minutes, etc. Specifications and prices of each style and size of grinder are to be found, also a good number of testimonials, by users of this tool, expressing their entire satisfaction. The Gardner grinder is used for a great variety of work—grinding and finishing leather, wood, hard rubber, steel, drop forgings, brass, copper, aluminum, cast iron, and an instance is given of a Gardner grinder being used in a marble works for grinding tops of mantelpieces.

ST. LOUIS AWARDS.

The Gisholt Machine Co., Madison, Wis., have been awarded the grand prize at the Louisiana Purchase Exposition.

The E. W. Bliss Co., Brooklyn, N. Y., have received the grand prize and gold medal for tools and machines exhibited at St. Louis.

The Electric Controller & Supply Co., Cleveland, O., announce that they have been awarded the gold medal for their St. Louis World's Fair exhibit.

The Norton Emery Wheel Co., Worcester, Mass., received the grand prize for their grinding machinery at the St. Louis Exposition, also two gold medals for other products exhibited by them.

The Goldschmidt Thermit Co., New York, were awarded the grand prize at St. Louis for their welding compound, thermit; also the Elliott-Cresson medal, which was conferred on them by Franklin Institute.

The Keuffel & Esser Co., New York, have received the highest award at the St. Louis Exposition—the only grand prize for Group 19 (instruments of precision, philosophical apparatus, etc), and a gold medal, for Group 115, instruments and equipments for underground surveying.

* * *

In a paper read before the Coventry Engineering Society, Mr. J. M. Gledhill outlines the process of making shear steel as follows: Five short lengths of blister bar are heated in a hollow coke fire, and which by use of a soft blast admits of being regulated to a welding heat. During this time the surface of the bars is covered with clay beaten fine and applied during the heating to exclude the air and prevent oxidation. The bars are then carefully hammered and welded together. This is known as "single shear" steel. To make "single shear" into what is known as "double shear" steel the bar made of "single shear" as above described is broken in the middle, the two pieces laid together, welded a second time and again drawn to the required shape. By this double operation the steel becomes more homogeneous and of a finer texture, and we thus obtain a material having a hard and steely exterior, and yet possessing a soft interior, thus securing both hardness and ductility where required.

MISCELLANEOUS.

MACHINERY.

January, 1905.

HEAVY WORK OF THE PORT RICHMOND IRON WORKS.

THE works of the I. P. Morris Co., Philadelphia, known as the Port Richmond Iron Works, date their origin as far back as 1828. Their history is almost coincident with that of the development of the iron and steel industry of this country, and they have carried through some of the most important engineering work in the way of pumping engines, turbines, blowing engines, centrifugal pumping machinery, etc., that has been done. Among these are included the Boston sewage pumping engine, and the Louisville Pumping Engine No. 3, both designed by E. D. Leavitt. The former of these is the largest in the world and the latter has proved itself the most economical of its type. Other notable installations are the 15,000 H. P. engine for operating the forging presses at the Bethlehem Steel Co.'s works, which have been illustrated in MACHINERY, and much of the massive machinery installed at the Calumet and Hecla Mines, most of which was designed by E. D. Leavitt. As a matter of historic interest, it may also be stated that they have built engines for certain of the monitors used in the Civil War, under the patents of Ericsson; and the old Cornish engines for the Buffalo water works which they constructed were among the first of the kind in the country.

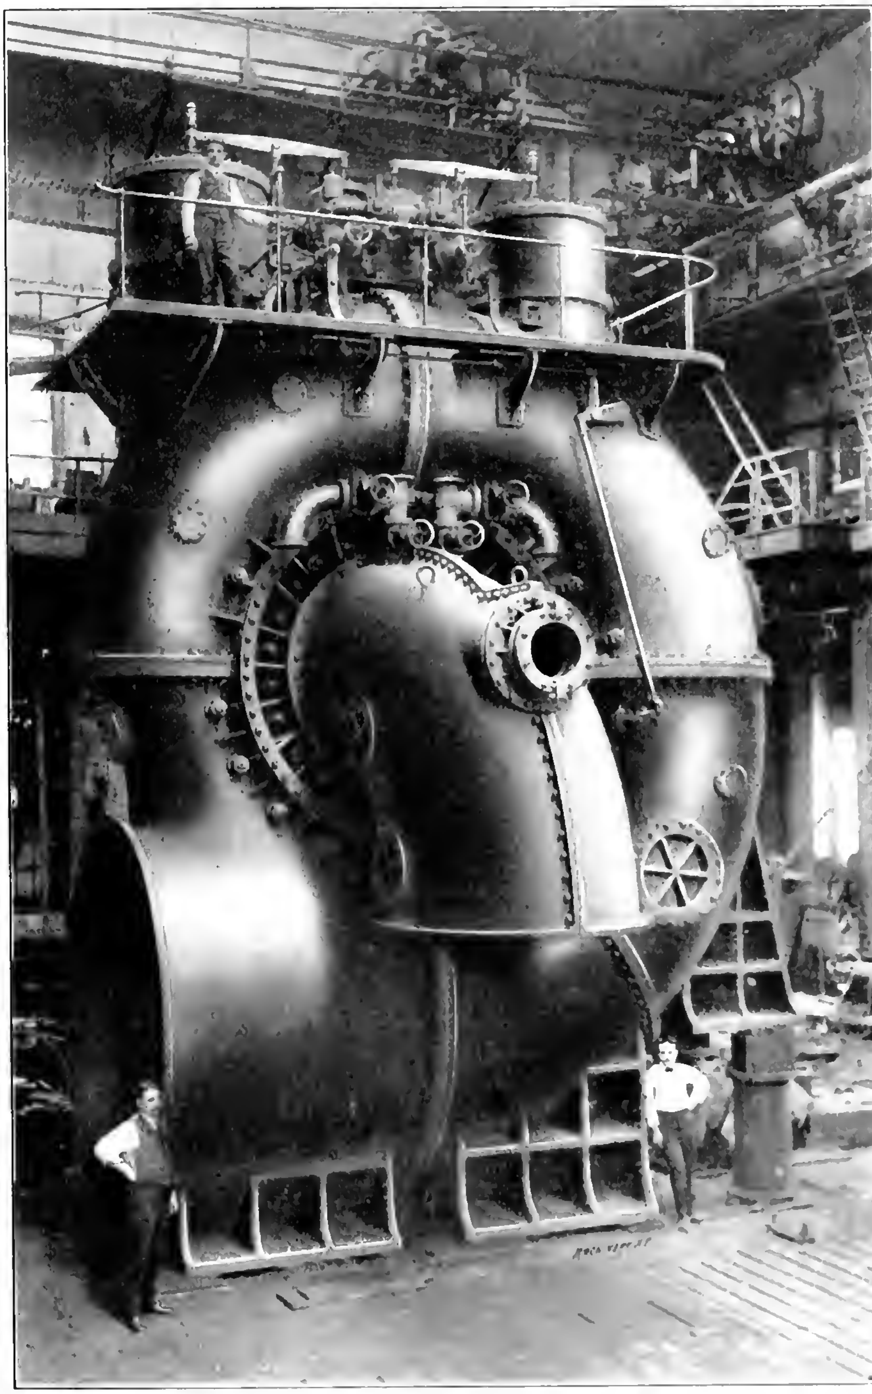

Fig. 1. 10,500 H. P. Turbine for the Shawinigan Water and Power Co., P. Q. Canada

In a bulletin recently issued by the I. P. Morris Co. is given an interesting account of some of the more recent engineering construction carried through by them, and for the account which follows we are indebted to the descriptive matter contained in this bulletin.

Fig. 3 is a view showing the interior of the south bay of the Port Richmond Works, with some of the large turbines of 10,000 H. P. capacity for the Canadian Niagara Falls Power Co. in process of construction. These turbines operate under a head of 145 feet at 250 revolutions per minute, and were built from designs of Escher, Wyss & Co., Zurich, Switzerland. The station will eventually have a capacity of 110,000 H. P.

When the Niagara Falls power plant was projected the I. P. Morris Co. secured the contract to build the turbines—the largest up to that time. The first installation consisted of 10 units of 5,000 H. P. each, and these were followed by 11 larger turbines of 5,500 H. P. for the second plant. An illustration from a photograph of one of the 5,000 H. P. units is shown in Fig. 2 with a portion of the shaft leading to the generator above, and of the elbow connecting the wheel case with the penstock and supporting the latter. It is estimated that the energy produced by the falls of Niagara is the equivalent of more than 7,000,000 H. P., and from this immense amount some 75,000 H. P. is now utilized by this plant, situated about a mile and a quarter up the river on the American side. Here a surface canal 250 feet wide and 12 feet deep leads the water to the power house. The solid masonry walls of the canal are pierced by twenty-one inlets through which the water enters the penstocks in the wheel pits, which are huge excavations 178 feet deep by 18 feet wide and 400 feet long running parallel to the canal, one on either side, about 75 feet away. Penstocks of steel plate $7\frac{1}{2}$ feet in diameter bring the water to the turbines near the bottom of the pit, and these drive the generators vertically over them through shafts 160 feet long or more. The discharge water from the turbines is conveyed from the bottom of the wheel

pits to the main tunnel, and thence into the lower Niagara River. The electric system used is the Tesla polyphase alternating current type, in this case generating a 2-phase, 25 frequency, 2,200 volt current. To consumers within a radius of one or two miles the current is sent, at the voltage generated, over lead-covered cables laid underground in a large conduit and transformed at the user's plant to the required voltage. For the long-distance transmission circuits, to Buffalo and in some instances to points 39 miles away, it passes through similar cables to the transformer house, where it is "stepped-up" to 22,000 volts, at which potential it is carried on overhead wires to sub-stations at the other end, where "step-down" transformers reduce the voltage to suit the local demands. The plant is so constructed that the available H. P. is 110,000, and this development may be made without a perceptible diminution of the flow over the falls.

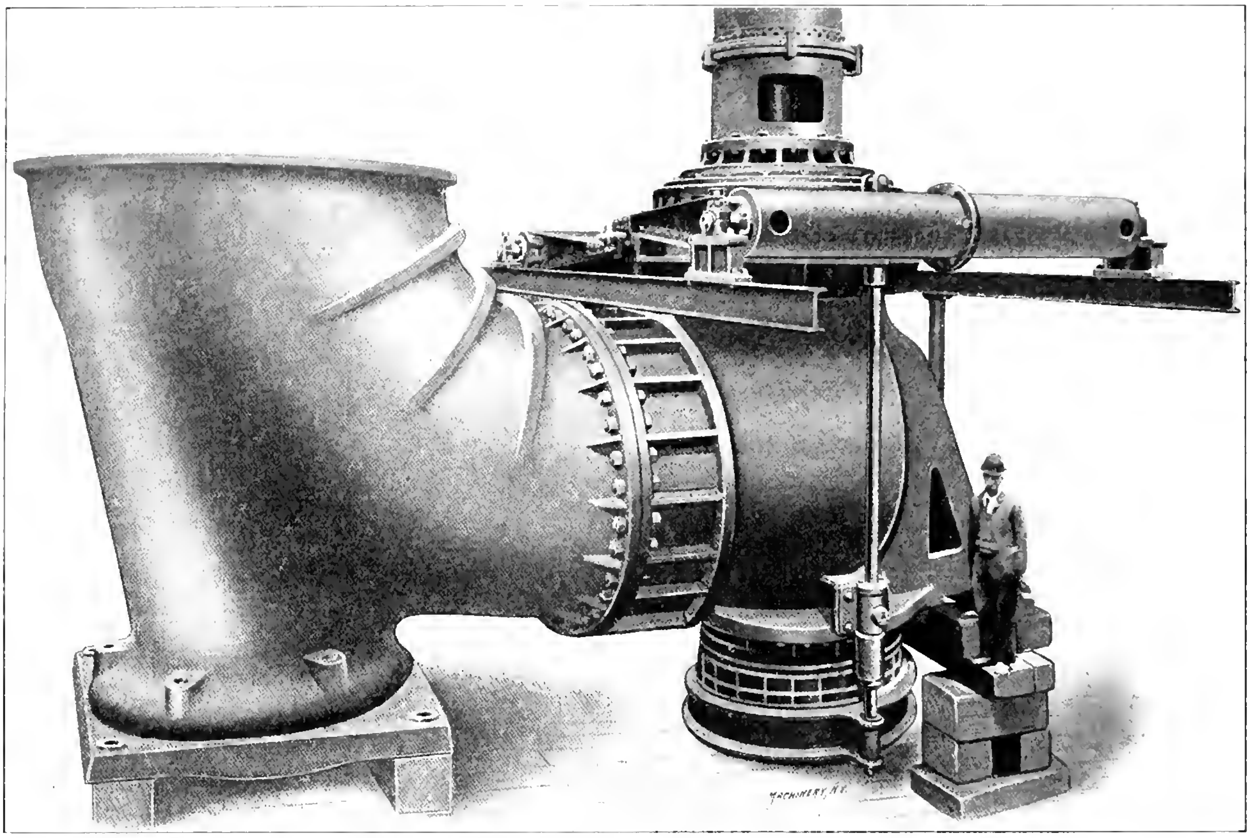

Fig 2 One of the 5,000 H P Turbines in Power House No 1 of the Niagara Falls Power Co. Shows Elbow connecting Wheel Case with Penstock.

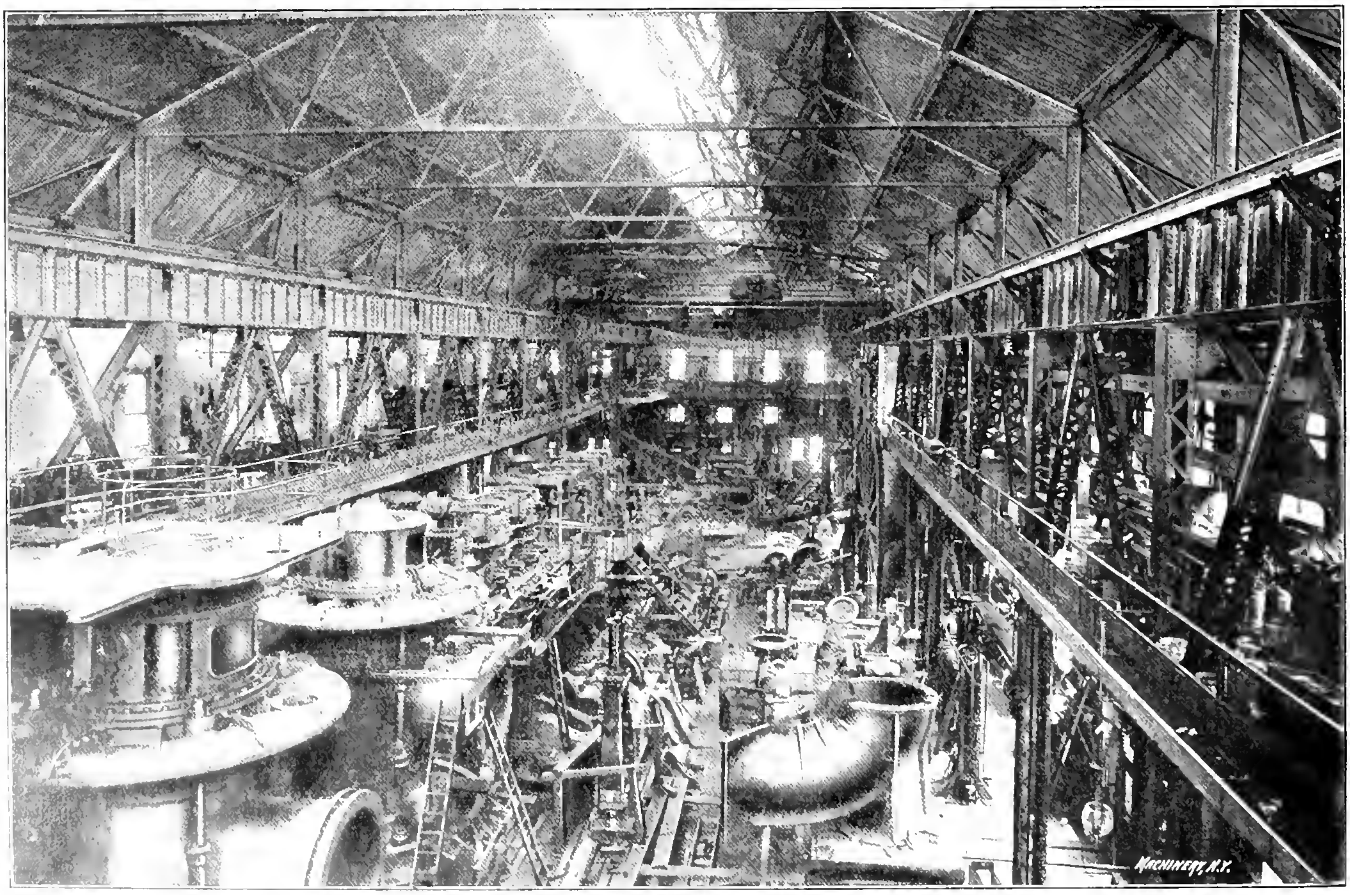

Fig 3 South Bay of Machine Shop, I P Morris Co., Philadelphia, showing 10,000 H P Turbines in Process of Construction.

In Fig. 1 is a view of a wheel of 10,500 H. P. now being installed by the I. P. Morris Co. at the plant of the Shawinigan Water & Power Co., Shawinigan Falls, province of Quebec, Canada. This is believed to be the largest water power unit ever constructed, and is one of four located at this plant, three of which were built by the Port Richmond Works. The plant is 84 miles northeast of Montreal, and is an ideal location for the generation of electricity by water power. Not only is there available a high head, a large quantity of water and a nearly constant flow, but the river widens out to a "lake" both above and below the falls and makes a right angle bend between the two lakes, thus bringing the upper and lower water levels within a short distance of each other and providing a convenient and economical location for the plant on the slope between the lakes. The company has purchased property on both sides of the river for factory sites and operatives' houses, for it is hoped that various industries will be attracted by the cheap water power. Already the wilderness of five years ago is a substantial city of 5,000 inhabitants, and this development has been accomplished without marring the natural beauty and surroundings of Shawinigan Falls. The power capacity of the stream at this point is estimated at 125,000 H. P., and the plant is so built that an ultimate development of 100,000 H. P. is possible when such an amount of power can be profitably disposed of. From the south end of the upper lake a canal 20 feet deep and 1,000 feet long was excavated through rock to a point where, in a distance of 500 feet, the ground makes a drop of 140 feet. At this point the canal was closed by a concrete wall containing outlets for six penstocks, each 9 feet in diameter. Three penstocks 150 feet in length carry water to a like number of turbine wheels in the power house, and two other somewhat longer penstocks lead to the power house of the Northern Aluminum Co., which purchases its power in the hydraulic form, using its own turbines and generators. Each of the three penstocks supplying the Shawinigan Falls Power House furnishes water to a 6,000 H. P. horizontal-shaft turbine direct-connected to a 3,750 K. W. revolving field generator giving a quarter phase, 2,200 volt, 30-cycle current. The new wheel now being installed is of the horizontal shaft inflow type, with spiral casing and draft tube on each side through which the water discharges outward from the center. The spiral casing permits the penstock to be received below the floor of the power house, thus leaving room for oil switches under the switchboard gallery. The design includes a hydraulic hand gear mechanism and other novel features. The wheel is designed to operate under a normal head of 135 feet. Of the present output of the plant about 10,000 H. P. is transmitted over long-distance lines 84 miles to Montreal and there used for street railways, electric lighting and general power purposes. The current is stepped up at Shawinigan to 50,000 volts, three phase, and carried over three cables to Montreal, where it is stepped down, with a loss of about 18 per cent in transmission. A second line to Montreal to carry another 10,000 H. P. is now being built, and a third is in contemplation.

Another plant in which the I. P. Morris Co. has installed machinery is the Niagara Falls Hydraulic Power & Mfg. Co., located on the bluff above the lower Niagara River. While the turbines in this plant are only about one-fourth the size of the one just mentioned, they are still very large and give a high degree of efficiency. The water is supplied by a surface canal

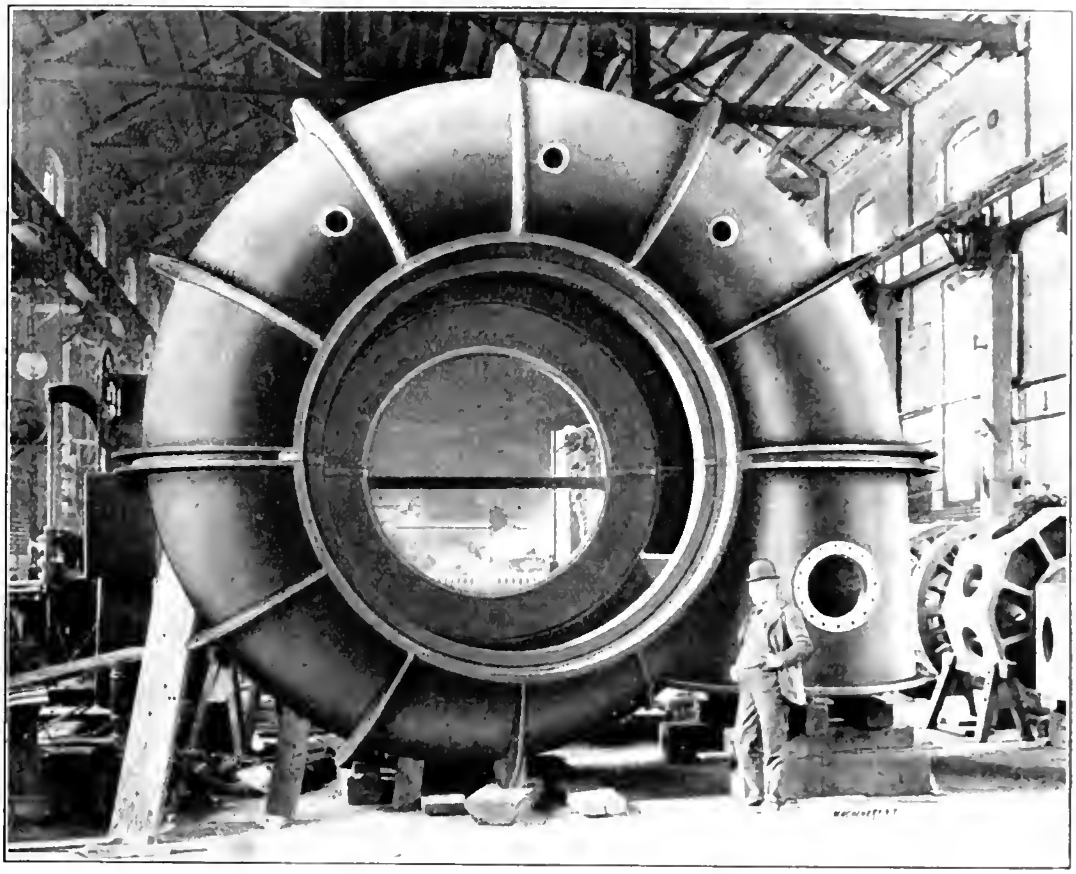

Fig. 4. Volute Casing of Vertical Shaft Centrifugal Pump for the Metairie Pumping Station, New Orleans, La. Diameter of Discharge, six feet. Said to be the Largest Pump made

running from the upper river through the city, a distance of 4,400 feet, to a reservoir on the bluff, whence it flows to the various mills and is discharged by short tunnels through the bluff into the river below. A new power house has now been built at the foot of the cliff where the entire available head of water can be utilized with a consequent increase of power; moreover in this way the need for long transmission shafting is avoided. The water is led from the canal to the wheels through huge penstocks which pass down over the bluff. The total present output of this plant is about 35,000 H. P.

Two large turbines now in course of construction at the Port Richmond Works are destined for the plant of the Canadian Niagara Power Co., which is now erecting its third power house on the Canadian side of the upper Niagara River. Its hydraulic features will be similar to those of the Niagara Falls Co., with which it is to operate in parallel. The units will, however, be of 10,000 H. P. capacity, and the generators will be wound for 11,000 volts, three-phase. The turbines are of the Francis inflow type with draft tubes on either side, and they share with the 10,500 H. P. unit built for the Shawinigan Co. the distinction of being the largest turbines constructed up to the present time. Another plant equipped by the I. P. Morris Co. is the Trenton Falls Plant of the Utica Gas & Electric Co. The power house is fitted up with four vertical shaft turbine units of 2,100 H. P. each direct connected to generators. This hydraulic plant gives very satisfactory service inasmuch as it is almost constantly run at its full capacity, and has established the record of a load factor of 98 per cent of the full output.

Another branch of hydraulic machinery to which the I. P. Morris Co. have devoted much care and attention is the construction of centrifugal pumps, and their most notable work in this line has been in connection with the pumping stations of the New Orleans Drainage Commission. At the Metairie Pumping Station, New Orleans, they recently installed

a vertical shaft centrifugal pump, the volute casing of which is shown in Fig. 4. This pump has a diameter of discharge of 6 feet, a diameter of impeller of 9 feet 4 inches, and a capacity of 320 feet per second at the lift of 10 feet, with an efficiency of 74 per cent. This is believed to be the greatest quantity of water ever discharged by a single pump. This pump is driven by a direct-connected 500 H. P. alternating current motor. Three centrifugal pumps of the horizontal shaft type have been installed in St. Bernard Pumping Station No. 3, also at New Orleans. These are all driven by direct-connected motors, and consist of one "constant service" pump having a capacity of 50 cubic feet per second with a lift of 12 feet, and two "special service" pumps lifting 8 feet with a capacity of 250 feet per second. Each of the larger pumps has a discharge of 6 feet diameter at the pump, enlarged to 10 feet diameter at the discharge basin. To secure the highest possible efficiency, centrifugal pumps and turbines should be designed for the particular lift, capacity, and speed at which they are to operate, in order to better meet the conditions under which they will be required to work.

* * *

HIGH-PRESSURE OILING SYSTEM FOR HEAVILY LOADED BEARINGS.

Almost every one who has had anything to do with the operation of machinery, knows that "friction of rest" is much greater than "friction of motion," or, in other words, that more force is required to start a machine than to maintain the motion without load. The reason, of course, is that the journals sink down into their bearings and displace the oil films so that there is actual metallic contact, which causes them to drag heavily until the oil films are re-established. There is one serious feature of this well-known fact that, we believe, generally escapes attention, and that is the damage often done on heavily-loaded bearings during the starting period. A babbitt bearing may be badly scored at this time although it would give no trouble from heating afterward. In a recent issue the *Engineering Record* tells how this trouble is avoided in the plant of the Puget Sound Power Co. The main shaft of each 3,500 K. W. unit is of fluid-compressed nickel steel, with journals 16 inches in diameter, which are supported by babbitted surfaces 4 feet long. In addition to special oil grooves cut into both the top and bottom halves of the bearing, there is a special high-pressure oil groove not connected with any of the others. This is located vertically under the axis of the shaft, and connection is made to it by a flexible high-pressure oil pipe from a motor-driven oil pump supplying oil at 2,000 pounds per square inch. This system is only used in starting the wheels in order to avoid damaging the babbitt surface, as the rotating element weighs in excess of 98,000 pounds. A centrifugal oil circulating system is otherwise provided so that the bearings may be flooded with an additional amount of cool oil if heating occurs. In each bearing a pair of thermostats is connected in parallel in an electric circuit for indicating at the switchboard a dangerous temperature rise in any of the journal bearings.

ANNUAL MEETING OF THE A. S. M. E.

The fiftieth meeting of the American Society of Mechanical Engineers was held in New York December 6 to December 9, as announced in the last number. The papers read were mostly of a highly technical character, there being fewer of a popular nature than has been the case for several years. The president's annual address on the evening of December 6 is abstracted in another part of this issue and following this Mr. C. W. Hunt addressed the society to present on behalf of an unnamed donor a portrait of Prof. John E. Sweet, one of the founders of the society. At the last session of the meeting Mr. James N. Dodge, of Philadelphia, also presented the society with a bronze bust of Capt. John Ericsson, made from a plaster bust of the great engineer, which was produced while Ericsson was alive.

The membership during the past year has increased largely, there now being 2,800. The expenses, however, exceed the income from dues of nearly $3 per member, and the dues, together with all other sources of income, are not sufficient to pay the running expenses of the society. The reports were given of the progress of the different committees on the Union Engineering Building and as a matter of course, much interest centered in this. Abstracts of some of the papers appear elsewhere in these columns and a brief sketch of the new president, Mr. John R. Freeman, Providence, R. I., together with his portrait, is published herewith.

The New President.

John R. Freeman, the newly-elected president of the American Society of Mechanical Engineers was born in 1855 in West Bridgeton, Maine. His early schooling was secured in West Bridgeton, and in later years he continued his studies at the public schools of Portland, Me., and Lawrence, Mass., finishing at the Massachusetts Institute of Technology, from which he was graduated in 1876, as civil engineer. His first position upon leaving the Institute was with the Lawrence Water Power Company, in whose employ he remained for a number of years, and where he acquired a vast knowledge of hydraulic engineering. He then took a position with the Factory Mutual Fire Insurance Companies as inspector, with a view to acquainting himself with the insurance business. He became particularly interested in fire protection engineering and, being made chief inspector and chief engineer, began a

John R. Freeman.

series of tests and investigations by which he was enabled to bring about many improvements and introduce many new methods. In 1896 he became president of the Manufacturers' Rhode Island & Mechanics' Mutual Fire Insurance Companies, whose business has increased greatly under his supervision. Recently he was made president and treasurer of three more insurance companies.

Mr. Freeman is also a member of the American Society and the Boston Society of Civil Engineers, of which latter society he was president in 1893. He has written several papers of great interest and value, among them one on the "Hydraulics of Fire Streams," and another on the "Nozzle as a Water Meter," for which he received the Norman medal awarded by the American Society of Civil Engineers.

* * *

Over 25 miles of one-inch steam pipe will be used in the hot blast heating and tempering coils to be installed by the American Blower Co. in the new Wanamaker store in Philadelphia. This pipe is being manufactured into one hundred and eleven heater sections, varying in capacity from 35,000 to 36,000 feet of heating surface. Twenty-eight ventilating fans will be used in the building, the largest having a housing of 220 inches and the smallest of 30 inches. The completed apparatus will make a 10-carload shipment. An "ABC" apparatus, of seven large fans and some 44,000 feet of 1-inch pipe, is also to be installed in the New York Wanamaker building.

A REVIEW OF STEAM TURBINE PATENTS.—3.

Seger, 1894.

Seger's turbine has been built and used to some extent abroad. His first patent specification, issued in 1903, shows an arrangement of wheels indicated in Fig. 36. Like Pilbrow and B. T. Babbitt, he seeks to secure a moderate speed of rotation by using two wheels turning in opposite directions.

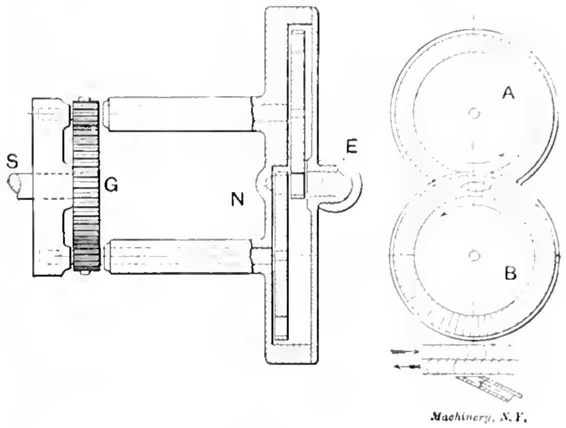

Fig. 36. Seger's First Patent.

The steam, in leaving the first wheel, impinges directly against the second without any intervening guide vanes. The turbine wheels, *A* and *B*, are on separate, parallel shafts, and at *G* are the gears by which the motion of the wheels is transmitted to the driving shaft, *S*. *N* is the nozzle through

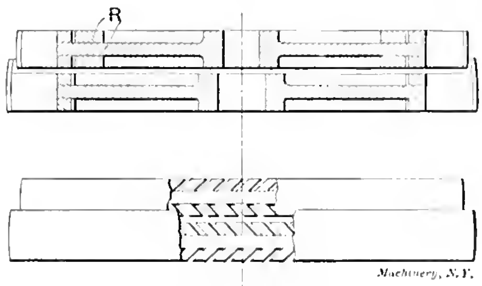

Fig. 37. Arrangement of Wheels.

which steam enters, and *E* the exhaust passage. His claim is for "a steam turbine in which the turbine wheels are placed in close proximity to each other, and are combined with one or more steam conduits discharging into the sides of said wheels in such a manner that the steam passes through the

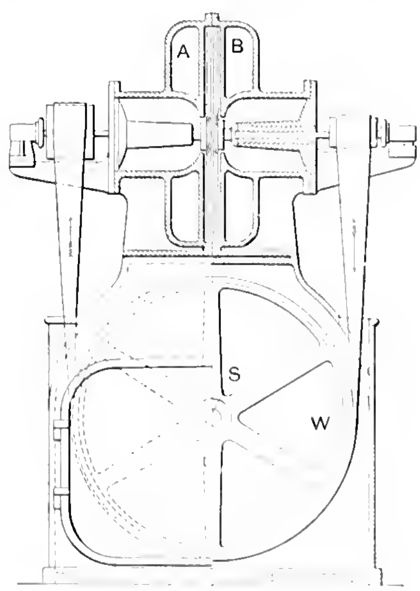

Fig. 38. Sectional Elevation of Seger Turbine

wheels in the direction of their axes; and in which the shafts are arranged out of line with each other so that the wheels only partly overlap each other."

In his patent of 1894, Seger shows wheels arranged on the same axis, but rotating in opposite directions. A feature of the patent is the method for fastening the buckets in diagonal slots cut in the wheel rims. The lower view, Fig. 37, shows these slots, and in the upper view the rings, *R*, formed inside the rim, hold the projecting ends of the buckets in position. This construction will be evident from Fig. 39, where *A* is one of the buckets. At *B* the bucket is placed in the rim and at *CC* its projecting ends are bent over underneath the rim. In 1897 Seger issued an English patent upon an arrangement of his turbine by which the belted connection could be used for driving the low-speed shaft, Fig. 38, from which power is taken. Here *A* and *B* are the turbine wheels rotating in

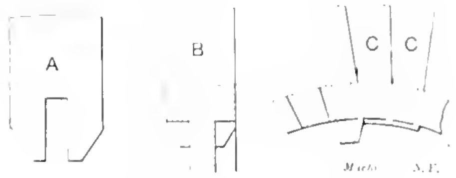

Fig. 39. Vanes of Seger Turbine

opposite directions and attached to the ends of shafts which carry, at their outer ends, small belt pulleys. On the shaft, *S*, are two pulleys, *W*, of equal diameter, one of which is fast to the shaft, while the other is loose on the same shaft. The belt passing around these several pulleys, as indicated, transmits power from the turbine wheels to the main shaft.

McElroy, 1894.

This year marks the beginning of the important patents on turbine wheels of the Pelton type for use with an elastic fluid. Two patents were issued, one to J. F. McElroy in this country, and one in England to Professer A. Rateau. The arrangement of the nozzles and wheel of McElroy's invention is shown at *A* in the sectional view, Fig. 40. Nozzles with diverging mouthpieces are used. At *B* is a section of a bucket in a plane parallel with the shaft, together with an enlarged view of one of the nozzles. At *C* is a section through a bucket taken in the other direction. While an efficient type of bucket

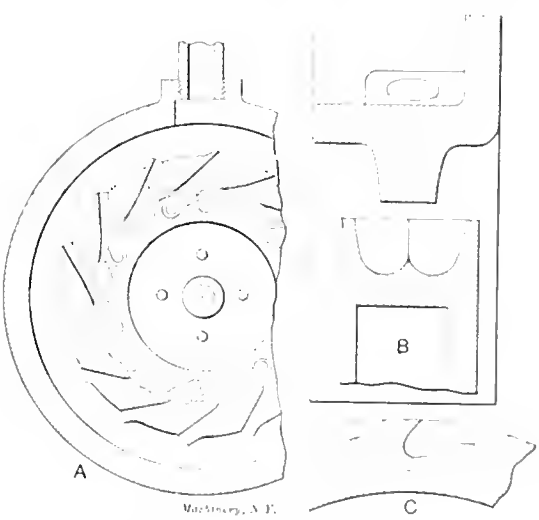

Fig. 40. An Early "Pelton" Type

is shown, and McElroy's claims as to its shape are broad, taken by themselves, they are combined with certain other constructive features which limit the scope of the patent. What he claims is, first, a wheel comprising a solid metal ring having a series of inclined pockets therein, the pockets of each pair being divided by a tapering ridge, in combination with a circular steam ring having a circular series of nozzles, and secondly, pockets as above described, but with a flat inclined cut-away portion for each, as shown in the sketch.

Rateau, 1894.

Professor Rateau, of Paris, was one of the earliest to experiment with a steam turbine having a single wheel of the Pelton type. The essential features of his English patent on this are shown in Figs. 41 and 42, which represent the wheel vanes. He intended primarily to produce a reversible wheel and uses buckets projecting radially, with double concave surfaces, *A*, *B*, Fig. 41, which form a dividing wedge at the center, just as in the Pelton water wheel. For reversing the direction of rotation, he uses steam jets flowing in the oppo

site direction and impinging against the backs of the blades. The backs are shaped as shown at *C*, with a single concave surface, instead of with the double curve, in order to avoid any obstruction to the steam when running in the normal direction. While the single curve is less efficient than the double curve, it answers the requirements for the brief periods during which the turbine has to be reversed.

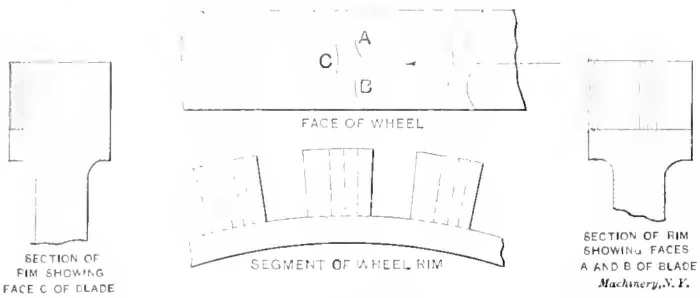

Fig. 41. Rateau's Reversing "Pelton" Wheel.

When the wheel is to be designed for forward motion only, Rateau presents the construction of Fig. 42. *A* and *B* are two concave vane surfaces and at the rear of each bucket an inclined groove, *C*, is cut, represented by the dotted line, *bp*, in the upper view. This allows the jets of steam to strike the buckets, one after the other, without interference from the successive buckets as they come into position. The sec-

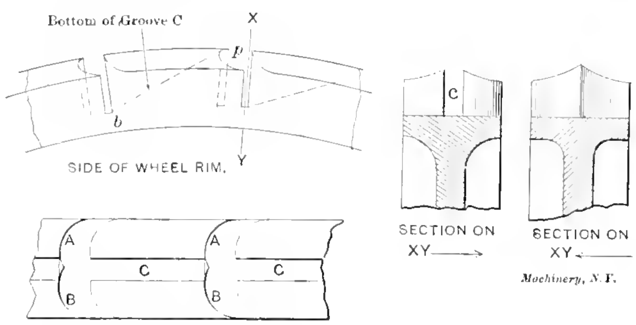

Fig. 42. Wheel for Forward Motion only.

tional views at the right are taken on the line, *XY*, looking, in each case, in the direction of the arrow drawn under each view.

While it is not introduced as a definite claim in this patent, Professor Rateau mentions that where the speed of the fluid is too great it may be necessary to arrange these turbines in series on the same or independent shafts, in which case the openings of the nozzles should all be designed to deliver the same relative quantity of fluid at the same moment. This he would accomplish by using distributing valves for supply-

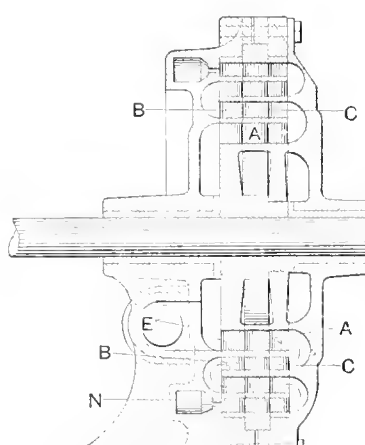

Fig. 43. Novel Compound Turbine.

ing steam to the nozzles, and having these valves all operated positively from the same source so that they would act in unison.

Pyle, 1895.

The patent issued to G. C. Pyle for the turbine shown in Fig. 43 is a variation on the usual plan for compounding. *AA* is a stationary disk, containing the rows of guide vanes, and *BB* are rotating disks. Steam enters through the nozzle, *N*, and passes longitudinally through several vanes in the direction of the arrows, until finally it exhausts at *E*.

Parsons, 1895.

In the method of governing used on Parsons turbines, an oscillatory motion is given to the throttle valve by an eccentric driven by the turbine, and the extent of this movement is controlled by a governor. In the illustration, *A* is a double-seated valve attached to a valve stem, *B*, which is connected with a piston, *C*, working in a cylinder above the valve chamber. At *D* is a pilot valve for controlling the motion of the piston. The steam enters the chamber, *E*, and flows downward through the valve to the turbine. An opening from *E* to the space below the piston allows the steam to push the piston upward against a spiral spring which pushes it downward in case the steam pressure underneath the piston is relieved. When pilot valve *D* closes the port leading from the space below the piston, the pressure maintained under the piston causes the latter to rise and with it the valve *A*, but when valve *D* uncovers the port, steam escapes from under the piston and passes around to the top, and together with the spring serves to close the valve.

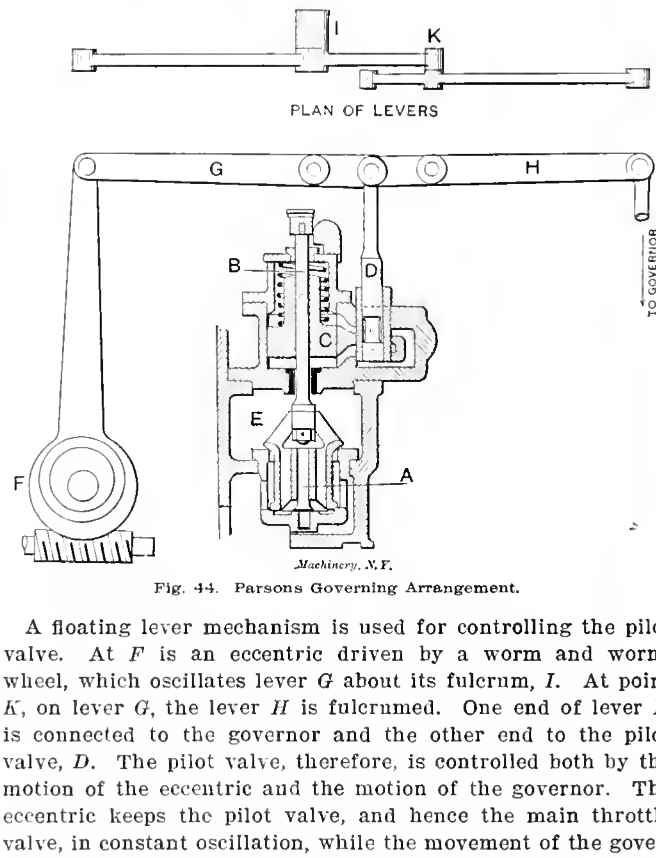

Fig. 44. Parsons Governing Arrangement.

A floating lever mechanism is used for controlling the pilot valve. At *F* is an eccentric driven by a worm and worm-wheel, which oscillates lever *G* about its fulcrum, *I*. At point *K*, on lever *G*, the lever *H* is fulcrumed. One end of lever *H* is connected to the governor and the other end to the pilot valve, *D*. The pilot valve, therefore, is controlled both by the motion of the eccentric and the motion of the governor. The eccentric keeps the pilot valve, and hence the main throttle valve, in constant oscillation, while the movement of the governor changes the positions of the limits of this motion. For example, if the turbine were running with a light load, the valve would oscillate in the lower end of its possible path of travel and would shut off steam entirely at each oscillation; but if the turbines were heavily loaded, the valve would be moved upward by the governor and its path of travel would be located higher, so that steam would flow through the valve continuously, although it would be throttled more or less as the valve moved up and down under the action of the eccentric.

Sebastian Z. de Ferranti, 1895.

The patent taken out by this inventor is to be classed with Hartman's patent of 1858 and that of the Societe Anonyme Maison Breguet, 1894. All three of these propose a compound turbine containing certain features employed in the Curtis patents now used by the General Electric Co. It is to be noted, however, that, like his predecessors, Ferranti fails to specifically state that he wishes to employ a diverging nozzle in combination with a compound turbine, which is an important feature of the Curtis type of wheel, although he says that he intends to utilize fluid in the wheel, "after complete

expansion and the acquisition of the maximum velocity," which, under certain conditions, can only be attained in a diverging nozzle. He advocates the use of superheated steam and also refers to gas turbines. The following is an extract from his specifications:

"I construct impact engines in which the working fluid impinges after complete expansion and acquisition of the maximum velocity, upon semi-circular rotating blades fixed round

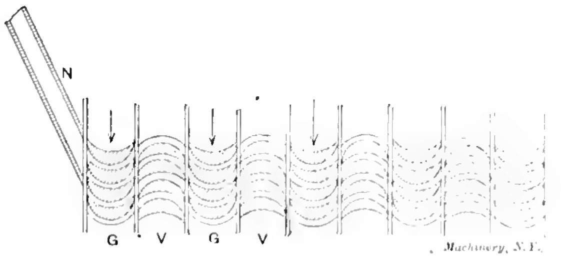

Fig. 45. One Plan for Compounding.

the rim of a motor wheel. The working fluid enters the blades at a high velocity and has its direction reversed, a portion of its energy being turned into work, and rotates the wheel, and then leaves at the other side of the blades at a diminished, though still high velocity. I then pass it through a set of standing semi-circular blades of exactly the same description as the rotating blades, but grooves in the opposite

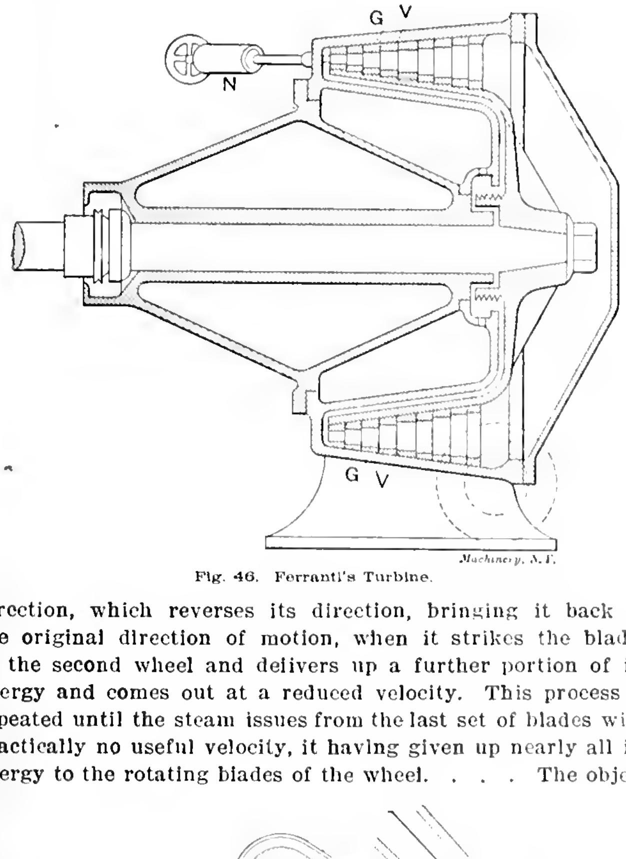

Fig. 46. Ferranti's Turbine.

direction, which reverses its direction, bringing it back to the original direction of motion, when it strikes the blades of the second wheel and delivers up a further portion of its energy and comes out at a reduced velocity. This process is repeated until the steam issues from the last set of blades with practically no useful velocity, it having given up nearly all its energy to the rotating blades of the wheel. . . . The object

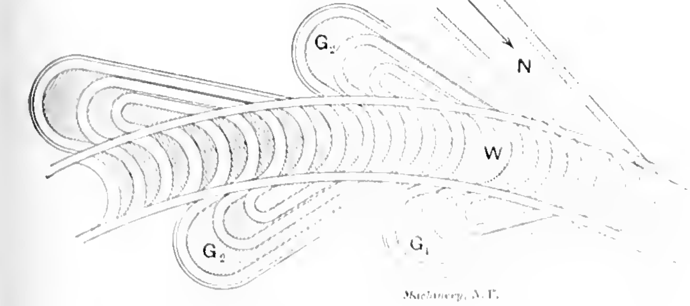

Fig. 47. A Second Plan for Compounding.

is to convert the whole of the energy and pressure in the working fluid into velocity of the particles, which then react backward and forward through the rotating and standing blades of the machine, thus constituting an impact multiple re-active engine.

"The engine may be made with one or more expansion tubes according to the power it is desired to obtain. More or less of these expansion tubes may be used and actuated by the governor according to the power required for the time being. . . . The expansion tubes stand tangentially from the periphery of the wheel and at a slight angle to the side of the wheel so as to deliver its working fluid in the most suitable position."

Fig. 45 shows the principle of his scheme, N being the nozzle, G a set of rotating vanes, V stationary guide vanes reversing the direction of motion, and so on. The design of turbine proposed by him is illustrated in Fig. 46, where N is a nozzle and V and G the rotating and guide vanes respectively, the rotating vanes being attached to a conical drum on the end of the turbine shaft and the guide vanes attached to a casing on the turbine. In this design he plans to have an increasing area for the steam as it flows through the turbine, after Parsons' plan, which is somewhat contrary to the statement of his specifications. In Fig. 47 is still another proposed arrangement in which the steam, directed by the nozzle, N, impinges against the wheel vanes, W, and is then taken up by the U-shaped passages, G_1, and returned to the wheel vanes, where it is again taken up by the U-shaped passages, G_2. This is another modification of the schemes advanced by Wilson, Perrigault & Farcot and a number of other early inventors, and, as previously stated, later by Profs. Riedler and Stumpf.

Curtis, 1896.

The important group of patents taken out in this year by Mr. C. G. Curtis, inventor of the turbine manufactured by the General Electric Co., covers most of the basic principles of this turbine. The leading feature of the Curtis machine is the combination of a diverging or expanding nozzle with a compound turbine wheel, although other features are included which had been found by the inventor to be necessary to the successful operation of a turbine of this form of construction. As already stated, previous inventors have patented turbines

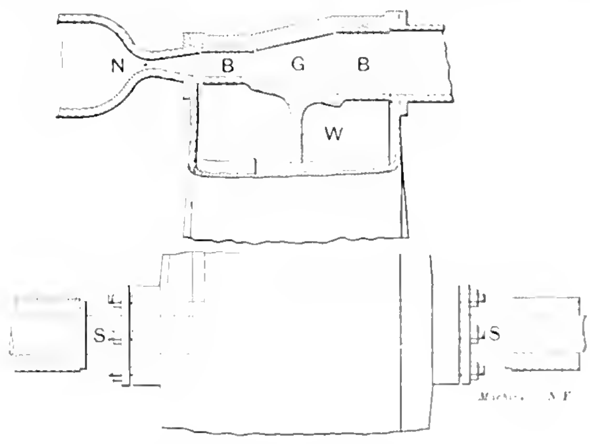

Fig. 48. Curtis' Turbine.

in which was arranged a nozzle for directing the steam against the blades of the rotating wheels of a compound turbine, but the Curtis patents are the first to clearly claim the diverging nozzle as a part of the combination, and they are, furthermore, the first ones to fully explain a practical method for carrying out the design so as to make an operative and economical machine. While the requirements for the successful operation of a compound impulse turbine were outlined by Moorhouse in his patent specifications of 1877, in which he provided for the progressive expansion of the steam from inlet to exhaust by using passages of gradually increasing areas, his patent was limited to the type of construction having a succession of compartments, in each of which is a single turbine wheel.

In Fig. 48 are shown the elements of the Curtis turbine. The shaft, SS, carries a turbine wheel on which are two annular rows of buckets, BB. At N is the expanding nozzle for directing the steam against the first ring of buckets, after which it passes through a group of guide vanes, G, to the second ring of wheel buckets. In the operation of a turbine of this type the ideal condition would be attained if the expansion of the steam could be complete in the nozzle and then it were to pass through the turbine in virtue of its inertia, giving up a part of its velocity to the first ring of buckets and the balance to the second or succeeding rings. This would allow the wheel to run at a comparatively low velocity,

depending upon the number of times the wheel was compounded. That is, if there were a single wheel, as in the De Laval type, it should run at approximately half the velocity of the steam; but if there were two wheels instead they could be run at a lower velocity so that the steam in leaving the first wheel would have a residual velocity to be taken up by the second wheel. By carrying the compounding still further a still slower speed of rotation could be used. Steam, however, is an elastic body, easily diffused, and has so small a mass that its inertia will not carry it through a succession of vanes in the above manner, unless there is an additional propelling force generated to overcome the frictional and other resistances during the passage through the vanes. This is

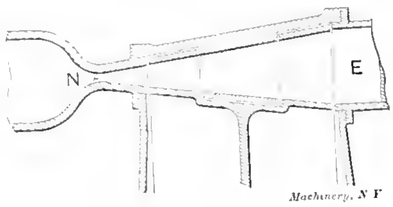

Fig. 49. Preferred Construction for Curtis Turbine.

accomplished in Fig. 48 by reversing a part of the expansion of the fluid to take place in the guide passages, *G*, which, as shown, are made diverging for the purpose. Accordingly, after the steam leaves the first set of vanes it receives an additional impulse in the guide passages before coming in contact with the second set of vanes. The preferred construction, however, and the one which is actually employed, is shown in Fig. 49. Here the steam is expanded in the nozzle, *N*, to nearly, but

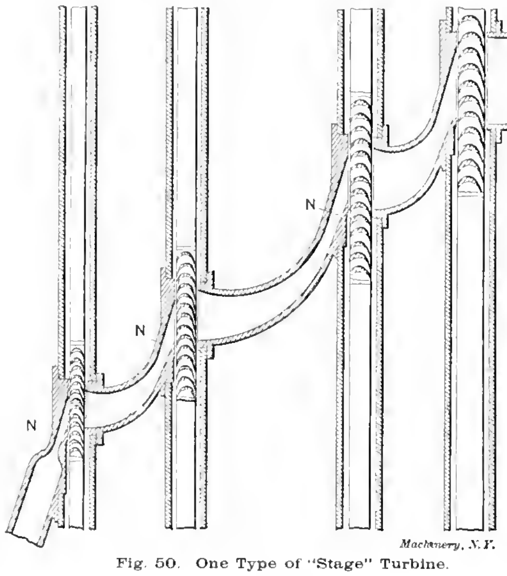

Fig. 50. One Type of "Stage" Turbine.

not quite the final pressure of the exhaust pipe, *E*. The balance of the expansion occurs during the passage between both the rotating and stationary vanes, and the pressure within these passages is, therefore, slightly in excess of the pressure within the chamber in which the wheel is rotating.

In Figs. 50 and 51 are sketches from the so-called "stage patents" of the Curtis turbines. In Fig. 50 each individual wheel is enclosed in a separate casing. Steam is directed to the first wheel by a diverging nozzle, *N*, thence it flows

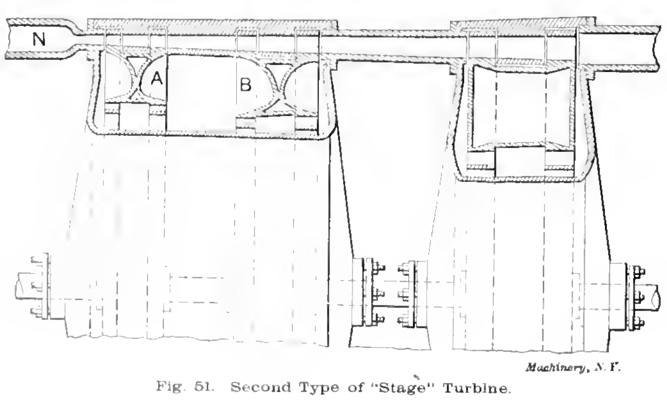

Fig. 51. Second Type of "Stage" Turbine.

through an enlarged passage, to take care of the increased specific volume of the steam, to a second diverging nozzle, *N*, which directs it against the second wheel and so on through the series. This drawing, while differing in details from the plan advocated by Moorhouse, follows very closely the principles outlined by the latter in his patent of 1877 except that Moorhouse apparently did not contemplate the use of expanding nozzles. The illustration, Fig. 51, shows each stage to be composed of one or more of the compound elements that go to make up the turbine represented in Figs. 48 and 49. In each of the two stages shown the wheel-and-bucket arrangement differs one from the other. In the first casing are wheels *A* and *B*, each carrying two sets of rotating rings or vanes, and in the second casing is a single wheel with two sets of blades. The advantage of dividing the turbine into

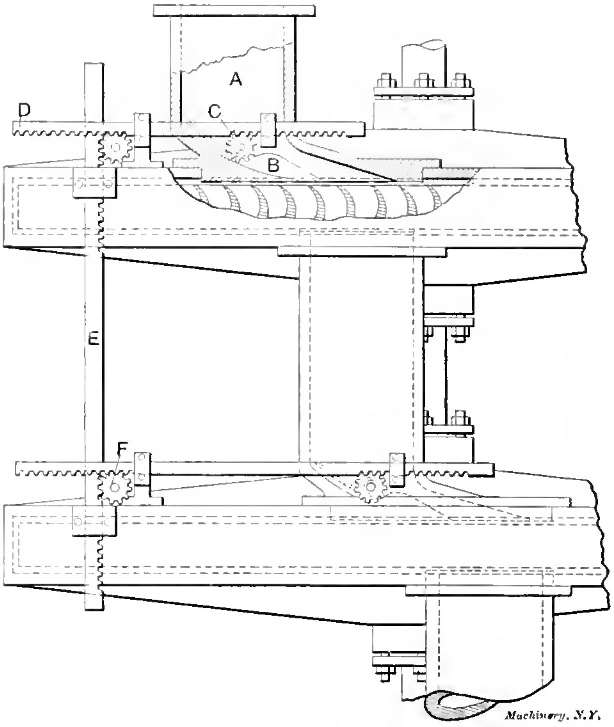

Fig. 52. Curtis plan for Governing a Compound Turbine.

stages in this way, is that there is less leakage between the guide vanes and the wheel vanes, since the differences of pressure are less; and there is also less diffusion of the steam since the number of rows of vanes for the steam to pass through in each stage is less than would be the case if all the rows were combined together in one casing and the steam were compelled to pass through them in virtue of the velocity acquired in the nozzle at the beginning.

A third patent taken out in this year deals with the problem of governing, and Mr. Curtis shows methods for changing the quantity of steam supplied to the turbine without throttling the pressure or reducing the velocity of flow. Obviously an expanding nozzle of certain proportions is adapted only to the steam pressure for which it was designed, and when the pressure is throttled the nozzle does not operate at its highest efficiency. It is proposed by Mr. Curtis to avoid this by using a nozzle of rectangular cross-section with one side adjustable in or out, regulating the quantity of steam flowing through the nozzle without making a great change in the ratio of the inlet and outlet areas. In Fig. 52 is a diagram showing the principle proposed, where the turbine is divided into two or more stages. *A* is the steam inlet, terminating in a nozzle having a sliding piece, *B*, operated by the rack, *D*, and pinion, *C*. This rack gears with another pinion, which transmits motion through the rack, *E*, to the pinion, *F*, and this in turn operates a similar sliding piece in the nozzle, directing steam against the second nozzle. The claims for the apparatus as used with a compound turbine cover first the principle of governing by changing the volume without great variations in the velocity of the steam, and second, the simultaneous and proportionate adjustment of the several passages leading to the turbine or connecting the different stages of the turbine.

PATTERN SHOP OF THE U. S. NAVAL GUN FACTORY.

EDWIN M. BIRRELL.

At Washington, the national capital, the U. S. government has established a plant for manufacturing the arms and armament of the ships of our navy. The Naval Gun Factory occupies what was formerly the Washington Navy Yard, and is situated on the Anacosta River, a branch of the great Potomac. The old buildings have nearly all been remodeled or torn down, and new shops built and equipped with machinery of the latest design. Large tracts of adjoining land

Fig. 1. Exterior of Pattern Shop—one of the Finest in the Country.

have been purchased for the extensions that will naturally take place on account of the great amount of work required to properly arm and equip our growing navy. The converting of the navy yard into the Naval Gun Factory was commenced under the administration of Hon. W. C. Whitney, Secretary of the Navy, and has grown from a small plant doing repair work on the ships to the present efficient one, capable (except for the heaviest forging and casting) of doing any of the work required in the manufacture of all guns and their mounts now in use in the navy. In this plant the government has gathered mechanics of the various trades from all parts of the country, and at the time of writing the force amounts to about 3,800 men.

One of the most important parts of the plant is its pattern shop. While the city of Washington outside the Naval Gun Factory employs fewer than half a dozen patternmakers, in this shop about fifty men find employment. It is here that the ideas of the inventor or designer assume their first tangible form. All machinery for the proper handling of guns and for furnishing ammunition to the same is designed at the Bureau of Ordnance, at the Navy Department or at the factory itself. Drawings from these designs are given to the patternmaker, who makes the wooden patterns from which castings of brass, iron or steel are taken.

The pattern shop, together with the other shops devoted to the manufacture of ordnance, is under the supervision of Capt. E. C. Pendleton, U. S. N., who is serving his second term as superintendent of the Naval Gun Factory. During his terms of office he has supervised some of the [illegible] important work needed to convert the old navy yard into the excellent plant our government now possesses. Capt. Pendleton is at present engaged in directing the installation of a new heating and power plant, which is to cost something like $750,000. Mr. M. A. Lynch is the foreman of a group of departments of which the pattern shop is one. Until about a year ago the pattern shop was under the immediate control of I. McKim Chase, a gentleman of national reputation as a patternmaker, and the author of "The Screw Propeller," "The Art of Patternmaking," and of numerous magazine articles. Mr. Chase was connected with the pattern department of the yard for thirty years prior to his death. Mr. B. M. Aitcheson is now the master patternmaker.

The pattern shop, situated in the southwest end of the yard, is a two-story brick building 250 feet long by 64 feet wide. It was entirely remodeled three years ago and is today pronounced to be one of the finest woodworking establishments in the country. The old machinery has been replaced by over seventy machines of the newest type and with the latest improvements. The first floor is occupied by joiners engaged in the manufacture of ammunition chests and boxes for holding shells of every size, wheels for field-gun carriages and limbers, file cases, sponge heads and handles, all kinds of cabinet work as desks and work benches, and indeed all varieties of machine woodwork. The second floor is used by the patternmakers. Fig. 5 is a view of the river from the windows, while Fig. 2 gives a view of the interior of this shop, showing the work benches on the right and the machinery on the left, also a number of unfinished patterns. It is here that the important work is performed. The benches, which are designed to accommodate two mechanics, are new, well made, and equipped with the latest Emmert vises. They are near the windows and run at right angles to them, thus affording ample light—one of the most necessary adjuncts of a pattern shop. The entire building is provided with the Sterling blower and pipe system by means of which all shavings, dust, etc., are forced by air through pipes leading from the benches and various machines to large receptacles outside the building. These large tanks, as they are called, are so arranged that carts can stop beneath them and the driver can, by pressing a lever, empty the contents into the carts. Fig. 4 shows some of the large pipes leading from the blowers, also a tank on the north side of the shop. For use on

Fig. 2. Interior View, showing one Floor of Pattern Building

cloudy days, or in the event of night work, a system of electric lights is installed on both floors. At each end of the building are elevators for the transportation of patterns, lumber, etc.

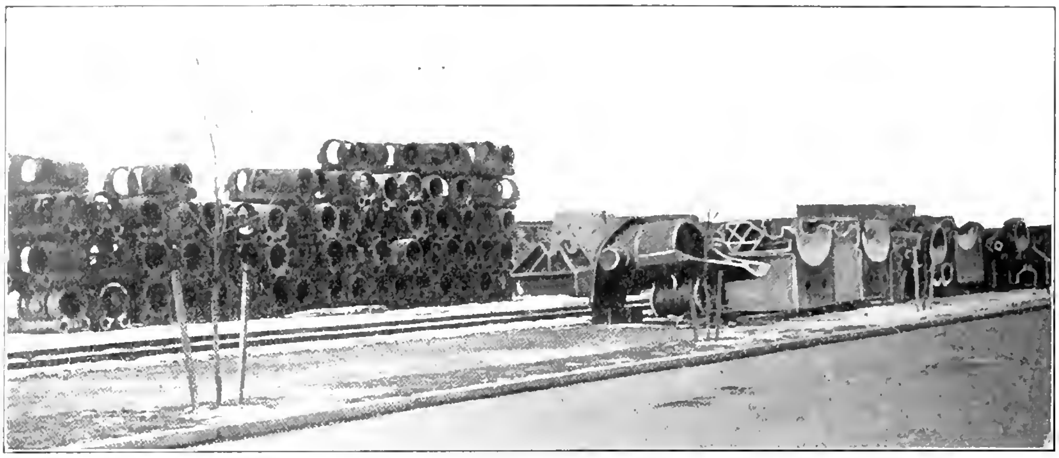

Fig. 3. Pile of Heavy Castings for Gun Mounts.

The pattern makers construct patterns for all the machinery used in manipulating the guns on board the ships of our navy, on the small torpedo boats as well as on the large battle-

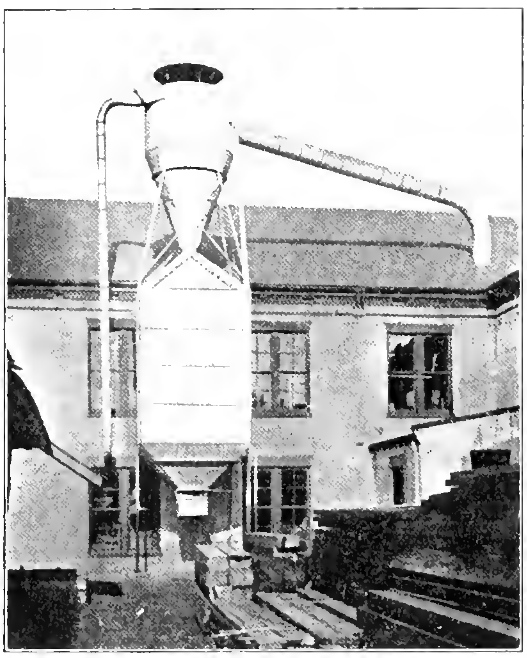

Fig. 4. Tank and Blower System for Gathering Shavings.

ships. In other words, patterns are made for the machinery required to mount the various size guns, for elevating and training them, and for loading devices by means of which the ammunition is brought in metal cars from the magazines of the ship to the breach of the guns; while patterns are also made for the different size shells, that is to say, for the ammunition itself. A group of castings is shown in Fig. 3 secured from patterns made in this shop and consisting of deck lugs, slides, and top carriages. A great deal of difficulty was encountered with the first steel casting made some years ago on account of the irregular shrinkage that occurred, but experience has corrected this and now there is very little complaint. Shrinkage scales provided by the government are used, and graduated to suit the various shrinkages. The scale is as follows: Iron, 1/8 inch to the foot; bronze, 15-100 inch to the foot; and manganese bronze and steel, 3-16 inch to the foot. Of course on large patterns the shrinkages have to be applied as experience shows to be best, as, for instance, in the construction of the pattern for the 8-inch deck lug shown in Fig. 6, where the shrinkage used was as follows: Length, 3-16 inch to the foot; width, 1/8 inch to the foot; height, 15-100 inch to the foot. The same shrinkages were allowed on the core box, except in the width, where only 5-200 inch was allowed. The castings secured from this pattern are estimated to weigh 5,335 pounds each, and form part of the mount for guns of this size on the U. S. S. *Virginia* and other ships of her class.

The patterns in this shop are made principally of white pine. Difficulty is encountered in securing well-seasoned lumber devoid of knots, hence in winter almost all the lumber used is subjected to a process of drying in the dry-kiln connected with the shop. Standard patterns of the smaller size, from which a large number of castings are required, are made of bay wood which, on account of its hardness, is very desirable for patterns that are often used. An example is: A pair of helical miter gears is used on the large 110-ton crane in the north gun shop of the yard. They are constructed of bay wood with the teeth made of cherry.

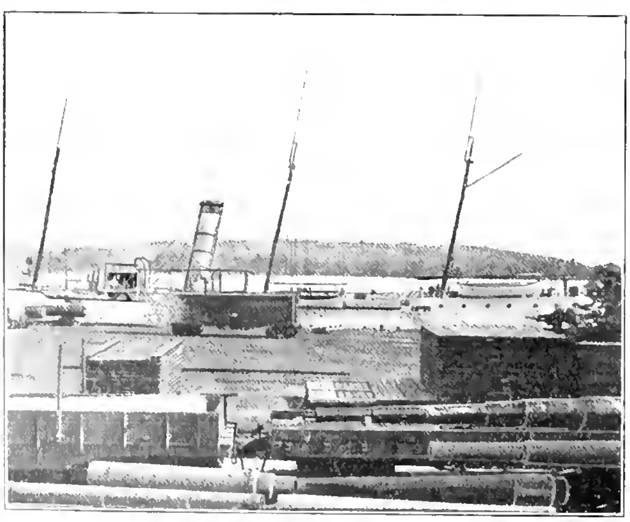

Fig. 5. View from Pattern Shop Window.

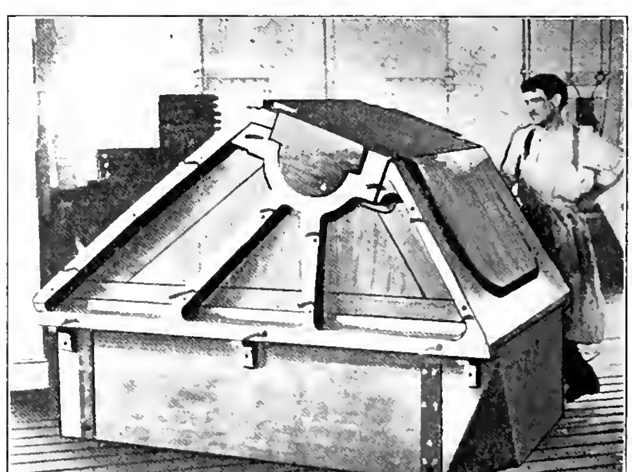

Fig. 6. Example of Pattern Work.

Each tooth is secured to the rim of the wheel by a dovetail which allows the tooth to be removed and worked off after being turned and laid off to the proper dimension on each end. Although their construction required some time, for they are a type of the costly pattern, it was an act of economy in the government to build a pair of these patterns for its own use, since patterns of this kind will, with good usage, last for a number of years.

Some idea of the amount of work done in this shop may be gained from the fact that over 1,500,000 feet of lumber are annually used in the pattern shop. A complete record is kept of all the patterns made. After being completed by the patternmaker, they are weighed and reported finished, and, after inspection by the officer in charge, are stenciled with name and number and sent to the foundry to be molded. The required number of castings having been secured, the patterns are sent to the pattern loft, a large building used for storing them. This building is now stored with a number of patterns whose value can be inferred when it is stated that the registered number of patterns is nearly 8,000, while in many cases months of labor were required for the construction of a single pattern. All patterns are given several coats of yellow shellac with core prints of black.

* * *

SOME REFINEMENT OF MECHANICAL SCIENCE.

In his address at the annual meeting of the A. S. M. E., held in New York last month, Mr. Ambrose Swasey, the retiring president, began by saying a few words concerning the growth and progress of the society since its organization. Continuing, he said, "I wish to speak of a few of those methods and mechanisms which have been developed and perfected to such a degree of refinement that they may be considered as almost beyond the practical, and yet were it not for such refinements they could not possibly be made to serve the utilitarian purposes which make them of such inestimable value to us all."

Mr. Swasey spoke first of the progress made in the accurate division and measurement of time, saying that before the christian era the length of the solar day had been fairly well defined, but it was not until 1582 that astronomers computed the exact length of the solar year, and with such precision did they then determine it that our present calendar will continue on for twenty thousand years, with an error not to exceed a single day. The device used for this calculation is still shown in the calendar room of the Vatican Observatory. In the center of the room, forming a part of the floor, is a large marble slab with a fine line cut exactly in the true meridian, and upon the line is a special mark indicating the altitude of the sun at noon of a certain day. On the south wall, near the top of the room, is a small aperture through which the direct rays of the sun pass at noon, projecting a bright spot on the meridian line. In this day of instruments such a simple device would hardly be thought of use, yet it served its purpose admirably and was considered one of the greatest scientific achievements of that age.

Since an unknown time the day has been divided into twenty-four hours, measured in turn by the sun-dial, the hour glass, the water clock, and from the twelfth century on, by clocks of the present type. The first water clocks used by the Greeks consisted of two jars so arranged that the water from the upper ran into the lower, and the time of day was determined by measuring the water remaining in the upper jar. To this day water clocks are used extensively in the East, and in the city of Canton even the standard time is kept by an improved water clock which has been running for eight hundred years, and which, notwithstanding its long service, shows no perceptible wear. This improved clock consists of four jars placed one above the other, and the hour is shown by the position, in reference to a cross bar, of a graduated upright attached to a float in the lowest jar.

Galileo's discovery of the isochronism of the pendulum was of great value in many respects, but in none more so than in its application to the measurement of time. Soon after that great discovery, the English clockmaker, Graham, invented the mercurial pendulum by which the variation in length due to temperature was compensated, and a few years later Harrison, another English clockmaker, invented a compensating pendulum consisting of a series of metal bars having different coefficients of expansion. Since that time every part of the clock has been the subject of study and improvement, and they are now made with such precision and delicacy that in testing them the question is, within how small a fraction of a second will they run. Some of the finest astronomical clocks are inclosed in glass or metal cases in which a partial vacuum is maintained, wound automatically by electricity, and set up in underground vaults so that errors due to vibration, change of temperature or barometric conditions are made practically impossible. A clock installed at the Observatory of Case School of Applied Science at Cleveland, running under these favorable conditions, has a mean error of fifteen one-thousandths of a second per day, and a maximum error for several months of but twenty-two one-thousandths of a second per day. This is a notable example of the present state of the art of clock-making and shows the wonderful precision with which minute intervals of time can be measured. From the time of the invention of Peter Hele, in 1477, of the "Nuremburg Animated Egg" or "pocket clock," which required winding twice a day and varied an hour and a half in the same length of time, the development of the watch has kept pace with the "Mother Clock."

The larger watch, or ship chronometer, with its escapement so delicately made and adjusted that it must always be kept in the same position, was greatly improved through the efforts of the British Government in 1714 by offering rewards of ten, fifteen and twenty thousand pounds to any who should make chronometers that would run so accurately that the longitude of a ship at sea could be determined within sixty, forty and thirty miles; and Harrison, the inventor of the compensating pendulum and the compensating balance, which is now used in watches, succeeded in making a chronometer, which, after being tested on a long voyage, was found to run so closely that the position of the ship was determined within eighteen miles, and he was therefore paid the full award of twenty thousand pounds. That historic chronometer, which marked a new era in navigation, is now numbered among the treasures of the Greenwich Observatory.

Modern ships are equipped with chronometers so accurate and so reliable, and with sextants of such precision that navigators can determine their position in latitude and longitude within a few miles. Therefore, with the increased speed of the powerful ships carrying hundreds or even thousands of passengers, together with their valuable cargoes, the methods and instruments used in navigation have been so improved as to greatly diminish the dangers in crossing the seas.

The perfection attained in the measurement of time, which is of such great practical value in nearly every sphere of life would not have been possible were it not for the even greater refinements that have characterized the methods and instruments used by the astronomer in determining the length of the day and of the year, which are the fundamental standards of time.

After saying substantially the above Mr. Swasey continued his address as follows:

"The division of the circle and the measurement of angles have ever been among the unsolved problems of the astronomer, yet in the instruments used by him, circles have formed a most important part.

Long before the telescope was invented, Tycho Brahe, the Danish astronomer "the founder of Modern Astronomy," constructed for his observatory, instruments of various kinds having graduated circles and arcs of circles. His instruments for the most part were improvements on those used by Arabian astronomers in the eighth and ninth centuries, and these in turn, were copied after similar instruments used by the Greeks and Egyptians, a thousand years previous, and it is supposed that such instruments were used by the Chinese at an even earlier period, so that graduated circles have come down to us from the far off ages.

The longer the radius the more accurate the graduations was the principle upon which the early instruments were

made. The Arabians, in about the year 1000, built a sextant with a sixty-foot radius and a quadrant with a twenty-one-foot radius, but to Tycho Brahe is due the credit of constructing instruments having circles, much smaller in diameter and graduated with a greater precision than ever before. It was by the use of such improved instruments of his own making, and by his observations which were made without a telescope or any means of magnification, that he was able to give the positions of a large number of stars within less than one minute of arc from the positions given by modern astronomers.

The first circular dividing engine was made in 1740 by Henry Hindley, of New York, for cutting the teeth of clock wheels, and it is interesting to note that in the same year Huntsmann, another clockmaker, of Sheffield, invented the process of making crucible steel, that he might have a metal suitable for the springs of his clocks.

Of the several engines constructed later, the one most successful and representing the greatest progress, was that made by Ramsden, in 1777. This engine, automatic in its movements, was made especially for graduating circles, and because of the great precision with which he divided the circles of the instruments used by the Government, the Board of Longitude awarded him the sum of six hundred and fifteen pounds.

In a dividing engine the chief essential is that the spindle carrying the master-plate shall be as nearly round and as closely fitted in its bearings as is possible, for the degree of excellence with which that work is done determines how closely a circle can be divided.

It seems almost incredible that a well-lubricated spindle of four inches in diameter at its largest part and tapering three-quarters of an inch to the foot, can be made so nearly round and so closely fitted in its bearings that a movement of one-thousandth of an inch in or out of its bearings, will in one case cause it to turn with difficulty, and in the other with perfect freedom; yet this has been found to be within the limits of mechanical refinements.

The greatest accuracy thus far attained in such engines, is one second of arc, which arc, with a radius of three miles equals one inch, and at twenty inches, which is the radius of the silver ring upon which the graduations on the master-plate are made, a line one-thousandth of an inch in width is equal to twelve seconds of arc, or twelve times the accumulated errors of any number of divisions, or twenty times the greatest error of any single division.

In automatically graduating a circle, it has been found to be impracticable to cut more than six lines in a minute, and it requires about thirty-three hours to divide a circle into two-minute spaces. As with the running of the finest clocks; the best results can only be obtained when the engine is surrounded with every favorable condition possible. Instead of the large circles and sectors used by the ancients, they have been made smaller in diameter as the methods for graduating have been improved, until those of the more modern instruments are seldom more than thirty inches, and some of the latest meridian instruments have circles of but twenty-five inches.

The smaller circles, which can be made and graduated with greater precision than the larger ones, are also less liable to change in form, owing to their weight and the variation in temperature, and with the aid of the reading microscope the results obtained would not be possible with the larger circles. A twenty-five-inch circle read with a microscope having a power of forty, would be equivalent to a circle of about eighty feet in diameter, and a single second of arc as seen through the microscope would be equal to 0.0024 of an inch, a quantity easily subdivided.

The cross wires, which are but common spider lines, because of their fineness and the remarkable qualities they possess, are indispensable in micrometric work.

That the repulsive and even dangerous spider has plenty of enemies among the human family, there can be no doubt, yet if the value of the contributions which it has made to the cause of science were generally known, it would surely have a greater number of friends than at present, and most certainly the astronomer will say naught against it, for after the experience of many years he has found that the spider furnishes the only thread which can be successfully used for the cross wires of his instruments.

The spider lines mostly used are from one-fifth to one-seventh of a thousandth of an inch in diameter, and in addition to their strength and elasticity, they have the peculiar property of withstanding great changes of temperature, and often when measuring the sun spots although the heat is so intense as to crack the lenses of the micrometer eye-piece, yet the spider lines are not in the least injured. The threads of the silk-worm, although of great value as a commercial product, are so coarse and rough compared with the silk of the spider that they cannot be used in such instruments. Platinum wires are made sufficiently fine, and make most excellent cross wires for instruments where low magnifying powers are used, yet as the power increases they become rough and imperfect.

Spider lines, although of but a fraction of a thousandth of an inch in diameter, are made up of several thousands of microscopic streams of fluid, which unite and form a single line, and it is because of this that they remain true and round under the highest magnifying power. An instance of the durability of the spider lines is found at the Allegheny Observatory, where the same set of lines in the micrometer of the transit instrument has been in use since 1859.

In the realm of the measurements of minute linear distances, and the perfection of curved and flat surfaces, the refinements are even greater than those pertaining to the measurement of time and of angles. Most important in the linear dividing engine is the screw, and although much had been accomplished in bringing such engines to a high degree of excellence, it was for Prof. Rowland to make an engine which has a practically perfect screw; and without doubt it is in all respects the nearest perfect of all the mechanisms that have been employed for ruling lines exactly parallel and equally spaced.

The Rowland engine was made especially for ruling diffraction gratings which are made of speculum metal, and with it a metal surface has been ruled with 160,000 lines, there being about 29,000 to the inch, and as many as 43,000 lines to the inch have been ruled. The gratings mostly used have from 14,000 to 20,000 lines to the inch, and with such exactness is the cutting tool moved by the screw that the greatest error in the ruling does not exceed one millionth of an inch.

The production of these gratings, which has enabled the physicist in his study of the spectrum to enter fields of research before unknown, has not only called for the highest degree of perfection ever attained in the spacing of linear distances, but it has also called for a refinement most difficult in the optical surfaces upon which the lines are ruled. To Mr. Brashear was given the problem of producing such surfaces, and notwithstanding the many difficulties encountered in working and refining the speculum metal plates, he has made many hundred plates with surfaces either flat or curved with an error not to exceed one-tenth of a wave length of light, or one-four-hundred-thousandth of an inch.

The established standards of length which are the yard of Great Britain and the meter of France, being made of metal, and liable to destruction or damage, Prof. Michelson conceived the idea of determining the lengths of these standards in wave lengths of light, which would be a basis of value unalterable and indestructible. For the purpose of carrying out these experiments, the interferometer was constructed, an instrument which required the highest order of workmanship and the greatest skill of the optician. Again Mr. Brashear proved to be equal to the occasion, and made for the instrument a series of refracting plates, the surfaces of which were flat within one-twentieth of a wave length of light, with sides parallel within one second. This was the most difficult work ever attempted in the refinement of optical surfaces.

Professors Michelson and Morley devised a method for using the interferometer for making the wave length of some definite light an actual and practical standard of length. So satisfactory was the result that Prof. Michelson was invited to continue the experiments at the Bureau of Weights and Measures, at Sèvres, France, where the standard meter, which is kept in an underground vault and inspected only at long

intervals, was used for that important work, which occupied nearly a year. The final result of the experiments shows that there are 1,553,164.5 wave lengths of red cadmium light in the French standard meter, at 15 degrees Centigrade. So great is the accuracy of these experiments, that they can be repeated within one part in two millions. Should the material standard of length be damaged or destroyed, the standard wave length of light will remain unaltered, as a basis from which an exact duplicate of the original standard can be made. These two marvelous instruments, the Rowland dividing engine and the Michelson interferometer, show the possibilities in the perfection of linear divisions and the standards of length.

CONTEMPORARY TECHNICAL EDUCATION.*

The young man who is to follow a narrow routine through life will not have added much to his efficiency, as a machinist, by the long elaborate course of the technical school. For those constitutionally deficient in ambition, or for those unfortunates who can never comprehend the art of getting on in the world, these four extra years are ill spent at school, but there are plenty of young men for whom this training of the technical school is the best possible training, and there is plenty of opportunity for a larger number of these men than all of our present schools can graduate.

Men cannot be shaped on the interchangeable system of the American machine shop; each will be a "special," and, as already remarked, there will be produced "firsts," "seconds," and "thirds," but fortunately the demands for all types and grades exceeds the possible supply for years to come. Among the graduates some will possess that rare faculty for which "initiative" is the phrase of the day, and among these there will be some who will possess that quality of balance and judgment, and attain such knowledge of men, that they will become great leaders—the captains—will establish their own industrial works or be called to the $10,000 positions which are always so hard to fill right. Others, without this business insight, but perhaps more learned and more skillful in engineering, will design machines and bridges, supervise factories, become the lieutenants and fill the $4,000 and $2,000 positions, and still a larger number will do noble work as the sergeants, corporals and privates and be made better men by the broadening of their minds.

The training of no school can make the square peg fit easy in the round hole, and, out of a hundred boys, but few are born with the ear of a musician or the eye of an artist, or with the observing, inquiring, ingenious, imaginative mind which schools can stimulate but cannot create, and without which conspicuous success in constructive engineering is impossible. But for the young man so fitted by nature, a technical school of broad scope and high aim is a royal road. The old statement that "There is no royal road to learning" is untrue. The man of affairs has come to understand that the technical school is a royal road to learning, a shorter road, an easier road, through a more beautiful landscape, and in equal time attaining a broader outlook.

A man with the earnestness and patience of John Brashier, the strong purpose of John C. Hoadley, the rugged common sense of Edwin Reynolds, the strong, kindly heart and quick intelligence of John Fritz, or the genius of Edison, may reach an equal height by a longer and more arduous road, and, like the athlete, increase his strength and harden his endurance in the greater effort, but the royal road of the technical school, in its four years, may, from its small group, gathered part by chance and part by process of natural selection from more than ten thousand school boys, bring perhaps ten to the point that otherwise not more than one or two or three could hope to reach in twice these four years.

* * *

FIRE PROTECTION IN MARSHALL FIELD DEPARTMENT STORE, CHICAGO.

The value of private fire apparatus for the protection of individual buildings and adjoining property was thoroughly demonstrated in the Baltimore and Toronto fires, and, in fact, the Baltimore fire department admits that many buildings on the immediate margin of the devastated tract were saved only by the effective work of private apparatus. These buildings were supplied with either standpipes or pumps connected with wet-pipe interior sprinklers and dry-pipe sprinklers for protection from outside fires, storage tanks holding from 1,500 to 15,000 gallons being placed on the roofs. Besides saving the buildings in which they were located these equipments stopped the advance of the fire, and undoubtedly many more buildings would have been destroyed in the absence of their efficient service. The buildings and contents protected by private apparatus in Baltimore were valued at five million dollars and at Toronto the saving from private protection was similar in extent.

The fact that such apparatus is on the ground, in position and ready for action averts the destruction of much property by both fire and water. A fire is usually well under way before the city fire companies can arrive, arrange their hose lines and make necessary couplings and connections. A drenching of the entire building is then often required, while a comparatively small amount of water would have put out the fire in the first place. The immediate availability of private fire apparatus gives it a great advantage over any other form and has long been employed by manufacturing concerns. Such apparatus usually consists of direct-acting pumps, steam-driven. A large installation of the kind, however, in one of the largest department stores is of interest because it is electrically-driven and seems to meet the needs of independent apparatus for office buildings and other structures in cities. An important consideration in selecting an apparatus of this sort is the readiness with which electric power can be obtained and utilized; there being hardly a building where a reliable supply of electric current cannot be cheaply and easily obtained. There is, further, no maintenance expense as with steam apparatus.

The installation referred to is in Marshall Field's immense department store, Chicago. The outfit consists of a Laidlaw-Dunn-Gordon duplex underwriter pump connected by single-reduction gearing to a water-proof electric motor. The pump cylinders are eight inches in diameter by twelve inches stroke, having a theoretical capacity of 700 gallons per minute at 600 R. P. M. against 140 pounds water pressure. There are large pressure and vacuum chambers, required by the underwriters' specifications. The pump is thoroughly rust proof in all moving or wearing parts, insuring prompt and smooth running when occasion arises.

The motor, which was furnished by the Chicago Edison Co., is shunt-wound for 220 R. P. M. at 230 volts and is inclosed, all connections being carried through pipes screwed into the frame, so that the device may be flooded without affecting its action. The fields and armature coils are cooled by fans on the armature shaft.

* * *

THE PANAMA CANAL PROBLEM.

The Panama Canal is likely to be a very costly undertaking for the United States Government, and the time of its building will probably be equal to that of a generation, if present estimates are right. Chief Engineer Wallace, of the Isthmian Canal Commission, has reported that a sea level waterway across the Isthmus, although it would cost far more and take much longer to complete than the three other canal projects under consideration, would in the end be the best. In his opinion the cost of the sea level canal would be $300,000,000, as against $200,000,000 for a 90 foot level canal, and he thinks that twenty years would elapse before its completion, or ten years more than for a canal with locks. Here apparently is a great opportunity for the development of machinery that shall make as great an advance in such work as was done on the Chicago Drainage Canal. It is imperative that the time of construction be reduced; every year that its completion is delayed means, in effect, greatly increased cost of construction when the loss to commerce is taken into account. It is a chance to put to use on an enormous scale the knowledge gained in hydraulic placer mining in the West. Both the loosening and transportation of the material to the sea might be accomplished rapidly in this manner.

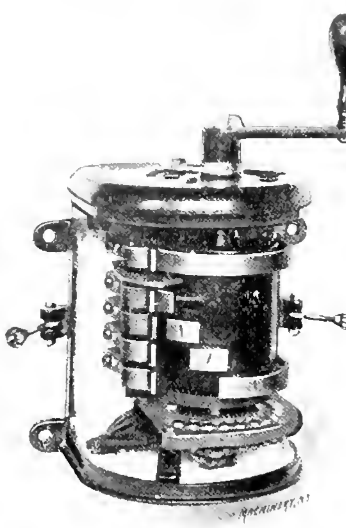
* Extract from an address by Mr. John R. Freeman at the Case School of Applied Science, May 11, 1904.

VARIABLE SPEED MOTORS.—9.

THE CUTLER-HAMMER VARIABLE-SPEED CONTROLLERS

WM. BAXTER, JR.

The Cutler-Hammer Mfg. Co., of Milwaukee, make a number of designs of controllers for variable-speed motors, some of which are of the drum type while others are of the slate front, or clock dial type. To describe all these designs would require too much space, but as many of them are but slight modifications of others, the description of a few, each one typical of its class, will serve to give a fair idea of their



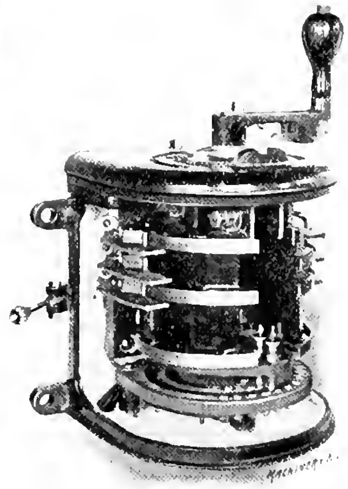


Fig. 1. Controller, Non-reversing Type. Fig. 2. Controller, Reversing Type.

construction and operation. These controllers are used in connection with many different designs of motors made by concerns that do not manufacture their own controllers.

Fig. 1 shows a non-reversing drum controller with the casing removed. A diagram showing the various contacts of this controller and their connections with each other, with the motor and the supply wires, is given in Fig. 4. Fig. 2

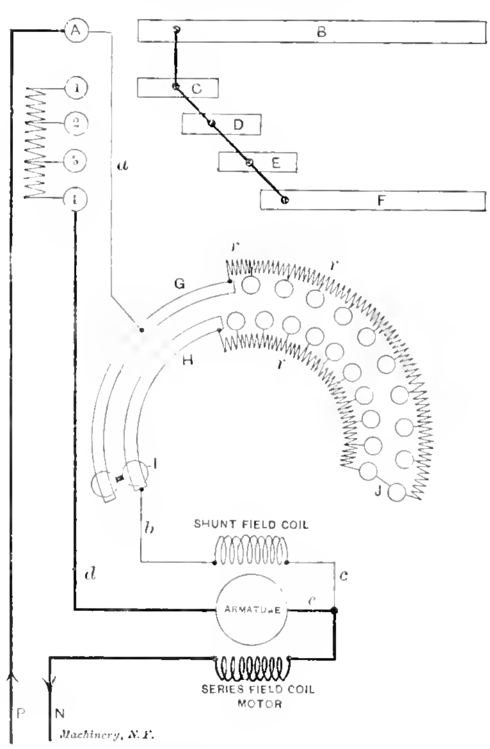

Fig. 4. Diagram of Controller, Fig. 1.

shows a reversing controller of the drum type, and a diagrammatic representation of the contacts and connections is given in Fig. 5. Fig. 3 shows a slate front controller of the reversing type. The development of this controller is shown in Fig. 6.

In these three controllers the speed variations of the motor are effected by introducing resistance in the shunt field circuit, that is, by field regulation.

Construction and Operation of the Non-reversing Drum Controller.

The diagram, Fig. 4, illustrates the arrangement of the contacts and circuit connections of the non-reversing drum controller. In this diagram the motor, which is represented as of the compound-wound type, is located at the bottom and the parts above it are the controller. The circles *A*, 1, 2, 3, 4, are stationary contacts that press upon rings *B C D E F*, mounted on the drum. These contacts and rings are clearly shown in Fig. 1. The drum rings *B C D E F* are electrically connected with each other. When the drum is turned to the first position, *B* and *C* make contact with *A* and 1, and then the line current from *P* passes from *A* to *B* thence to *C* and to 1. The armature starting resistance is connected, as shown, between the stationary contacts 1, 2, 3, 4, hence when only *A* and 1 are connected with the drum rings, as is the case in the first position, the current must pass through all the starting resistance to reach wire *d*, and thus the armature. From the armature through wire *e* the current passes to the series field coil of the motor and thence to line wire *N*. The

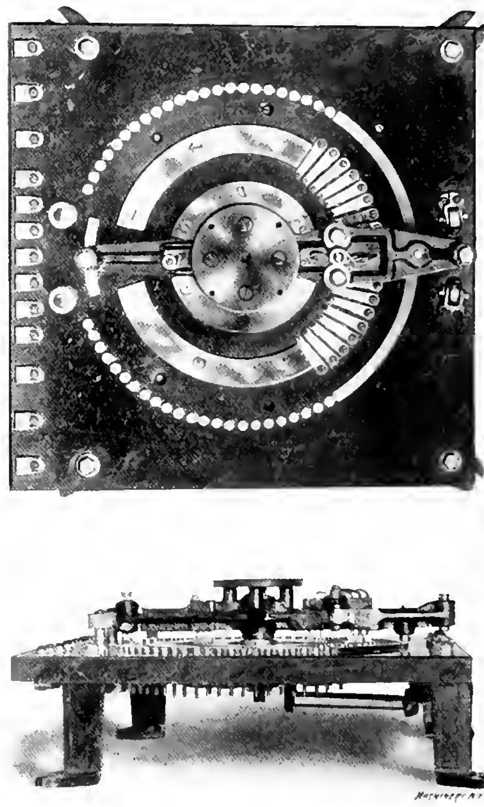

Fig. 3. Controller, Slate Front, Reversing Type.

current for the shunt field starts from *A* through wire *a* to segment *G*, thence through the sliding contacts *I* to *H* and by wire *b* to the field coil, from which it passes through wire *c* to *e*.

The further rotation of the controller cylinder causes the rings *D E* and *F* to come in contact with 2, 3 and 4 one after the other, and thus the starting resistance is cut out of the armature circuit in three sections.

The segments *G* and *H* and the circular contacts following them are stationary and are located at the bottom of the controller, as clearly seen in Fig. 1. The sliding contacts *I*, which are electrically connected with each other, are carried by the cylinder, and slide over *G H* and the small contacts as the cylinder advances. While the cylinder is advancing to cut out the starting resistance, *I* slides over *G* and *H* and reaches the ends near the circular contacts, by the time *F* connects with 4. If the controller is left in this position, the motor will run at its lowest speed. If a higher speed is desired, the controller handle is advanced and then *I* slides over the circular contacts and cuts into the shunt field coil circuit more or less of the resistances *r r r*. When the controller handle is rotated as far as it will go the sliding contact *I*

will rest on the end contacts J and all the resistances $r\ r\ r\ r$ will be cut into the field circuit and the motor will be running at its highest velocity. Any speed between the high and the low can be obtained by moving the controller handle until I rests at the proper point. As the field resistance $r\ r\ r$ is divided into many sections and these can be cut out one at a time, many different speeds can be obtained.

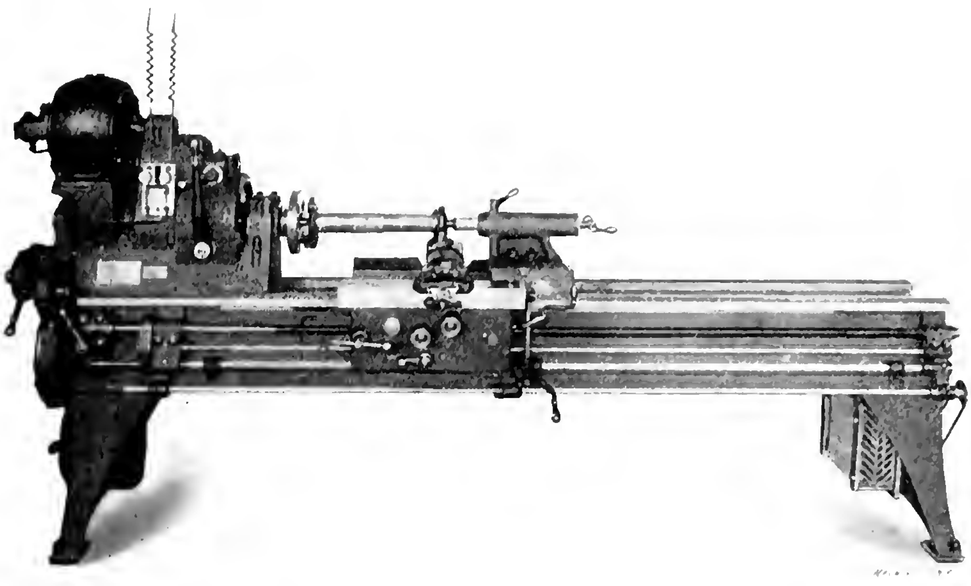

Fig. 7. "Northern" Variable-speed Motor, operating Springfield Lathe, with Cutler-Hammer Slate Front Controller.

The Reversing Type of Drum Controller.

The arrangement of the contacts and connections of drum controller of the reversing type is shown in Fig. 5. As in Fig. 4, the motor is located at the bottom of the diagram, and is of the simple shunt type. The controller can be used with a compound wound motor, however, by simply connecting the series field in either one of the wires P or N, but not in the armature wires 7 and 8, for in the latter position the reversal of the current through the armature would also reverse it through the series field coil, and thus make the motor of the cumulative type for one direction of rotation, and of the differential type for the opposite direction.

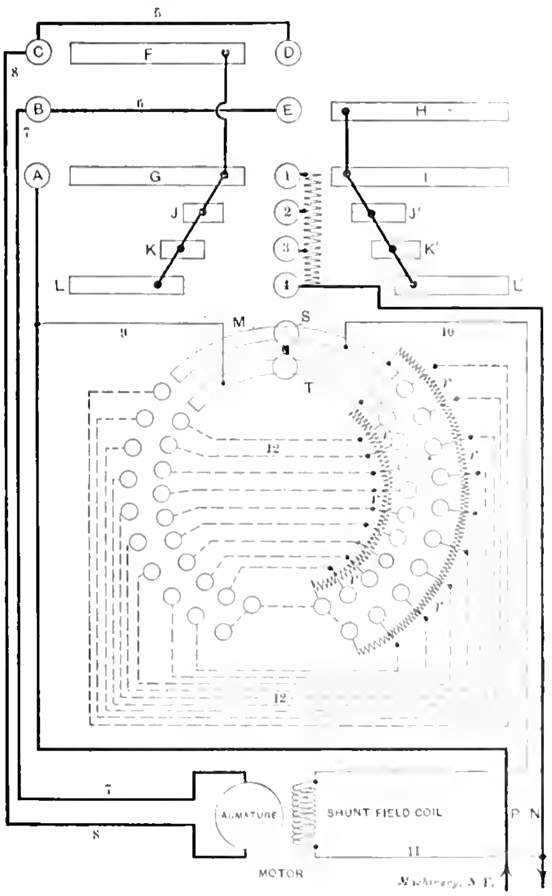

Fig. 5. Diagram of Controller, Fig. 2.

In the reversing controller there are two sets of stationary contacts, one located at the center of the diagram and marked $D\ E$ 1, 2, 3, 4, and the other located at the left of the diagram and marked $A\ B\ C$. In Fig. 2 these two sets of contacts can be seen one on each side of the cylinder. In Fig. 5, if the cylinder is rotated so as to move to the left, rings F and G will connect with C and A respectively, and rings H and I will connect with E and 1. With these connections, the current from P will pass to A, thence to G to F to D through wire 5 to C and wire 8 to the motor armature. Returning from the armature through wire 7 to contact B and wire 6 to contact E the current reaches contact 1 through the drum rings H and I. From 1 the current passes through the starting resistance connected between contacts 2, 3, 4 and thus reaches the line wire N. The shunt field current branches from P through wire 9 to segment T, and through the sliding contacts S to M thence through wire 10 to the field coil, and from the latter through wire 11 to line N.

The rings located at the lower end of the drum are arranged the same as those in Fig. 1, but are in duplicate so as to cut out the starting resistance whichever way the cylinder may be turned. The segments M and T and the circular contacts in line with them are stationary and are located at the bottom of the controller as shown in Fig. 2, and the sliding contacts S which are electrically connected with each other are carried by the cylinder. As with the non-reversing controller, the contacts S do not pass off segments M and T until after ring L, or L', has made contact with 4. The further rotation of the controller handle carries S over the circular contacts and cuts into the shunt field coil circuit more or

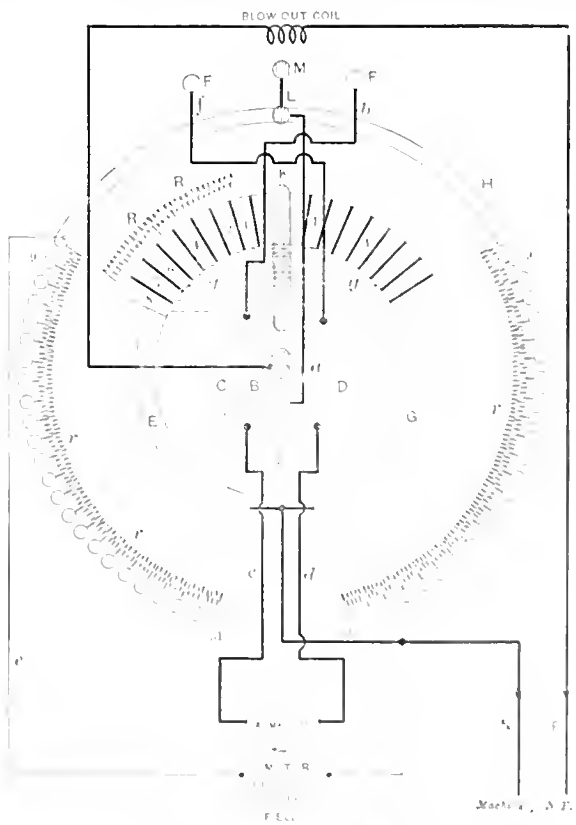

Fig. 6. Diagram of Controller, Fig. 3.

less of the regulating resistance $r\ r\ r$ according to the distance through which S is carried, the action being the same as in Fig. 4.

To reverse the direction of rotation of the motor, all that is necessary is to reverse the direction of the current through

the armature; in other words, the current from line wire P must enter the armature through wire 7 instead of through wire 8. If the controller handle is turned so as to carry the cylinder rings to the right, then rings F and G will connect with stationary contacts D and 1, respectively, and rings H and I will connect with B and A. With these connections it will be seen that the current from line wire P will pass through A to I and thence to H and to B and through wire 7 to the armature, returning from the latter through wire 8 to C to 5 to D to F to G to 1 and through the starting resistance to line wire N.

As the sliding contacts S rotate in one direction for the forward motion of the motor, and in the opposite direction for the reverse motion, the segments M and T are located in a central position and with circular contacts at each end, so that whichever way S may move it will cut in and out in the proper manner the field resistance r r r r. In these drum type controllers, as a rule, the resistances are not made a part of the controller, but form a separate structure, and for that reason the contacts on opposite sides of segments M and T are connected with each other in the manner indicated by the broken lines 12.

Arrangement of the Contacts and Connections and Operation of the Slate Front Controller.

The diagram, Fig. 6, shows the arrangement and connection of the contacts of the slate front controller illustrated in Fig. 3. The switch lever carries the connecting contacts J K L and M. Of these contacts K is isolated, but J L and M are connected with each other, as shown by wire a. The center stud B, on which the lever swings, is connected with line wire P. The two segments E and G are connected with line wire N. The contacts 8 8 are connected with E and with G, but the remaining contacts in this circle, that is, 1, 2, 3, 4, 5, 6, 7, are insulated from each other and the only connection between

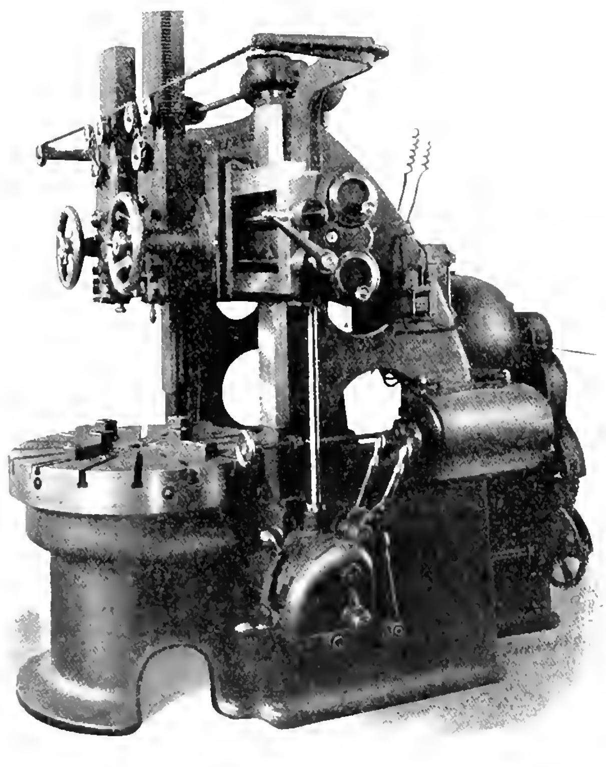

Fig. 8. "Northern" Motor operating Gisholt Boring Mill, with Cutler-Hammer Gear-driven Drum Controller.

them is through the armature starting resistance R. One end of the shunt field circuit is connected with segment H and the other with line wire N.

If the switch lever is turned clockwise, the current from wire P after reaching B will pass through J to C and thence by wire c to the motor armature, returning to D through wire d. From D through K the current will pass to 1 and thence, through the connection shown in broken lines g, to the left side of the controller, and through the starting resistance R to segment E and to line wire N. The field coil current will start from J through wire a to contact L and to H, thence through wire e to the field coil, and from the latter to wire N.

As the switch lever is advanced, K will pass over the contacts 2, 3, 4, etc., to 8, and thus cut out the starting resistance. If the switch lever is left with K resting on 8, the motor will run at the lowest velocity, but if it is advanced until L rests on 31 the speed will become the maximum, as then all the field regulating resistance r will be cut into the circuit.

If it is desired to run the motor in the opposite direction, the switch lever is turned counter-clockwise, and then the current from wire P will pass from B through J to D and thence through wire d to the armature, passing through the

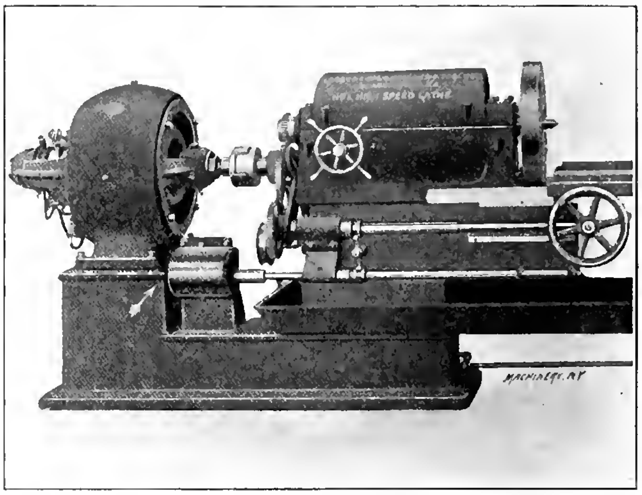

Fig. 9. Lodge & Shipley Lathe operated by "Northern" Motor, with Cutler-Hammer Direct-driven Drum Controller.

latter in the opposite direction. From the armature the current will return through wire c and reaching segment C will pass through K to the contacts 1 2 3—8 to E and to line wire N.

At F F are located contacts the purpose of which is to prevent sparking between J and C, or D, when the motor is stopped. As will be seen, the circuits would be complete if the contacts F F and the wires b and f were removed, but in returning to the stop position, J would separate from C or D—whichever one it happened to be in contact with—and a heavy spark would be produced at the point of separation. With F F and wires b f added, when J breaks contact with C or D, the circuit is still kept closed because at that instant the contact M is resting on one of the F contacts. After J has broken contact with C or D, M separates from F and thus the circuit is opened at this point, and it is here that the sparking occurs. These isolated contacts can be made large so as to stand heavy sparking without serious injury; but for the purpose of reducing the spark as much as possible, a blow-out coil is located so as to blow out the spark when M separates from either one of the F contacts.

The contacts 9—31 on either side of the circle are not connected with each other in the manner indicated in Fig. 5, because in this type of controller it is more advantageous from a mechanical standpoint to provide a double set of field resistances r r. The starting resistance R is not made in duplicate as it is more desirable in this instance to cross-connect contacts 1, 2—8 as shown by the broken lines g.

A slate front controller of the type above described is shown in Fig. 7 mounted on an "Ideal" Springfield lathe, which is driven by a Northern variable speed motor. The controller is placed under the lathe bed at the tailstock end, and is operated by means of a shaft running along the side of the bed under the carriage, in a manner that is clearly shown.

Fig. 8 shows a drum type controller mounted on a Gisholt boring mill driven by a Northern variable speed motor.

Fig. 9 shows a Lodge & Shipley lathe with Cutler-Hammer direct-driven drum controller, driven by a Northern variable speed motor.

* * *

It is reported that the Southern Pacific Railroad Company are experimenting with an internal combustion locomotive built on the Diesel principle.

ELECTRIC REPAIRING.

ARMATURE WINDING.

NORMAN G. MEADE.

The repair shop of a manufacturing plant or electric railway plant should have at hand suitable stands or "horses" for holding armatures during the winding process. If the armature is small, short stands may be mounted on a work-bench.

When an armature comes in to be repaired, carefully caliper its diameter outside of the bands and the winding. Observe particularly the shape of the ends. As the workman proceeds to tear apart the armature, he should note the size of wire, style of winding, number of coils, convolutions per coil, number of layers, style of winding, etc. All such data

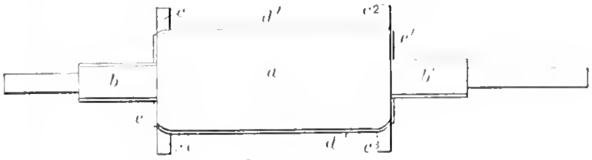

Fig. 1

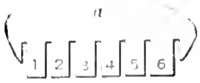

Fig. 2

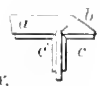
Fig. 3



Machinery, N.Y.

Fig. 4

should enter a notebook, as this information will be of future value. It is well to head the entry with the name of the machine, horse-power, voltage and current, speed and serial number of the armature.

The first step in unwinding an armature is to unsolder the leads and remove the commutator. Then cut off the bands and remove the wire. If the coils are of the formed type, laid in slots, raise the upper half around the entire circumference, and remove the coils, in the reverse order to that in which they were put in. After the core is entirely stripped of winding and insulation, it is ready to re-insulate.

Fig. 1 is a sectional view of a smooth-core drum armature insulated ready for winding. In the figure, a is the bore; b and b' the ends of shaft covered as shown; c^1, c^2, c^3 and c^4 are fiber pegs for separating the coils; d and d' insulation on core, and e and e' insulating end disks.

Fig. 2 shows the manner of notching the core-insulation to

Fig. 9.

fit between the fiber pegs. Flexible micanite 1-32 inch in thickness, and held in place temporarily by a few turns of "flax," forms an excellent insulation. A ring armature, partially in section, is shown in Fig. 3. The shaft, a, pressed into the hub, d, carries the spider, to which is attached the ring, b. One wing of the spider is shown at c. A flexible micanite insulation, e, covering the outside, inside and ends of ring, is held in place by a tight wrapping of cotton tape, as shown at g. The wings of the spider must be insulated. This can be done conveniently, as shown in Fig. 4, which shows a sectional end view of an armature, a being the armature ring, b the spider wing, and c and c' triangular-shaped pieces of micanite extending the length of the wing. The triangular pieces are retained in position by the wrapping of cotton tape.

A section of a slotted armature is shown in Fig. 5. Here a is the end in section; b and b' are slots not yet insulated; c is a hard-wood or fiber block the length of the slot and slightly narrower; d is micanite insulation driven in place by the block, c; e is a slot insulated ready for the coil; f and f' are armature coils; h is the insulation between the coils; and i and i' the slot insulation trimmed flush with core a. The micanite is cut into strips of the required size, and folded over the block, c, to form troughs, as shown.

Another form of slot coming generally into use is shown in Fig. 6, in which a is the end of armature; b and b' V-shaped slots cut for receiving the wood retaining-strip, c; e and e' coils in the slot, with insulation, d, between them.

Fig. 7 is an end view of an armature partially in section. This view illustrates the winding process with a form of coil in common use. In the figure, a is the shaft; b the end of the armature; c, a piece of sheet brass the length of the slot and about 4 inches wide; 1, 2, 3, 4, 5, 6, 7 and 8 show the coils with one-half free and one-half in slots; 9, 10, 11, 12, 13, 14, 15 and 16 show one-half of the coil in cross-section. Proceeding to wind an armature of the type shown in Fig. 7, the first process is to insulate the slots in the manner already described, then drive one-half of the coil into place, continuing around the armature, thus filling half of each slot. The armature will then appear as shown. Fig. 8 is a piece of vulcanized fiber, shaped for driving coils into slots. In a four-pole ma-

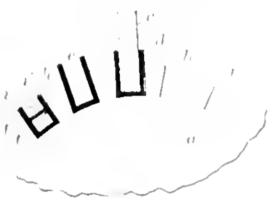


Fig. 5

Fig. 6

Fig. 7

Fig. 8

chine each coil will have a pitch of 90 degrees, that is, it will cover one-fourth of the periphery of the armature. The coils slip into the slots easily, with the exception of those on the last quarter. Beginning at a point three-fourths of the distance around the armature from the first coil, the outer half of the coils that have been laid in, will lap over the empty slots. At this point a little more labor is involved in getting the coils into their respective places.

Having completed the first process, start at any point to drive the outer half of the coils into slots. Hold the piece of brass, c, before referred to, in the left hand and slip it into the position shown. In this way it guides the coil 8 into the slot. With a mallet and the tool shown in Fig. 8 drive the coil snugly into place. Continue with each coil in like manner until all have been driven into their proper positions.

In Fig. 9, the periphery of the armature, A, is supposed to be laid out flat. In the figure, a, b and c are coils of the oblong type, which form a chordal winding. It will be seen that the coils are staggered, that is, the projecting ends alternate backward and forward. With this style of winding, the ends of the armature core must be well insulated. The coils, if not pounded into shape with a mallet, will interfere at d, e, f, g, h, i, j and k. The coil, a, extends from slots 1 to 6; b from 2 to 7, and c from 3 to 8. No specific directions can be given here for shaping these coils, as no two makes of armatures

are alike. By noting carefully the shape of the original coil, it will be an easy matter to form the new one. The winding is executed in a manner similar to the formed-coil winding previously described.

Taking up the subject of smooth-core drum armatures, let us study Figs. 10 to 15 inclusive, which illustrate some common types of winding. Starting with Fig. 10, we will assume each coil, for the sake of simplicity, to be one layer deep and three convolutions in width. Stand facing the commutator end of the armature, and tie the end of wire a to the fiber peg. Pass the wire downward over the end of the armature core and between the two pegs, diametrically opposite to the starting point. Turn the armature over and draw the wire tightly along its surface to the back end. Carry the wire around the shaft, on the side opposite to that followed on the front end, and through the pegs back to the starting point, having in the meantime turned the armature over to its original position. It is convenient to have the reel of wire suspended over

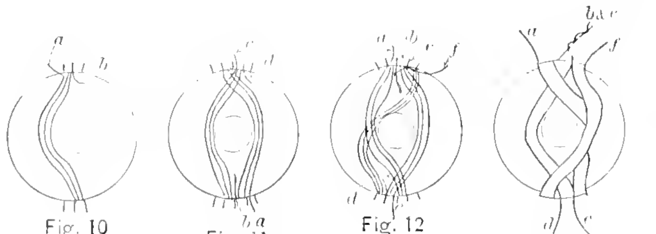

Fig. 10 Fig. 11 Fig. 12 Fig. 13

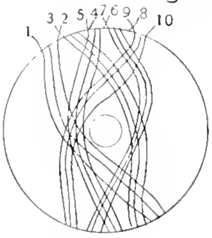

Fig. 14

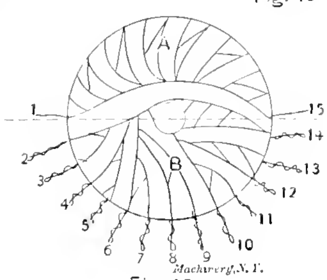

Fig. 15

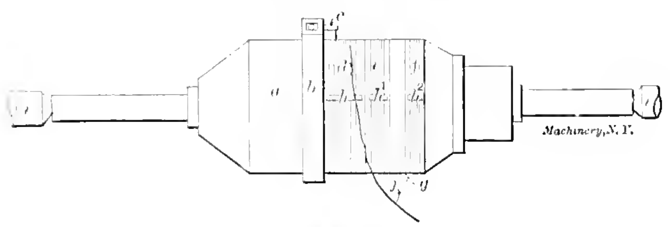

Fig. 21.

the workman's head, so that the wire will pay off freely. Cut the wire from the reel, leaving end b. The ends must be long enough to be soldered into the commutator.

Now turn the armature over and begin the second coil to the right of the first one. This will bring the second coil to the left of the first one at the bottom side, as shown in Fig. 11. The ends c and d are left for connecting to the commutator, as in the first instance. To commence the third coil, turn the armature over again and start at the right of the second coil, Fig. 12, twisting the end c around end b. Proceed in this

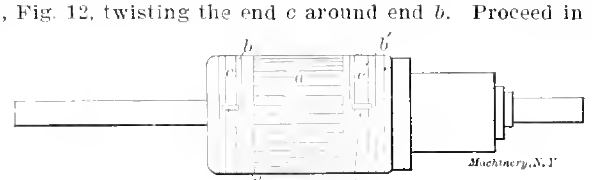

Fig. 22.

manner until all the coils are wound. Fig. 13 gives an idea of the appearance of the armature end after three coils have been wound. It will be seen that every second space between the pegs has two ends. The inner end of the first coil is connected to the outer end of the third coil, there being a blank coil between the two, thus forming a closed or re-entrant winding. Any number of layers or convolutions may be used in this winding. Fig. 14 shows a similar winding, that can be used for two layers or a multiple of two. The only difference is that the second coil is commenced at the ending of the third, and so on until every space is filled, as shown in Fig. 15. If the winding when completed is to be four layers deep, the coils from 1 to 15 inclusive will have two layers, and the remaining coils to be wound will also have the same number. The half, A, of the armature will have no ends at this stage of the winding. The second set of coils, whose ends protrude in the half, A, commences at 15 and extends around to 1. The outer end of one coil joins to the inside of the

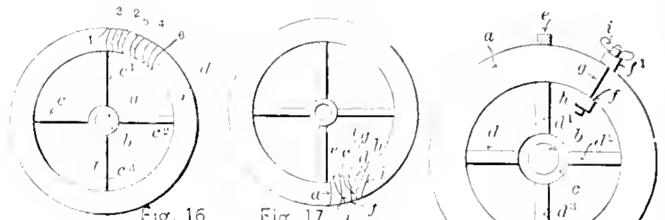

Fig. 16 Fig. 17 Fig. 18

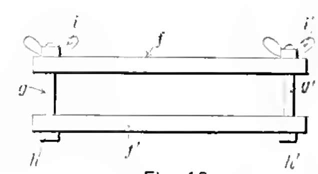

Fig. 19

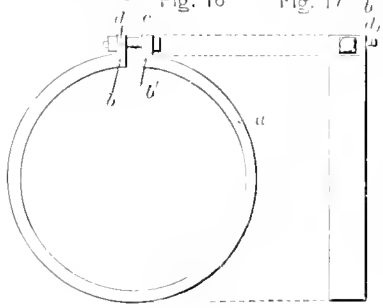

Fig. 20

next. This is clearly shown in Fig. 14, where end 3 of the second coil joins end 2 of the first coil, and so on. It is unnecessary to cut the wire, as it can be left in loops as shown at 1, 2, 3, etc., in Fig. 15.

We will now turn to smooth-core ring armatures. In Fig. 16, a is the shaft and b the spider hub, to which are attached the wings, c, c^1, c^2 and c^3, bearing the ring, d. The winding forms a continuous spiral, the end 2 of coil 1 being attached to end 3 of coil 2, etc. As the space on the inner surface of the armature is less than that of the periphery, the winding will have a greater number of layers inside than on the outer surface. An exaggerated view of a method of winding to accomplish such a result is shown in Fig. 17. The wire starts at a, then passes around the ring and comes to the front at b, passes under at c, and returns at d. It is then carried under at e, between a and c, starting the second layer on the

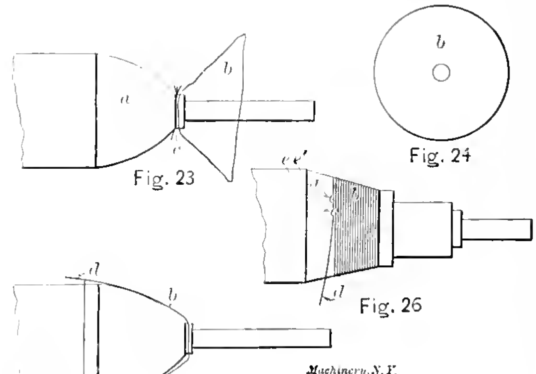

Fig. 23 Fig. 24 Fig. 25 Fig. 26

inner surface. From f, the wire goes to g, and back to h, thence to i, between c and g, coming back at j. Thus we have five convolutions and one layer on the outer surface, and two layers—one of three and one of two convolutions—on the inner surface.

In Fig. 18 the application of the clamp shown in Fig. 19 is given. This clamp consists of two wood pieces, f and f', and two bolts, g and g', with heads, h and h', and thumb nuts, i and i'. This clamp serves to hold the wire of each coil in position while winding, and is moved around as fast as a coil is completed. Referring again to Fig. 18, the wood piece, e, is used for filling the gap in the outer surface of the winding caused by the spider wings, d, d^1, d^2, d^3. It is made equal in width to the wing, and of the same depth as the winding. In bal-

ancing an armature one or more of these strips may be removed and lead strips wound in tape substituted.

All armatures must be carefully balanced, which can be accomplished by several methods, one of which has just been mentioned. If the air-gap of the machine has clearance enough, solder may be flowed onto the bands. With slotted armatures, some makers bore holes in the core on the heavier side, thus equalizing the weight. Another method is to bind a piece of sheet lead on the front end of the armature over the lead wires, by a tape and cord.

As no definite rule can be given for soldering lead wires into a commutator, only a few suggestions will be offered. Tin the slots in the segments and the armature leads before soldering. See that the slot is flowed full of solder. Do not use acid for flux on small wire, as corrosion will take place. Be extremely careful that no drops of solder lodge between or back of the segments. Each coil should be tested for grounds as it is wound, and to make sure that the right ends are connected. A convenient testing arrangement was explained in a previous article entitled "Commutators," and can be applied to this purpose. A magneto bell, a galvanometer or a Wheatstone bridge may be used for testing purposes.

Fig. 20 gives two views of a clamp that is used in winding armature bands, *a* being a hoop of band-iron, with its inside diameter equal to the outside diameter of the armature. The ends *b* and *b'* are bent up as shown, and bored to receive a clamping bolt, *c*. A pin, *d*, is attached to the end, *b*, for fastening the binding wire.

Fig. 21 shows clearly the practical application of the clamp. In this sketch, *a* is the armature; *b*, the clamp; *c*, the pin; *d*, the band being wound; *e* and *f*, finished bands; *g*, mica insulation under bands; *h*, h^1 and h^2, brass clips for holding the bands together. The lathe centers are shown at *i* and *i'*. The end of the brass wire *j* passes through the fiber friction blocks in the toolpost.

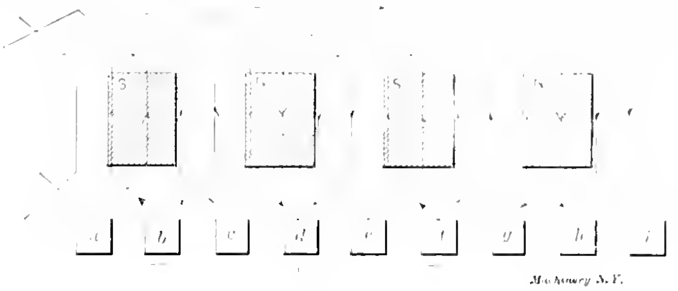

Fig. 27.

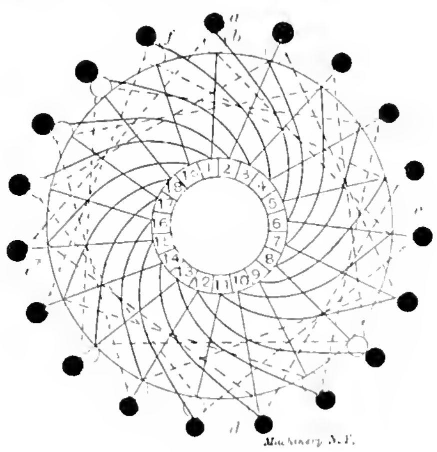

Fig. 28

The manner of winding an armature is essentially the same as that of a commutator, which has already been fully described in an article under the latter head.

A completed armature, with slots of the type shown in Fig. 6, is illustrated in Fig. 22. The core, with wood retaining strips driven into slots, is shown at *a*. Mica strips *b* and *b'*, under bands *c c*, are for the usual insulating purpose. Brass chips *d* and *d'* are attached in the regular manner. Armatures with wood retaining-strips in slots require but two bands, which are wound on the coil ends that project beyond the core.

A method of protecting the ends of a surface [illegible] armature is illustrated in Figs. 23, 24, 25 and 26. A [illegible] disk, *b*, Fig. 24, is tied by a cord, *c*, to the end of armature [illegible] Fig. 23. The disk is then drawn over the end and tied temporarily with a cord, *d*, as in Fig. 25. The armature band serves to hold this hood in place permanently.

An effective manner of finishing the commutator end of an armature is illustrated in Fig. 26. The end, *a*, is wound tightly with cord about 1/4 inch in diameter, as shown at *b*. Two loops of string, *c* and *c'*, are caught under the last two or three turns of cord and the end, *d*, is passed through them, after which the loops are drawn up, the ends trimmed off and the cord cut close to the last loop. After the armature is completed, it should be given a thorough coating of shellac and placed in an oven. When fully dried out, put on two even coats of P. & B. compound, which gives it a good black and waterproof finish.

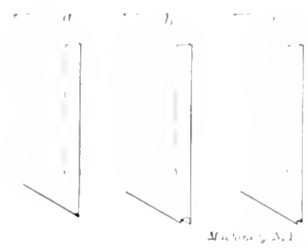

Fig. 29

As a complete description of the numerous styles of connecting up armatures is beyond the scope of this article, only a few of the common types will be taken up. For further information on this subject the reader is referred to one of the many text-books on dynamo-electric machinery.

Fig. 27 illustrates, graphically, a lap-winding. The poles of the machine are represented at *S*, *N*, *S*, *N*, and the commutator segments are indicated by the squares *a*, *b*, *c*, etc. We will take, for example, the coil starting at *b*. The conductor passes over the left face of the *S* pole, and then returns over the middle of the *N* pole, to the adjoining segment, *c*. This series of loops is continued around the armature, forming a complete circuit. The large arrow indicates the direction in which the conductors are moving, and the small arrow-heads on the wires show the disposition of the current.

A diagram of a hand-wound armature, with a wave winding, is shown in Fig. 28. To avoid complications, nineteen coils only are shown. This type of armature is extensively used by the Shaw Electric Crane Company. The small white circles around the circumference of the armature, as at *b*, represent the first layer of wire; the black circles, at *a*, show the outer layer. The dotted lines indicate the conductors passing over the back end of the armature. Starting at the commutator segment 1, the conductor goes to *b*, then to *c*, and connects to segment 10. Here we start a new coil, going to *d*, then to *e*, and connecting to segment 19, one remove from the starting point. The third coil starts here and leads to *f*, and so on until one layer is completed, when one-quarter of the circumference of the armature on each side will have ends protruding, that is, the first quarter will have leads, the second will be blank, the third will have leads again, and the fourth will be blank. Start the second layer at the end of the first one. When the winding is completed, each slot will have two ends, as shown in the figure. An armature with formed coils can be connected in a like manner.

A few handy tools can be made from fiber; they are shown at *a*, *b* and *c*, in Fig. 29. These tools are used for driving the wires into place, etc.

Rewinding an armature requires great care and neatness. The dimensions and shape of the original winding should always be closely followed, as an armature which is but a fraction of an inch too large is useless.

* * *

Referring to the item "Cast Iron Sinks" in the November issue, Mr. Robert Grimshaw, Hanover, Germany, writes: "'Cast Iron Sinks' is at any rate true, but how about the sign in the next window of the same plumber's shop, 'Copper Floats?' If we believed that literally, we would believe anything."

TOOL MAKING.—13.

MILLING MACHINE CUTTERS.

E. R. MARKHAM.

Milling machine cutters are either made solid or with inserted teeth. Those 6 inches and under in diameter are usually made solid, but in most shops those over 6 inches are made with inserted teeth, though in some it is considered good practice to make them solid up to 8 inches diameter. Certain forms of cutters, much larger than the size mentioned, must be made solid, and it is advisable when hardening these to employ a method that will insure the desired degree of hardness with little or no risk of cracking.

When selecting steel for cutters first price should never be a consideration provided the higher-priced article is the best for the purpose; however, for most purposes, steel can be procured for a reasonable price that answers as well as some of the more costly ones. There are several alloy steels on the market, made especially for cutters of this class, which work nicely; they will stand higher speeds and run longer between grindings than steel made for all-around work. Most of these, however, are rather "cranky," and require very careful treatment in the fire and hardening bath, and should not be used unless the hardener is thoroughly experienced and understands handling "special" steels. If conditions are such that they can be worked successfully they prove very satisfactory and their use is to be advocated; on the other hand, if conditions are not favorable they give best satisfaction "when left alone."

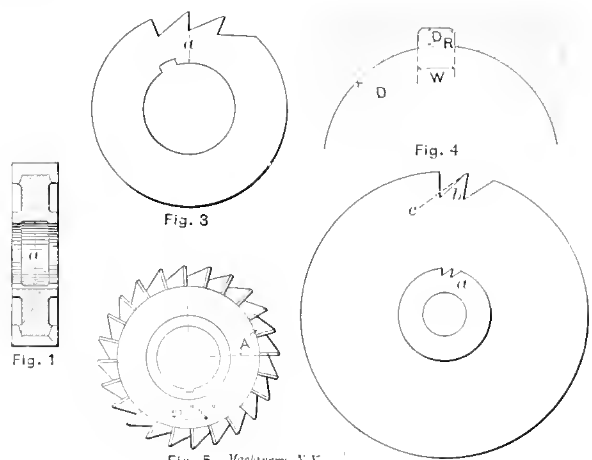

Fig. 1 Fig. 3 Fig. 4 Fig. 5 Fig. 6 *Machinery, N.Y.*

It often happens that a cutter is desired which calls for stock larger than any on hand, and as but little is wanted, and that little right away, it seems advisable to take a piece of the largest available and upset it to a size that will machine to the desired dimensions. Right here we meet a whole "heap" of trouble. When steel is made, the drawing by rolling and hammering is all in one direction—namely, in the direction of the length of the bar. Now if the steel is upset *somewhat*, the "grain" is in all directions, and the adhesion between the molecules is weakened perceptibly; and when the steel is hardened it is liable, and in fact almost sure, to go to pieces, or at least crack in all directions. But if the piece of steel is upset enough to overcome this difficulty the trouble mentioned will not be experienced. As an illustration, the writer at one time saw a cutter 6 inches in diameter, stock for which had been upset from 5-inch steel. The upsetting was done on an anvil, by means of hand sledges, and the cutter was finished to size and shape. When hardened it went to pieces, the cracks running from center to circumference in irregular lines. Another cutter was made at the writer's suggestion from a piece of 4-inch stock upset under a steam hammer. The hardening was done by the same man, in as nearly as possible the same manner as the first one. It came out all right, as have a number of others made since then. Of course this can be carried to an extreme, but unless stock is to be upset sufficiently to change the direction of the "grain" steel that is to be hardened should never be upset at all.

As has been stated a number of times in these articles, there is a decarbonized portion at the surface of all tool steel as it comes from the steel mill. Stock must be selected sufficiently large to allow removing this surface when the cutter is machined to size. When upsetting steel it is best to allow more than would be necessary when cutting from a bar of the right size; for the steel at the circumference, not having anything to restrain it, flows under the blows of the hammer more readily than any other portion, and as this is the very portion where strength is required, sufficient stock should be removed to cut away this portion. Of course we could hammer around the circumference with light blows, but the effect would not be that desired, as we might again change the grain. The writer's experience has convinced him that while it does very well to occasionally hammer around the circumference when flattening out, there should be no heavy blows—if any at all—after the final blows of upsetting.

When forging large pieces of steel it is necessary to strike blows sufficiently heavy to make the steel flow as uniformly as possible. Light blows on the surface of a large piece of steel have the effect of drawing a portion of the surface away from the stock underneath, and this will break away when the contraction incident to hardening takes place, or if not then, it is sure to do so when in use. On the other hand, extremely heavy blows on small sections crush the grain, thus spoiling the steel.

Steel for cutters should be annealed after a hole has been machined in the center, and the blank blocked out somewhere near to shape. The object in annealing is not necessarily to make the steel soft, but to remove the strains set up in the steel by the operations of rolling and hammering in the steel mill, or forging in the blacksmith shop. If a piece of steel is annealed ever so thoroughly when solid and a hole then machined in it, strains are liable to manifest themselves in a very unpleasant manner when the piece is hardened. If, however, the piece when annealed is, as near as is practicable, of the same form as when hardened, all harmful tendencies will be overcome by the annealing process. The hole made must be somewhat smaller than finish size—say 1-16 inch—and the diameter of the cutter must be somewhat large. All scale on the surface must be removed and the steel annealed. There are several methods of annealing, probably the most satisfactory being the packing in a hardening box with powdered charcoal, placing in the furnace and running until the steel is uniformly heated to a low red. The annealing heat should be as high as the hardening heat, to overcome strains; but never high enough to open the grain. The steel should not remain *red* hot any longer than is necessary but it should be a long time in cooling off *from* a red heat. An excellent method which can be practiced in almost any shop consists in placing hot ashes in an iron box—or other receptacle—to the depth of 2 or 3 inches. On this place a piece of board and after the steel has been uniformly heated to a *low* red lay it on the board with another board over it and bury the whole with hot ashes. Pieces annealed by this method are not likely to be over-annealed, and as they cool below a red more quickly than with the former-mentioned method, and yet cool from a red to a temperature of 300 or 400 degrees F. very slowly, excellent results are nearly always obtained, provided the heat was uniform.

A common practice is to heat red hot and place in a box of cold ashes, or lime. Ashes and lime should be well heated before the steel is placed in them, which is done by heating a piece of iron, or scrap steel, red hot, placing in the ashes or lime and allowing it to remain while the steel to be annealed is being heated. It is then removed and the steel put in its place. It must always be borne in mind that if the red-hot metal is brought in contact with cold or damp substances, the heat is extracted from it rapidly, thus causing it to harden somewhat. Moisture, even though it be warm, must be avoided in anything that red-hot steel is buried in. For steam, if projected against red-hot steel, under certain conditions, would cause it to harden. For this reason never bury steel in damp ashes or lime.

After annealing, place the blank in the lathe chuck and machine the hole to desired size. In many shops it is the custom to make the hole about .005 inch smaller than the milling machine arbor on which it is to be used, and after

hardening it is ground to size with the internal grinding attachment provided with all universal grinding machines. In shops where there is no appliance for internal grinding, the blanks are very carefully annealed to remove, as far as possible, all strains incident to working in the steel mill or forge shop, then the hole is machined .0015 or .002 inch smaller than the arbor and is lapped to size after hardening. When I say arbor I do not wish to be understood as advocating working to the milling machine arbor, as all holes should be ground to a standard gage, a hardened plug gage or a standard disk. When the hole is machined to the required size the blank is placed on a mandrel and machined to the desired length and diameter.

To facilitate grinding or lapping the hole to size after hardening it is advisable when machining it to recess it, as shown in Fig. 1, leaving a bearing portion at each end. For, the same reason it is generally considered best to cut away a portion at each end, as shown at *a*, Fig. 2, thus saving time

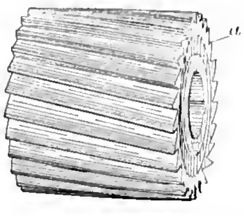

Fig. 2.

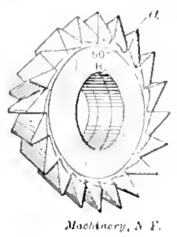

Fig. 7.

when grinding the ends. The operator should never leave ***sharp*** corners when recessing the holes, or cutting in at the ends, as sharp corners are likely to cause cracks when the steel is hardened.

The number of teeth in a milling machine cutter is a subject that has been debated for years, and one on which mechanics fail to agree, as conditions vary in different shops. Most manufacturers, I think, are agreed that reasonably coarse teeth work better than fine, for with the latter it is necessary to feed very slowly, as the spaces between the teeth fill with chips, thus causing the teeth to break. The following, from Brown & Sharpe's book, "Construction and Use of Milling Machines," seems to express the opinion of most men whom the writer has met who have had a broad experience in milling machine work: "Of late years mills have been made with coarser teeth than formerly, the advantages being more room for the chips and less friction between the teeth and the work. When the teeth are so fine that the mill drags, or where the stock is powdered, the mill heats quickly and does not cut freely."

When cutters are used on hand milling machines it is generally necessary to make the teeth somewhat firmer than when they are used on power milling machines.

It is considered best practice in most shops to make cutters of as small diameter as possible consistent with economy. By this is meant they should be large enough to allow of working over two or three times if this is practicable. Speaking from a theoretical standpoint each tooth should do its proportionate amount of cutting and the feed can be graduated to correspond with the number of cutting edges. But experience has proven that it is almost impossible to get a cutter on a milling machine arbor and have it run true enough to insure all the teeth cutting. And when but comparatively few teeth are doing any work it is necessary to feed as fine as when using a smaller cutter, and the speed of the cutter is necessarily slower, so the progress made is not as great.

In designing cutters, however, they must be of a size that insures sufficient strength at the point between the hole and the bottom of the cut between the teeth. The distance necessary to insure the proper amount of strength depends somewhat on the nature of the work to be done with the cutter. However, for general use there should be at least ⅜ inch at this point, as shown at *a*, Fig. 3. If milling cutters are hardened by the process known as "pack hardening" this space may be made somewhat less, as the steel will not be as brittle as if hardened by the ordinary methods.

To prevent the cutter turning on the milling machine arbor a keyway must be provided. In order that cutters having holes of given diameter may have a given size of key, manufacturers of milling machine cutters have adopted standard sizes of keyways. Fig. 4 represents a sectional view of a portion of a cutter showing a keyway, and herewith is given a table of sizes. The various dimensions are designated by letters, as will be readily seen. The drawing and table are taken from Brown & Sharpe's catalogue and apply to cutters furnished by them:

Diameter (D) of Hole.	Width (W) of Keyway.	Depth (D) of Keyway.	Radius R
3-8" to 9-16"	3-32"	3-64"	.020"
5-8 to 7-8	1-8	1-16	.030
15-16 to 1 1-8	5-32	5-64	.035
1 3-16 to 1 3-8	3-16	3-32	.040
1 7-16 to 1 3-4	1-4	1-8	.050
1 13-16 to 2	5-16	5-32	.060
2 1-16 to 2 1-2	3-8	3-16	.060
2 9-16 to 3	7-16	3-16	.060

Cutters used for cutting narrow surfaces have their teeth cut straight. In some shops all cutters used in cutting surfaces wider than ½ inch have their teeth cut spirally; in others they are cut straight unless ¾ inch or more in width.

The shape of the tooth plays a very important part in the way the cutter works. If the tooth is slender it springs into the work when heavy cuts are taken, as explained in the article in the December issue. It has been found by experiment that a cutter tooth having its face and back at an angle of about 50 degrees, as shown at *A*, Fig. 5, insures a strong tooth and sufficient depth of groove between teeth for chips. To produce a tooth of the proper shape for cutters of various sizes it is obvious that angular milling cutters of various angles are necessary. A cutter that would produce a tooth of the desired shape on a mill 2 inches in diameter would not

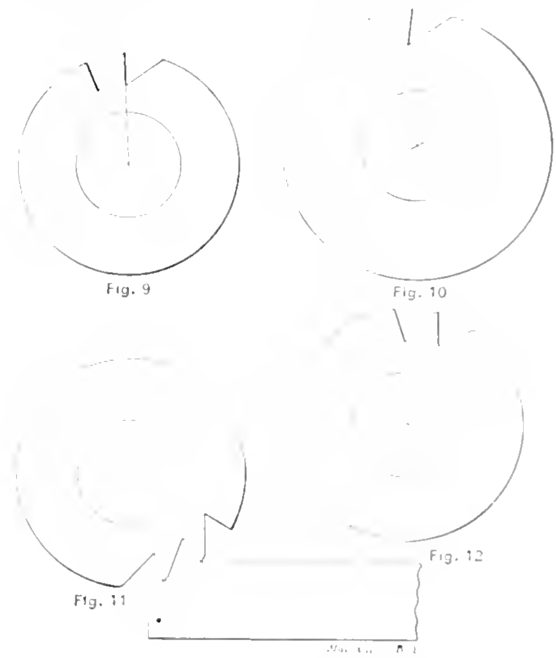

Fig. 9

Fig. 10

Fig. 11

Fig. 12

answer when producing teeth on one 6 inches in diameter. This is shown in Fig. 6, where *a* represents a portion of a cutter of 2 inches diameter whose teeth are produced with a cutter of 60 degrees angle, and *b* a tooth produced by the same cutter on one 6 inches in diameter. The dotted line shows the back of tooth if it and the face were at angle of 50 degrees. The tooth should be left about 1-32 inch broad across the top. The exact measurement cannot be stated arbitrarily; for small mills and light cuts .02 inch answers nicely, while for large mills which are to take heavy cuts it is necessary to leave them .04 inch across.

The angular cutter for producing the teeth should have the corners of the teeth, *a*, Fig. 7, slightly rounded rather than sharp. The amount of round need be but slight, but it makes a stronger cutter when the groovers are cut a trifle rounding in the bottom and it also reduces the tendency to crack when the cutter is hardened, sharp corners being an invitation to crack.

Milling Cutters with Spiral Teeth.

It is necessary when cutting mills of this type to use an angular milling cutter—having a slight angle on one side and the other side of a shape that will form an included angle of the form of the groove to be cut. The side which cuts the face of the tooth is generally made of an angle of 12 degrees, as shown in Fig. 8; while the opposite side may be either 40, 48 or 53 degrees, according to the size of the cutters to be cut.

When rigging up the universal milling machine if the angular milling cutter is set as shown in Fig. 8, so the distance *A* is about 1-12 the diameter, the face of the tooth cut by the side having an angle of 12 degrees will be nearly right for cutters of the usual proportions. The setting of the angular mill for the location of tooth must be made before turning the spiral bed to the desired angle of spiral. For cutting spiral milling cutters choose a helix that will produce the desired angle on the cutting edge. This varies, but for general purposes an angle of about 15 to 20 degrees with a plane passing through the axis of the cutter, gives good results. The helix may be either right- or left-hand, as desired, but unless the arbor is supported at the outer end it is best to make it of a hand that will force the arbor into the hole in the spindle rather than tend to draw it out. Then again it is better to have the thrust caused by cutting action against the solid shoulder of the spindle at the outer end of bearing rather than against the take-up nuts on the inside end of bearing.

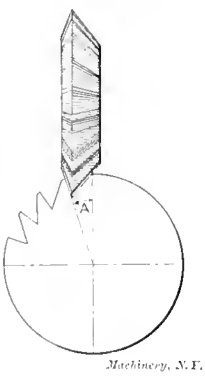

Fig. 8.

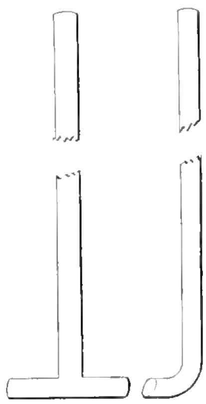

Fig. 13.

If two cutters are to be used on the same arbor it is a good plan to cut one with a right-hand spiral and the other with a left. In this manner the strain is equalized. This might, however, be objected to by some, on the ground that it would be more difficult to grind two cutters whose teeth were of opposite spirals to exact size than if they were of the same hand; but this need be no objection if reasonable care is exercised when grinding.

When the mill is to be used for the general run of work the cutting face of teeth is usually made radial and it is safe to say that as a rule the face of the teeth should be radial, as shown in Fig. 9. For certain classes of work it is necessary to depart from this custom. When the cutter is to be used for sinking a slot into a piece of metal it works better if the teeth are cut somewhat hooking, as shown in Fig. 10. When a mill is to be run onto the work, as shown in Fig. 11, there is less liability of its being drawn onto the stock and catching if the teeth are given a negative rake, i. e., cut ahead of the center, as shown in Fig. 12. While the generality of shops make cutter teeth radial, there are large manufacturing concerns which make most of their cutters with their faces receding, as shown in Fig. 10. However, to prevent chattering it is necessary to use heavy, stiff milling machines and to provide arbors somewhat larger than when cutters with radial teeth are used. Teeth cut as shown in Fig. 10 cut more readily than those cut radial.

As previously stated, no arbitrary rule can be given for the number of teeth for a cutter of a given size. Yet it is necessary to have a standard—if it can be so called—which may be departed from as occasion requires and the following table was in use in a shop where the writer was in charge and seemed very satisfactory:

Diameter of Cutter.	No. of Cutting Edges.	Diameter of Cutter.	No. of Cutting Edges.
½"	6	2½"	20
¾	8	3	24
1	10 or 12	3½	26
1¼	14	4	28
1½	16	5	30
2	18	6	32

If reference is made to engineers' hand books for information it will be found that various authorities are cited and that in some cases the pitch advocated by these writers differs greatly, showing that the distance apart of the teeth to insure best results depends on the class of work and the machine employed when doing it, as well as on the ideas of the designer in charge.

If the angular cutter used when cutting the teeth was in proper condition it should leave the surfaces of the teeth very smooth. The size and distinguishing marks should be stamped on the cutter, and then it is ready for hardening. If possible use the method known as pack hardening, as all danger of cracking is eliminated, and the cutter can be run much faster than when hardened by the ordinary methods; and even at the higher speed it will stand up longer between grindings.

If the cutter is to be pack-hardened and is made of steel containing more than 1¼ per cent carbon, use charred hoofs rather than charred leather as packing material. Do not use any wood charcoal, but simply charred hoofs. This method was described in a previous article. If necessary to harden by the ordinary methods, best results when heating are obtained by the use of some form of muffle furnace. Of these there are several forms on the market, any of which give good results. If only an open fire is available excellent results may be obtained if the operator will use the proper amount of care when heating. Have a large, high fire so as to get the cutter well up from the blast inlet. Use a *new* fire of charcoal, but have the coal well lighted so the heat will be uniform around the cutter. If an old fire (one that is nearly burned out) is used considerable blast will be needed to keep it alive and the air from the blast striking the heated cutter will cause innumerable cracks in the lighter portions of the teeth.

The cutter should be heated as rapidly as possible and the heat should be uniform. Do not attempt to force the fire, or the teeth, being lighter than the balance of the cutter, will heat more rapidly and so become overheated before the center is hot enough. The heat must be uniform and no higher than necessary to produce the desired result. A piece having projecting portions, like the teeth of a cutter, need not be heated as hot as a solid piece of the same size.

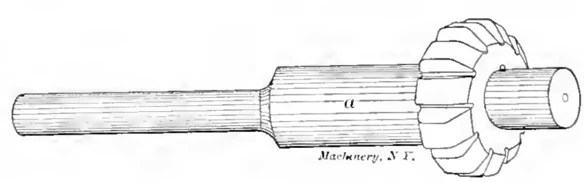

Fig. 14.

Should the cutter, through carelessness, become overheated, do not, as is the custom with some hardeners, hold it exposed to the air until it has apparently cooled to the desired temperature, and then plunge in the hardening bath; the grain of the steel always shows the effect of the highest heat it receives until it cools, and is again heated. Then again the surface cooling more rapidly than the internal portions would apparently be about right, while the stock nearer the middle would be much hotter; in other words it would be unevenly heated, and would contract unevenly and be very apt to crack. An overheated piece that is not *burned*, may be laid to one side and allowed to cool off, then reheated and hardened. If allowed to cool to a low red from a high heat and dipped, and it did not crack, the grain would be open and the steel weak, and it would crumble when in use.

Care must be exercised when dipping milling machine cutters in the hardening bath that the heat will be taken from the cutter by the bath uniformly. For this reason I prefer a bath having perforated pipes coming up from the

sides, by means of which jets of liquid are projected against the teeth uniformly at all points. If such a bath is not at hand, the cutter must be worked around in the liquid quite rapidly, to insure uniformity of results. Cold baths should not be used for this class of work, as they cause much trouble; the writer prefers a bath of brine which is of a temperature of about 70 degrees F.

As previously stated, all cutter blanks should be annealed after having a hole drilled through them and the outer surface of the stock removed, otherwise trouble may be experienced when hardening, especially if the cutter is to be of an irregular shape. Unless the cutter blank is annealed while in a form somewhere near that of the finished cutter, the strains in the steel will manifest themselves by irregular contraction when the cutter is cooling in the bath. To overcome this tendency to crack from unequal contraction, the cutter is slowly heated to a low red, removed from the fire and allowed to cool off until all traces of red have disappeared, when it may be placed in the fire again and reheated to the proper hardening heat and dipped in the bath. As the teeth are the only portion of the cutter which need be hard, the cutter may be removed from the bath as soon as it is hard and immediately placed in a tank of oil and allowed to remain until cool. Allow the contents of the bath access to all parts of the cutter. Hold the cutter in a manner that permits the liquid to circulate through the hole freely. A wire bent in the form shown in Fig. 13 answers nicely. The usual forms of tongs would not answer, as a portion of the outer surface would be covered by one of the jaws, thus causing unequal contraction.

After hardening, the cutter is reheated sufficiently to overcome any tendency to crack from internal strains due to hardening. It is then brightened, and the temper drawn to a light straw color, by placing on a plug of the form shown in Fig. 14. Do not have the portion marked *a* fill the hole in the cutter. Before placing the cutter on this plug it is heated somewhat, as the extreme heat in the plug if brought in contact with the walls of the hole in the cold cutter would cause rapid expansion, and perhaps cracking. While on the plug the cutter is held over the fire and the outer portion heated thereby, and when the proper temper color is visible, it is placed in warm oil and allowed to cool to the temperature of the oil. When a number of cutters are to be tempered, best results are obtained by heating in a kettle of oil, gaging the heat by a thermometer, 430 degrees being equivalent to a light straw color. If the cutter is hardened at the proper heat—the refining heat—the temper need not be drawn as low as when higher heats are employed.

Before grinding the hole in the cutter to size, remove all scale and gum, as this tends to glaze the wheel. The hole should be ground to a standard. The outer end of the cutter may be ground before removing it from the chuck, which insures the end being true with the hole. Then remove the cutter from the chuck, and hold the cutter on an expanding plug, with the end that has been ground against the faceplate provided for such purposes, and grind the opposite end as shown in Fig. 15.

It is customary in some shops to simply grind the walls of the hole while the cutter is held in the chuck, the ends being ground while the cutter is held on a mandrel like that in Fig. 16. By this method the ends must be parallel. However, if reasonable care is exercised regarding the condition of the faceplate and freedom from dirt, excellent results are obtained by the first-named method.

After grinding to length, the teeth are given the necessary clearance for cutting. A suitable wheel should be used, free from glaze to avoid any possibility of softening the cutter teeth by the heat generated by friction between a glazed wheel and the cutting tooth. A machine shop having even a few milling machines should be provided with suitable means of grinding the cutters. A dull mill wears away very rapidly and produces very unsatisfactory work and it pays to exercise care as to the condition of the teeth.

The wheel used on the cutter grinder should be as large as can be conveniently used without danger of striking the adjoining tooth. It should be the proper grade and number of emery (if an emery wheel). It is a mistake to use a hard wheel; it should be soft enough to allow of being easily scratched with a pointed instrument. The size of emery used in making the wheel cannot be definitely stated as the class of work must, in a measure, determine this, and wheels made of a certain size emery (or other abrasive material) by one manufacturer do not agree as regards results with wheels of the same size emery, and of the same designated grade, made by another. However, it is not generally best to use an emery coarser than 60 or finer than 90. A wheel of the proper grade should be about ¼-inch wide. If the wheels at hand are thicker than this, cut a corner off as in Fig. 17, until the face does not exceed ¼-inch width. If necessary to use a wheel that is too hard, the face should be narrower than the measurement given above; if very hard, reduce to ⅛ inch or even less. A soft wheel should be run faster than a hard one, but as a rule the maximum speed should not exceed 5,000 feet per minute; that is, the circumference of the wheel should travel at the rate of 5,000 feet per minute. This is termed the periphery speed. If the wheel is glazed, remove this by the use of a piece of emery wheel a trifle harder than the one being used. This produces an open appearance on the surface of the wheel.

For most purposes an angle of clearance of 3 degrees answers nicely; that is, 87 degrees from a radial line as shown in Fig. 18. When grinding for clearance, take light cuts and move the cutter tooth rapidly by the wheel. As so much depends on the emery wheel used for grinding for clearance, it is well to procure wheels of a reputable maker, stating when ordering, the class of work to be done. Their experience in

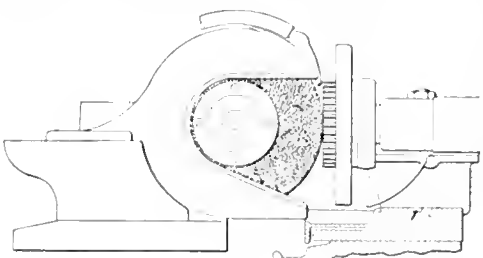

Fig. 15

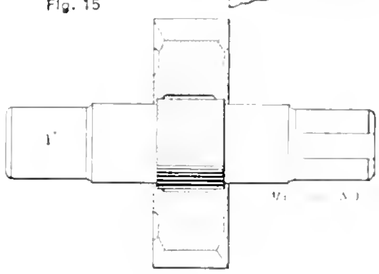

Fig. 16

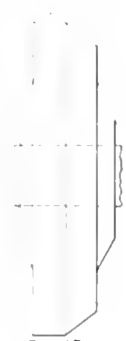

Fig. 17

Fig. 18

furnishing wheels for various purposes has taught them exactly what wheel is suitable for the job in hand.

When using mills suitable speeds and feeds must be employed. A 6-inch mill if run at the number of revolutions per minute that would be maximum for a 3-inch, could not stand up on the same work; the periphery speed must be right. When taking light cuts, a mill may be run more rapidly than when taking heavier cuts. When cutting hard metals a slower speed must be used than when machining softer ones. Cutters which are properly "pack hardened" will stand, as a rule, a speed 50 per cent greater than if hardened by ordinary methods. We must, however, have a basis from which to start, and some authorities claim for ordinary grades of machinery steel a speed of 35 feet, for cast iron, 60 feet; and for brass 125 feet, but as all these metals vary in hardness the above figures are only approximate. Cutters stand best when given proper feeds. If the feed is too coarse, the cutting edges are knocked off; if too fine, the cutter dulls owing to the teeth rubbing against the stock. In the ordinary shop there is greater danger of feeds being too fine than too coarse.

In the next article we will conclude the subject of milling machine cutters and take up side milling cutters, milling cutters with inserted teeth, etc.

If the job of being a foreman were not more difficult than being a mere machine man, it would not pay better.—*Woodworker.*

MACHINERY

DESIGN—CONSTRUCTION—OPERATION.

PUBLISHED MONTHLY BY

THE INDUSTRIAL PRESS,

66-70 WEST BROADWAY, NEW YORK CITY.

LESTER G. FRENCH, Editor.
FRED E. ROGERS, Associate Editor.

The receipt of a subscription is acknowledged by sending the current issue. Remittances should be made to THE INDUSTRIAL PRESS, and not to the Editors. Money enclosed in letters is at the risk of the sender. Changes of address must reach us by the 15th to take effect on the following month; give old address as well as new. Single copies can be obtained through any newsdealer.

We solicit communications from practical men on subjects pertaining to machinery, for which the necessary illustrations will be made at our expense. All copy must reach us by the 5th of the month preceding publication.

JANUARY, 1905.

NET CIRCULATION FOR DECEMBER, 1904,—22,917 COPIES.

MACHINERY is published in four editions. The practical work of the shop is thoroughly covered in the Shop Edition—$1.00 a year, comprising more than 430 reading pages. The Engineering Edition—$2.00 a year—contains all the matter in the Shop Edition and about 250 pages a year of additional matter, which includes a complete review of mechanical literature, and forty-eight 6 x 9 data sheets filled with condensed data on machine design, engineering practice and shop work. The Foreign Edition, $3.00 a year, comprises the same matter as the Engineering, but is printed on thin paper for transmission abroad. RAILWAY MACHINERY, $2.00 a year, is a special edition, including a variety of matter for railway shop work—same size as Engineering and same number of data sheets

IMPORTANCE OF ELEMENTARY PRINCIPLES.

In reviewing the steam turbine patents of the past century for the series upon this subject in the Engineering Edition, it has become evident to the writer that a great many inventors who have wasted their good money on worthless patents would have been far better off if they had invested the same amount in a course of lessons in the principles of physics, heat and steam. A fact that has been demonstrated time and time again is that the reaction of a jet of fluid, such as steam or water, when flowing from a nozzle, is equal and opposite to the impulse due to the momentum of the jet; and it makes no difference whether the jet discharges freely into the atmosphere or whether some obstacle is held in its path. So long as an obstacle is not placed near enough the outlet of the nozzle to choke the discharge, the reaction will remain the same, whether the jet strikes against some stationary object or not.

In spite of this well-known principle, many inventors have taken out patents on devices for turbines of the reaction type in which the jet is made to impinge against stationary projections as the wheel revolves, with a view to giving the wheel a harder push backward than the inventor believed would be the case if the jet flowed freely into the air. The idea appears to be prevalent that if the jet has an opportunity to push against something its effect will be greater.

One of the necessary requisites in a steam turbine is that in some way the speed of rotation shall be reduced, and what has seemed to many inventors to be a plausible method has been that of employing the injector principle for combining the steam with some heavier gas or liquid, with a view to reducing the velocity of the jet and hence the velocity of the wheel.

A turbine on this plan would undoubtedly work, but it would also cost many times more to operate it than its owner would care to pay for. The velocity of the combined jet consisting of steam and the other fluid—water, for example—is given approximately by the formula $V_1 = \frac{V}{W+1}$, where V is the velocity of the steam as it leaves the steam nozzle, and W is the weight of water used for each pound of steam. This formula is derived by the well-known principle that momentum before impact must be equal to momentum after impact. The ability of the steam jet to perform work on the wheel, however, is given by the expression $\frac{V^2}{2G}$ for each pound of steam, and of the water jet $\frac{(W+1)\,V_1^2}{2\,G}$. We will not attempt to apply these equations here, but the reader can easily perceive that inasmuch as the ability of the jet to do work is measured by the second power of the velocity and only the first power of the weight, the combining of the heavier fluid with the lighter will have the effect of reducing the kinetic energy and so of making the turbine inefficient.

What becomes of the kinetic energy lost in this process? Obviously part of it is converted into pressure and part of it appears as heat energy. The injector affords a striking example of this, where we find that, considered simply as a mechanical machine, without regard to heating the feed water, it will consume some 12 to 15 times as much steam per H. P. hour as a steam engine of the same power would consume.

* * *

THE POSSIBILITIES OF BOG FUEL.

Investigations of bog fuel made by the Insurance Engineering Experiment Station under the direction of Mr. Edward Atkinson apparently demonstrate beyond question that the possible exhaustion of our coal supply need not immediately trouble us, since this country possesses vast quantities of available fuel in its marshes and bogs. The Irish peasants have for generations been making use of peat, which practically forms their sole basis of fuel supply, but the bogs of Ireland differ from those in this country inasmuch as they are composed of moss and other vegetable products only partially decayed, while the larger deposits here are more of the nature of mud. Many failures have resulted from attempting to work the contents of mud bogs into fuel at low cost, and apparently for very simple reasons. The efforts heretofore have been to dry and then compress the fuel, using some other substance as a binding material to overcome its friable nature. This, of course, made necessary a lot of expensive machinery for compressing the briquettes, and required the addition of various foreign materials for the binder. According to Mr. Atkinson's report investigation in Germany disclosed the fact that the carbonaceous contents of these bogs consist of fixed carbon and hydrocarbon, the latter being a very adhesive substance contained in minute vesicles. These vesicles are broken up, which is done very simply by running the mud through a machine resembling a sausage chopper, and the broken hydrocarbon vesicles and their contents become diffused through the mud and act as a binder. Moreover, the mechanical breaking up of the mud mass liberates the water and allows it to evaporate rapidly under ordinary conditions. It is said that briquettes made in this manner contract or condense into a more or less solid form, in some cases increasing in specific gravity to that of the ordinary types of bituminous coal.

Apparently, from Messrs. Atkinson and Norton's reports, there are many opportunities for the development of fuel plants with comparatively small capital, wherever bogs or marshes of the proper constituency exist. Of course, many bogs are not possible sources of profitable fuel supply, and in any case careful investigation should be made before an attempt is made at development. Mr. Atkinson thinks that a plant costing about $2,500 will, as an average, turn out 20 tons of bog fuel per day, or allowing for holidays and storms about 5,000 tons per year. There are many regions now, more or less remote from coal mines, where a cheaper fuel supply would be greatly appreciated, and if such happen to possess supposedly worthless swamps, it may be instead that they have an inexhaustible supply of good fuel at their very doors.

* * *

While high-speed steel is said to make excellent razors, it appears inadvisable to use it for this purpose, if we accept the testimony of one of the members of the Iron and Steel Institute at the recent New York meeting. He said that there had been one curious fact noted in connection with high-speed steel. Any wounds caused by it are very painful and take a long time to heal.

ENGINEERING REVIEW.

CURRENT EVENTS, TECHNICAL AND MECHANICAL—LEADING ARTICLES OF THE MONTH.

From a cursory examination of some of the mechanical toys exhibited for sale in the shops and stores in great numbers at Christmas time, it would seem that the makers thereof have arrived at the acme of accomplishment in the manufacture of machines that will actually run—for a very brief period—and then, like the deacon's "one-horse shay," they go to pieces all in a day.

An amusing example of the perplexities that frequently beset the piecework shop was furnished at the last meeting of the National Railroad Master Blacksmith's Association. In the discussion on high-speed steel one of those who took part related how one of their machine men had suddenly greatly increased his output over that of the other men. For some time it was a mystery how he was able to turn out work so fast, and then it was discovered that he was more progressive than the firm and had secretly bought some high-speed steel for his own use, and was thus reaping the benefit of his progressiveness in the shape of good hard cash. Now let the managers of piecework shops arise and tell us how they would have handled a case of this kind prior to finding out what was the reason of this man's extraordinary production, and what they would have done afterward.

A circus train was pulling out of Spokane, Wash., a few weeks ago when suddenly the injector "broke" and persistently refused to take up water. After working with it a few minutes the engineer ordered an examination made of the tank; it was found nearly empty, although filled at the water crane but a short time before. No explanation of this mystifying condition was apparent until water in numerous streams was seen running from the elephant car next to the tender, and then the cause was found. "Jumbo" had amused himself by reaching his trunk through the open end of his car into the manhole of the tender and sucking up the water with which he had deluged the other animals in the car. They looked like "drowned rats," and needless to say had enjoyed their involuntary baths no more than the trainmen had the delay.

Not long ago it was freely predicted that much of the large machinery provided in our leading electrical and steam engineering works would become more or less useless on account of the much smaller sizes of units made possible by the steam turbine, but apparently the growth of the big machine tool industry will suffer little or no check from the advent of the steam turbine. The huge turbines now building for the 25-knot Cunarders have made necessary the building of a number of large special machines, one being a boring machine for the casings, constructed by Thomas Shanks & Co. for John Brown & Co., Clydebank. The total weight of this machine is about 95 tons and it has an over-all length of 76 feet. The base plate is 17 feet wide and 53 feet long, with wings bolted to each side where necessary to serve as supports for the overhanging parts of the turbine casings.

One of the interesting exhibits at the Louisiana Purchase Exposition was a steel boiler plate made by Worth Brothers, Coatesville, Pa., which is said to be the largest boiler plate ever rolled. It is 558 inches long, 142 inches wide, and 0.72 inch thick. The total weight is 16,120 pounds. The tensile strength of the material is 58,000 pounds per square inch; the elastic limit 37,000 pounds; and elongation 37 per cent. There is a most striking difference between this monster plate and the small iron plates available, say, one hundred years ago. It will be remembered in the article "Early Steam Engines.—3," which appeared in the August, 1901, issue of MACHINERY, it was stated that the firebox of the boiler of the Center Square pumping engines at Philadelphia, Pa., was made of wrought-iron plates 15 x 36 inches. These were the largest that could be obtained at that time.

In a paper on the modern steam fire engine read by Mr. F. F. Loomis before the ninth meeting of the Ohio Society of Mechanical, Electrical and Steam Engineers, it was stated that the first steam fire engine dates back to 1840 and was built by Mr. P. R. Hodge, a mechanical engineer of New York City. Strange to say this machine was of the automobile type, being self-propelling. The rear wheels, which were the drivers also, served as balance wheels when the engine was in use at a fire, the machine then being jacked up so as to clear the ground. Although it worked very well for its small capacity, weighing only 3,000 pounds, it was opposed by general prejudice and by the volunteer fire departments of those days, and allowed to fall into disuse. Mr. A. B. Latta built the next steam fire engine for the city of Cincinnati in 1852, and its great success paved the way for its general adoption in all cities.

The ice man is an important personage during the hot term, but there are indications that his vocation may be less important to many in future years. The ideal condition for every household maintaining a refrigerator would be that in which a refrigerating system is operated by power, preferably electric. Then the refrigeration could be maintained as the weather demanded, and not as suited the convenience of the ice man. We understand that a small electric refrigerating plant for the household has been placed on the market which has a capacity equal to the melting or use of about 200 pounds of ice per day. It is said to be automatic, and so simple in the matter of care as to be operated by the ordinary kitchen help. It is driven with a one-half horse power electric motor, which operated about half of the twenty-four hours will manufacture nearly 20 pounds of ice, besides refrigerating two storage compartments to a temperature of 35 to 38 degrees F.

Professor Bach recently made some experiments to determine the effect of high temperature on the strength of steel. The tests were made on groups of four bars each. The first four were tested at ordinary temperature, and the other lots at 390, 570, 750, 930 and 1,020 degrees F. respectively. At ordinary temperature the tensile strength of one bar was 51,000 pounds per square inch and the elongation 26.3 per cent. The tests on the successive lots showed that the strength increased with the temperature up to 750 degrees F., at which the total increase was about 6 300 pounds per square inch, but above this temperature the strength decreased directly with the temperature, and was found to be only 26,000 pounds per square inch at 1,020 degrees F. As a result of these tests the professor thinks that boiler steel plate should also be tested at higher temperatures than normal, as there are surprising variations from the results of tests made at ordinary temperatures.

In the paper "The Development and Use of High Speed Steel," read by Mr. J. M. Gledhill before the Iron and Steel Institute, it was intimated that the famous Damascus steel of antiquity, to which marvelous cutting powers have been attributed, is really a form of high-speed steel, containing as it does those alloys which have been found necessary in the manufacture of our modern product. He states that Damascus steel contains certain percentages of tungsten, nickel, manganese, etc., and hence a latent high speed steel may be said to have existed centuries ago. All that was necessary to bring out its inherent powers was a very high temperature, such as was long thought to destroy its nature, in other words, "burn" it. It remained for Messrs. Taylor & White, of the Bethlehem Steel Co., to burn alloy steels and thus develop their high-speed quality which perhaps has worked and is working the greatest revolution in machine shop practice.

According to the statement made by the United States consul at Milan, Italy, that government has recently made an

interesting experiment with automobiles to demonstrate their emergency value in war time. Fifty owners of automobiles were invited to take part in the maneuvers and thirty responded. Thirteen routes were selected from Brescia leading to various points on the eastern, western, and northern frontiers. The thirty machines participating all left the town in the early morning, each bearing a sealed order containing the route laid out for that machine. The distance had to be covered within twenty-four hours, and means had been provided for verifying the routes, times of departure, etc. All the cars returned to Brescia before midnight of the same day, and only one of them had an accident. The longest distance covered was 335 miles. The result of the test is said to be highly gratifying to the military authorities, as it proves the great value of the automobile in war time for transporting officials, papers, maps, light apparatus, food, etc.

One of the most famous patents in the matter of litigation is that of James Knibbs, who some forty years ago invented a relief valve for fire engines. The invention was very simple, but is a very valuable adjunct to the steam engine, being practically indispensable in fire fighting. It essentially consists of a relief valve and pipe attached to the box to which the pumps deliver the water, and from whence the streams are distributed to the various lines of hose. The pipe to which the relief valve communicates leads back to the suction of the pump. When the fire engine is supplying water for fighting a fire, the demand for water is likely to be the full capacity of the engine, but one or more lines of hose may be suddenly shut off at any time without warning to the engineer. Without the relief valve the pressure would likely rise so high as to burst one of the remaining lines of hose, but with the Knibbs device the excess pressure merely raises the valve and allows the water to flow back to the suction where it is pumped over and over again. Thus not only the hose is protected but water is saved and the flooding of the streets prevented. Knibbs neglected to patent his invention until it had been used over two years. He then secured a patent for it and its use became general on fire engines. In 1877 suit was begun against New York City for infringement of the patent, and as time passed on the claims mounted up to over $26,000,000. The United States Circuit Court recently decided in favor of the city, holding that Knibbs had abandoned his invention, inasmuch as he did not secure a patent within two years of its inception.

RAISING THE MAINE.

Since the sinking of the *Maine* in Havana harbor, February 15, 1898, there have been many rumors that the wrecked vessel was to be raised by private contractors who expected to be recompensed for the work by the actual value of the vessel and its equipment, and the curiosity of the public who would be willing to pay a good admission price to view the relic. None of these proposed schemes have resulted in any actual work being done, so far as we know, but it now appears from the *Engineering News* that plans have been made, and work will soon be started by a salvage company. The United States government has relinquished all claim to the battleship, and it is now the property of the Cuban government, which desires to remove the obstruction from the harbor, where it is a serious menace to navigation. The salvage company proposes to build an immense wooden circular coffer-dam 354 feet inside diameter, with inner and outer concentric timber walls spaced 8 feet apart. Each wall will be composed of 3-inch pine planks, and the inner and outer walls will be tied together by radial and diagonal planks, and ¾-inch tie rods. The depth of the water where the Maine sank is about 35 feet down to a mud stratum, and the mud is about 20 feet deep before a hard stratum is reached, hence the coffer-dam may have to be built fully 55 feet high, provided it is found necessary to sink it completely through the mud stratum. It is proposed to build the dam complete and sink it around the vessel by loading it with about 2,000 tons of ballast. Water will also be admitted within the inner and outer walls. When the dam has been sunk to the mud stratum pumping will begin, which will facilitate the sinking of the dam through the mud. When the water has been pumped out, the work of temporarily repairing the vessel so that it can be floated will be done. The company is alive to its opportunities and will charge photographers a high price for taking photographs of the work and of the wrecked vessel as it is uncovered. They also propose to make up souvenirs of brass, bronze, and copper, which will be sold as mementos, and will be accompanied by certificates of Cuban and American officials as to their genuineness. After the vessel has been floated, it will be placed on the Havana floating drydock and there completely repaired. When repaired it is proposed to exhibit it in the principal seaports of the United States and charge visitors an entrance fee for the privilege of going over the vessel. After all these various sources of revenue have been exhausted the company will have on its hands a complete battleship which they will sell to some government. The Maine cost the United States something like $5,000,000 to build and equip, and the machinery alone cost $735,000. The proposed work is of great interest from both an engineering and a historical standpoint, as the coffer-dam proposition is perhaps the most ambitious of the kind ever projected, and, if successful, it will restore to the world a vessel round which much sentiment centers.

FANS VS. POSITIVE-PRESSURE BLOWERS.

An interesting and valuable paper to foundrymen was presented at the March 7th meeting of the Pittsburg Foundrymen's Association. It described tests which were made by a committee appointed by the association for the purpose of determining the relative efficiency of fans and positive-pressure blowers. The tests were conducted at the works of McIntosh, Hemphill & Co., on a 54-inch cupola, under the supervision and direction of Mr. W. H. McFadden. The first test was made with a Sturtevant No. 10 fan, driven by a 50-horsepower, 220-volt, shunt-wound motor. For the fan test the motor was run at a speed of 839 revolutions per minute, and the power required throughout the test was determined from voltmeter and ammeter readings. 60,700 pounds of metal was charged into the cupola, one-half being scrap and one-half pig. The test began at 2:02 P. M., and at 3:30 the first iron was run into the ladle, its temperature being 2185 degrees. The test was concluded at 5:50 P. M. During this period the average pressure of the blast was 13.6 inches, the average power required 35.8 electric horse power, and 57,680 pounds of iron were melted. The average amount of iron melted per hour was 15,312 pounds; 17,200 pounds per hour were melted during the first part of the heat, 15,000 pounds during the middle period, and 12,200 pounds at the last. The second test was made two days later with a 33-cubic foot Connersville blower. The same conditions existed as with the previous test with the exception that the piping to the cupola contained one more elbow. The same motor was used to drive the blower, and the cupola was charged with the same proportion of iron and scrap, but 63,000 pounds were charged instead of 60,700 as before. This test began at 2 P. M. and continued until 4:50. The average wind pressure was 20⅝ inches, and the average electric horse power was 40.6. The first iron was run into the ladle at 3:30 and indicated a temperature of 2165 degrees. The total amount of iron melted was 59,677 pounds and the time required was 2 hours 49 minutes as against 3 hours 46 minutes with the fan. During the first of the heat the iron was melted at the rate of 20,500 pounds per hour, during the middle at the rate of 22,300 pounds, and during the last at the rate of 17,700 pounds. A complete log of the tests shows that the average electric horse power for the fan was 35.8 and for the blower 40.6, as has already been stated. The highest horse power required for the fan was 43.2 against 48.3 for the blower. The fan required 134.8 horse power hours for 60,700 pounds, while the blower required 114.49 horse power hours for 63,000 pounds. Hence the fan required 4.41 horse power hours per ton of iron charged, and the blower, 3.63 horse power hours per ton, making a difference of 0.78 horse power hours in favor of the pressure blower; the difference in time for melting the two heats was 57 min., also in favor of the blower. This would allow the user of the blower to postpone putting on the blast

about one hour longer for a 30-ton heat than could be done with a fan. It has been found that the blower causes a much greater wear on the lining of the cupola than does the fan. Additional tests of a non-official character were also made with a No. 8 Sturtevant fan. The conclusions of the author are as follows:

1. The test has proved that, under favorable conditions, a 40-horse-power motor is sufficient to supply power for a blower or fan furnishing blast for a 54-inch cupola.

2. The rate of melting is not proportional to the amount of air supplied to the cupola. Too much air will tend to cool the cupola around the tuyeres and thus reduce the melting area.

3. In a 54-inch cupola when all heavy scrap and pig was charged, the 33-cubic foot positive pressure blower melted more economically and faster than did the No. 10 fan blower.

4. A No. 8 fan melted much more economically and faster when the cupola was kept open by a small amount of light scrap than did the No. 10 fan when all heavy scrap was used.

5. The high pressure produced by the positive-pressure blower has a much more severe cutting effect on the lining than had the lower pressure produced by the fan blower.

6. The original cost and the cost of installation of the positive-pressuro blower would considerably exceed that of the fan blower.

7. The actual saving in horse power is not a large item. The saving due to the shorter time taken by the blower would depend upon the number of men employed and the price of work.

8. The difference in economy between the two types of blower depends largely upon the cupola practice. The above tests would indicate that where the tuyeres were kept clean and the cupola not packed too tight, there would not be any great difference in favor of either of the types of blowers. If the tuyeres are allowed to become partially closed, the positive type would prove the better.

EXPERIMENTS WITH HIGH-SPEED STEEL DRILLS.

Abstract of Paper presented by W. W. Bird and H. P. Fairfield before the December Meeting of the American Society of Mechanical Engineers.

The introduction of the high-speed twist drill into modern machine shop practice has brought with it many new problems and the tests recorded in this paper were designed to supply some definite data on the subject.

In order to measure the twist or moment and the thrust of the drill an apparatus was devised to go on the table of a milling machine, the drill being held in a chuck in the milling machine spindle. The apparatus is in effect a double dynamometer. It consists of a chuck with trunnions, mounted on roller bearings so that it is free to revolve about its axis; at the same time it is free to move in the direction of its axis, being mounted on a carriage which is on rolls resting on the frame of the machine. This frame was placed on the table of a milling machine so that the axis coincided with the center line of the drill, which was driven by the spindle of the milling machine. The thrust of the drill is transmitted through the trunnion of the chuck to a plunger which is fitted to a long cylinder filled with oil. At the end of this cylinder is a smaller one also carrying a plunger. This small plunger is attached to a ball-bearing piston in a regular indicator. The drum of the indicator moves proportionately to the feed so that the card taken is a record of the thrust during the drilling of a hole. The chuck is held from turning by a steel band which is attached by a yoke to a second indicator, and a card from this one shows the twisting moment at each stage of the operation. Both indicators were calibrated before and after the tests.

The correct moments were obtained by hanging known weights over the chuck and noting the rise and fall of the pencil point. The thrust cylinder was placed in an Emery testing machine and known loads applied, and a corresponding record taken on the cards. From these tests, curves were plotted so that readings from the cards could be readily reduced to pounds. It was decided to take up first the drilling of cast iron with high-speed steel. Blocks of soft gray iron were obtained and tested in the machine itself so as to get a number for each set of experiments as near the same degree of hardness as possible. A 5/8-inch Novo steel drill was taken as a good representative of the new steels.

The first experiments were on the effect of speed or number of revolutions per minute, all other conditions remaining the same. The revolutions were varied, from 110 to 600 but no material difference was shown by the cards in either thrust or twist. In other words, the power required to turn the drill varies directly with the number of revolutions, while the thrust does not increase with the speed, but depends upon the feed or the advance per revolution.

The next set of experiments was made to determine the relation between thrust and feed, the revolutions per minute remaining constant. From the first set of experiments it was shown that the limit of speed would depend upon the endurance of the drill, and with heavy feeds 420 revolutions was not far from this limit. Accordingly, the second set was run at this speed, which for a 5/8-inch drill is about 70 feet per minute for the cutting rate for the outer edges, and for .020-inch feed a rate of drilling of about 8 inches per minute. The range of feed was taken from .004 to .020 inch per revolution, the drill at the coarsest feed being somewhere near its limit. These feeds were all positive, a train of gears being substituted for the regular belt drive. The following table shows the results:

TABLE I

Feed—inches per revolution—								
.004	.006	.008	.010	.012	.014	.016	.018	.020
Thrust—total in pounds—								
240	280	330	360	410	460	525	620	725
Moment—total in inch-pounds—								
55	67	83	92	103	115	124	132	138

The figures in regard to moments indicate that less power is required to drill a given hole in a given time by increasing the feed per revolution rather than by increasing the revolutions. For example, to drill a hole in a 1-inch plate in 10 seconds could be done by running the drill 600 revolutions per minute and feeding .010 inch per revolution, but would require more power than by running at 300 revolutions with a feed of .020 inch. The question of proper angle of drill was next considered and a set of experiments made with a constant speed and feed, the half angle varying from 37 degrees to 70 degrees, 22 degrees less and 11 degrees more than the standard 59 degrees. The following table shows the results:

TABLE II.

Angle of drill, deg.	37	45	50	55	59	65	70
Thrust in pounds..	215	225	240	260	290	325	375

It was found that with the drill ground with a smaller angle than 59 degrees there was less thrust, but when the angle was as small as 37 degrees, however, the drill would not stand up on repeated work. At 45 degrees it seems to do the work as well as at 59 degrees and with much less thrust. This would suggest a change in the standard angle for the new steels. The moment for the various angles remained practically constant, so that the driving power does not change with the angles of the drill.

Another interesting point in drilling which can be shown with this machine is the effect of first removing the center of the hole by the use of a small drill. Ten holes were drilled in a bar of cast iron with small drills, ranging from No. 53 to 1/2 inch in diameter and then each one counterbored with a 5/8-inch drill at 420 revolutions per minute and a feed of .008 inch per revolution.

Table 3 gives the thrust in each case and shows that a hole 1-10 inch in diameter takes off about one-half the thrust for a 5/8-inch drill.

TABLE III

Size of first hole—										
.000	.0595	.0760	.0935	.120	.157	.189	.221	.250	.375	.50
Thrust for counterbore—										
340	190	180	170	155	145	130	120	90	70	30

CONDENSERS FOR STEAM TURBINES.

Abstract of Paper by George I. Rockwood, read before the December, 1904, Meeting of the American Society of Mechanical Engineers.

Mr. Rockwood has recently installed a 400-kilowatt Westinghouse-Parsons turbine at the Atlantic mills, Providence, R. I., and in this paper gives some of the results of his experience with the installation, especially with reference to the condenser outfit. The condenser used is a 16-inch Bulkley injector condenser, and the falling of the injection water through the throat of the condenser is what constitutes the air pump, and it is found to be the only air pump needed, since a vacuum of 28½ inches of mercury can be maintained, regardless of whether steam is passing through the turbine or not. The action of the condenser is such as to warrant the belief that a 14-inch condenser would answer every requirement for a 400-kilowatt turbine.

The injection water comes 500 feet from the river to the power house under a slight head and is elevated into a vertical tank 30 inches square by 15 feet deep. The level of the water in this tank is maintained 6 inches below the water inlet nozzle of the condenser, and the injection pipe takes the water from the tank at a point near the bottom. Apparently the depth of the tank acts efficiently as an air separator, in view of the excellent vacuum maintained, and no air in the form of bubbles can be detected passing over into the condenser with the water.

The cost of a condenser equipment of this type, fully installed, with centrifugal circulating water pump, tank, piping and valves, ranges from $2.00 to $2.50 per kilowatt, and the room occupied is practically none at all.

In contrast to this is the experience of the unusually large condenser and auxiliaries usually found in turbine plants which, by comparison with the diminutive turbine, appear unduly prominent. Aside from the type installed by Mr. Rockwood there are three other accepted designs for turbine condenser plants:

1. The combination of a surface condenser, a centrifugal hot well pump, an air cooler, a single-cylinder dry vacuum pump, a centrifugal circulating pump with their connecting drip piping and valves.

2. The same arrangement, but with the hot well pump, the air cooler and dry vacuum pump omitted, substituting therefor the wet vacuum pump—preferably of the Edwards type. The cost of these two equipments is about $7.00 to $10.00 per kilowatt.

3. An equipment like the first, except that an elevated jet condenser with a barometric tube and hot well takes the place of the surface condenser and hot well pump. This takes up less floor space and costs but $5.00 to $6.00 per kilowatt. The dry vacuum pump used with barometric condensers must have a two-cylinder air pump, and the exhaust from the turbine cannot be used again in the boilers.

The author contends that the injector condenser would seem to bar out all other condenser systems in situations where the water is pure. For example, if the city water is pure and costs about seven cents per 1,000 gallons, water enough for a 400-kilowatt machine at 100 per cent load factor would cost per factory year of 310 days, 10 hours a day, at 1,000 gallons per hour, about $217. With interest at 5 per cent and fixed charges at 8 per cent this sum warrants the capital expenditure of not to exceed $1,670. It is thus clear that it does not pay to buy the surface condenser system simply to save the cost of paying city rates for boiler feed-water. Where the feed water contains salt, sulphate of lime, acid, grease or other hurtful pollution, however, then it pays to use one of the surface condenser systems.

Much talk has been made about the freedom of the condensed exhaust steam in turbines from cylinder oil, and the advantage which this purity gives to it as compared with the oily exhaust from reciprocating engines, where the condensed steam is returned to the boilers.

It should not be forgotten that great purity of feed water is not in itself a desirable thing, being only better than very impure water; for it pits the tubes and water legs of steel boilers, unless some lime is added. Where the waste injection water from a jet condenser is used for washing in a dye house, this freedom from oil is a great advantage. Such is the aversion of dyers to using exhaust steam to heat water on account of the supposed presence of cylinder oil—no matter how careful one may be to provide, and operate successfully, oil eliminators—that this freedom of the turbine from the use of cylinder oil is sufficient cause to determine the purchase of turbines in place of engines for power in such places.

The method of sealing the spindle of the Parsons turbine against air leak where it passes out to its journals from the low-pressure chambers, namely, by pumping water with centrifugal pumps formed in small recesses in the shaft cover, so as to keep a water pressure in these recesses in excess of that of the atmosphere, is a perfect success.

In starting the turbine at the Atlantic mills, injection water is first turned on, then steam is admitted to the turbine without admitting water to the air seals where the shaft passes through the turbine casing. After the load begins to come on, the drip pipe from the exhaust chamber to the atmosphere, which has been open all night and up to this point, is now closed, the water turned on to the air seals, and the vacuum immediately draws down to 28 inches. It is not found absolutely necessary to start in this way, as the turbine can be run hours before the water accumulates in quantity. The object is simply to drain the turbine up to the moment when the load begins to come on.

It is necessary to exclude any accumulation of water in the exhaust pipe for fear that it will sway back and forth until it flushes up on to the large low-pressure blades of the turbine. Running as they do at a very high velocity, sudden contact with water from the exhaust pipe will strip the last row off clean if such contact is permitted. Any further damage, however, to the other rotating blades seems to be prevented by the presence of the fixed row, which, by dividing up the water into small streams, seems to protect the moving rows from contact with solid water and therefore from injury. It is not, however, necessary to provide a drip pipe or drip pump, for removing the water of condensation or the leakage into the exhaust chamber from these air seals.

DIAMOND TOOLS.

Abstract of Paper by G. C. Henning, presented at the Meeting of the A. S. M. E., December, 1904.

Steel is, of course, the one material in almost universal use for cutting and working stone, metal, wood and other materials, because of its great strength and the degree to which it can be hardened. There are some materials, however, which, because of their hardness, structure or non-conductivity of heat, cannot be worked economically by means of steel tools. The latter become worn rapidly, losing their shape and dimensions to such degree and extent that the work produced becomes inaccurate, causing constant interruption of operation, loss of time, and the use of new tools or frequent regrinding or shaping of the old ones. This causes great expense and delay in production. The great friction produced by cutting materials in some cases draws the temper of steel tools, making them useless. Hard rubber, paper and hardened steel cannot be readily worked by use of steel tools, as is also the case with hard stone. In these cases a much harder material is required, and for this reason diamond is used. The diamond used is of two kinds, totally different in appearance and quality. 1. The black diamond has a very dark purple brown color, and is an amorphous, granular stone with rarely any crystallization visible or traceable. It is called carbon or black diamond. It is the hardest material known and has great strength. 2. Bort, is entirely crystalline, and is generally transparent and of all colors of the rainbow, as well as clear and transparent as glass. The latter is considered of greater hardness than all other bort except some which is almost black. Bort is extremely brittle and is readily fractured or "cleaved" in the three directions of its cleavage planes parallel to the sides of the octahedral crystal, in which shape it is most commonly found. The dodecahedral crystals are also readily cleaved in a similar manner.

In spite of the very great hardness of all kinds of diamonds, they are readily sawn, drilled, cut and polished; carbon (black

diamond) cannot, however, be polished, as is the case with bort.

Diamond cuts diamond, while steel saws and drills, and cast iron discs charged with diamond dust are used for the other operations. All kinds of grinding wheels, being made of extremely hard materials, are most readily kept free from filling or glazing and in perfect shape by diamond tools. In certain classes of work, where great accuracy and precision are primary requirements, or extremely fine lines are essential, the diamond is the only material that answers the purpose. Thus lithographers, engravers and scale-makers use them for fine work. Another very important field of production in which diamond is all but imperative to obtain satisfactory results at reasonable cost is that of wire drawing. Formerly all small wire was drawn through holes in hardened steel plates, but these wear so rapidly that the wire soon loses its caliber and becomes unround. As it is all-important, especially in electric work, that the wire be of absolutely uniform size, so as to maintain constant resistance and permit symmetrical distribution of weight about spindles and shafts, it became necessary to use a material harder than steel, and hence diamond was again resorted to. This made it possible to avoid delays in replacing worn dies, and because of the great permanence of accuracy of the calibers of the holes in the diamonds, the cost of producing fine wire of copper, brass, steel, iron, nickel, and of other metals was materially reduced.

It is, of course, well known that stone is drilled and sawed by the use of diamonds, these having been used in core drills, which, in an extreme case, have cut solid cores of about 21 inches diameter. In diamond drills, stone saws and grinding wheel dressers, the rough diamond is used in appropriate holders, set either by staking, brazing, soldering, or by casting molten steel around the diamonds. A peculiar property of the diamond is that it can be plated like any metal; this property is made use of in the galvanoplastic setting. The galvanoplastic setting consists in first plating the diamonds and then casting other molten metal around them, which alloys with the deposited metal. Thus an absolutely firm and rigid setting is produced.

Very high temperature does not affect the diamonds either in their hardness or, when sound, in their solidity, and does not produce checks or other flaws. A temperature higher than that sufficient to melt steel will, however, burn the diamond, and that of the electric arc will do so readily. The diamonds in tools used for doing accurate work are, however, all "shaped" by cutting and polishing, so as to imitate the customary shapes of steel tools.

Glass and china are also drilled by shaped diamonds, in which case a triangular splint is generally provided with a flat triangular pyramidal point, which, when using turpentine as a lubricant, penetrates glass and china more readily than any other tool, and lasts for from one to two years, unless broken by carelessness or accident. There are various styles of tools. In the round-nose tool, the diameter or curve of cutting edge and its clearance from a right angle can be produced at will. In the sharp-nose tool also the angles can be varied at will. The square-nose tool is used mainly for producing very high finish of hard rubber, and a tool commonly used for turning paper calender rolls, which must be very accurate and smooth, consists of a piece of black diamond shaped as a round-nosed tool, and simply clamped in proper position between two pieces of steel. The last three tools are most commonly used for turning hard rubber, because the diamond lasts a very long time without wear and produces absolutely smooth and accurate work, while steel tools wear off in a few minutes at most and get very hot. One other reason why it is economically advantageous to use diamond tools for turning hard rubber is that very high speeds can be used, 450 to 500 feet per minute being common.

It may here be added that diamond tools are most suitable for working carbon used for electrical purposes.

A diamond die used for drawing wire consists of a bronze block in which is set a diamond perforated by a tapering, polished hole through which the wire is drawn. The holes in these diamonds are rarely made larger than .064 inch diameter, because steel draw plates or dies are considered sufficiently accurate and economical for larger sizes, and [illegible] great cost of diamond dies. The smallest di[illegible] come to the notice of the writer had holes of .001 in[illegible]ter, although clients have called for calibers as sm[illegible] .00055 and .00065. It is common practice to make the [illegible] in diamond dies accurate to .0001 inch, which to many e[illegible]neers may seem almost impossible, and is therefore here mentioned. In drawing copper wire, it is customary to draw a .061 wire in one pass from a rough wire of .072 diameter. Smaller sizes are then produced by the following consecutive reductions: to .053, .045, .040, .036, .032, .028, .025, .022, .020, .019, then by 1-1000 down to .0075 and by half thousandths down to .001.

It may be mentioned that diamonds wear increasingly when drawing the following metals in the order stated, viz.: gold, silver, copper, brass, bronze, platinum, soft steel, nickel, iron and crucible steel (piano wire).

In order to show why such expensive material as diamond can be used economically it may be stated that diamond dies wear up to eight years under constant use. One die of .004 caliber has, according to the record drawn over 550,000 pounds of soft copper wire. Diamond drills for drilling glass wear from one and one-half to two years before requiring recutting.

As is well known, diamonds are also used for spindle bearings in watches, and most recently have been introduced as cupped bearings for the pivots of electric meters, because they produce the minimum of friction, and do not wear out in many years. Another purpose for which diamonds are used is that of drilling teeth, especially artificial teeth. In these drills minute chips of diamonds soldered into steel shanks are used. These diamonds are not prepared in any manner, as their points and edges when properly selected are sufficiently hard and sharp to penetrate bone and porcelain. The shapes of chips most generally used are flat, triangular points and three-sided pyramids. The most perfect drills for this purpose have diamonds of triangular sections with a pyramidal polished point.

THE BURSTING OF FOUR-FOOT FLYWHEELS.

Abstract of Paper by Prof. C. H. Benjamin read at the December 1904, Meeting of the A. S. M. E.

Prof. Benjamin has continued his destructive work of bursting flywheels, for the benefit of the engineering public, by running some tests of this character upon flywheels four feet in diameter. To insure safety to the students and to the building of the Case School of Applied Science, these tests were conducted outdoors, in consequence of which they nearly proved disastrous to the neighbors. The flywheels were run in a casing of steel castings, located in a pit lined with brick. The flanges of the lower half rested on brick piers and were bolted in place. The entire upper half of the casing could be hoisted up, giving access to the interior for hoisting or removing the wheels. Two wheels were broken successfully, but the third one burst through its bounds and carried the casing with it many feet in the air. Fortunately every precaution for safety had been taken, all the observers being located far away from the plane of rotation of the wheel. These interesting experiments are to be continued, but hereafter the wheels are to be mounted on a vertical shaft and are to run in a pit in the ground, so that however great the violence with which the wheels go to pieces no possible harm can be done.

In carrying out these experiments the shaft supporting the wheel to be tested turns in bearings bolted to angle irons on the lower halves of the side plates, and was connected to the driving mechanism just inside the building by a flexible sleeve coupling. After the wheel was in place, the casing was lined with wooden blocks to absorb the momentum of the flying fragments. Instead of using a steam turbine as in former experiments, the flywheel shaft was speeded up by means of a Reeves variable speed countershaft, interposed between line-shaft and the driving-shaft.

The first wheel to be experimented on was a well-proportioned cast-iron pulley, such as is used on shafting for transmitting power. This pulley was 48 inches in diameter, had six arms and weighed 191 pounds. The rim was whole and was $8\frac{1}{2}$ inches wide and about $\frac{3}{8}$ inch thick, finished on

the outside. The arms were elliptical in section, 3⅛ inches by 1 1-16 inches at the hub, and 2 inches by ¾ inch at the rim. On the whole the wheel was well-designed and showed no signs of shrinkage strains. It had, however, been balanced in the customary manner by riveting a cast-iron washer inside the rim at the lighter side, and this proved its undoing. The combination of a thin place in the rim, a rivet hole and a heavy mass of cast-iron, is enough to wreck any wheel.

As has been shown by previous experiments on whole rim wheels of cast-iron, a bursting speed of 400 feet per second may be reasonably expected. The circumference of a four-foot wheel being about 12½ feet, such a wheel should burst at about 32 revolutions per second, or 1,920 revolutions per minute. The pulley in question burst at 1,100 revolutions per minute, as recorded by a tachometer connected to the driving-shaft. The balance weight weighed 3½ pounds, and its center was approximately 23 inches from the axis of rotation. At 1,100 revolutions per minute the centrifugal force of the balance weight alone would be 2,760 pounds. Add this radial pressure at a weak point between the arms to that due to the weight of the rim itself, and the low bursting speed is easily accounted for.

The linear speed of the rim at rupture was 230 feet per second. As 100 feet per second is considered the limit for belt speed, this pulley would have a working factor of safety of $(2.3)^2$ or 5.3. But suppose the rim had been a little thinner and consequently a bigger weight had been put on with a larger rivet?

Wheel No. 2 was a cast-iron pulley of the same general style and dimensions as No. 1, but with a split hub and rim. The balance-weight was present here as in the former case, but was obliged to yield the palm to its rival, the flanged joint. The wheel had been cast in one piece, as is usual in such cases, with cavities cored at the joints of rim and hub.

After finishing it had been broken apart by wedges, making a fracture joint. The flanges, being located midway between the arms and bolted at some little distance inside the rim, were in the worst possible position to withstand the bending action due to centrifugal force, and their own weight only aggravated the difficulty. The flanges weighed with their bolts 7½ pounds. This wheel burst at less than 700 revolutions per minute, the tachometer not recording below this speed. The writer believes the speed to have been about 600 revolutions per minute. At this speed the centrifugal force of the flanges on one side would have been 1,680 pounds. At 600 revolutions per minute the linear speed of rim would be only 125 feet per second. At the very common belt speed of 4,500 feet per minute the factor of safety would have but 2.8, which is altogether too low, considering the nature of the material and the shocks to which a pulley may be exposed.

There is one instance on record of the wrecking of an engine by the breaking of a generator pulley, which had a heavy balance weight inside the rim.

It was reserved for wheel No. 3 to develop the most dramatic series of incidents of any yet experimented upon, big or little. This wheel measured 49 inches in external diameter and weighed about 900 pounds. The rim was 6¾ inches wide and 1⅛ inches thick, and was built of ten segments, the material being cast-steel. Each joint was secured by three prisoners of an I-section on the outside face, by link prisoners on each edge, and by a dove-tailed bronze clamp on the inside, fitting over lugs on the rim. The arms were of phosphor bronze, twenty in number, ten on each side and were a cross in section. These arms came midway between the rim joints and were bolted to plane faces on the polygonal hub. The rim was further reinforced by a system of diagonal bracing, each section of the rim being supported at five points on each side, in such a way as to relieve it almost entirely from bending. The braces, like the arms, were of phosphor bronze, and all bolts and connecting links of steel.

This wheel was designed by a Baltimore firm as a model of a proposed 30-foot flywheel.

On account of the excessive air resistance it was found necessary to enclose the wheel at the sides between sheet-metal disks, before any great speed could be attained. Even then repeated trials failed to reach a speed of more than 800 or 900 revolutions per minute on account of the great inertia of the wheel, and the consequent slipping of belts. But putting on more and wider belts, by a liberal use of "Cling-Surface" and with the aid of a 7½ horse power electric motor belted on in parallel, it was found possible to get a speed of 1,650 revolutions per minute, and after the wheel had been run at this speed it was stopped and examined.

The inspection showed fracture of several of the I-shaped prisoners on the outer surface of the joints and a slight opening of the joints themselves, to the extent of perhaps one or two hundredths of an inch. On June 2, 1903, the casing was closed for the last time, and the combination of driving mechanisms set to work. The observers were all well protected by the thick piers of the building, while other spectators were kept at a safe distance and well away from the plane of rotation. Two of the observers watched the pointer of the tachometer through opera glasses, another kept the time, while a fourth manipulated the driving levers.

As the hand of the speed counter reached and slowly passed the 1,600 mark, the feeling of suspense on the part of those watching reached the acute stage. The pointer crept slowly on and as it quivered on the mark of 1,775, there was a sudden crash, a sound of rending and tearing, and the writer saw the countershaft inside writhing on the floor like a wounded snake. On stepping outside he was saluted by a shower of falling splinters and fine debris, and was surprised—putting it mildly—to note the disappearance of the greater part of casing and wheel.

The steel rim of the casing was broken off short, six inches below one of the flanges, and the entire upper half weighing half a ton was projected about 75 feet into the air and landed some hundred feet away on the campus. On its way up it carried away part of the cornice of the building, and this collision was probably what caused it to deviate so much from a vertical path. The hub and main spokes of the wheel remained nearly in situ, but parts of the rim were found two hundred feet away, while one large fragment landed on the roof of the building.

This sudden failure of the rim casing was unexpected, as it was thought the flange bolts were the parts to give way first. The tensile strength of the rim at the point of fracture was about 1,200,000 pounds, or about four times the strength of the wheel rim at a solid section. Examination of the break in the casing showed a clean, bright fracture, with almost no imperfections.

The failure of the wheel itself was due to a gradual opening of the joints, occasioned by the fracture of the outside prisoners, and to flaws in the bronze castings of the arms near their junction with the rim. On putting the pieces of the wheel together in their original order it was easy to locate the joint which first gave way, on account of the symmetry of the breaks either side of a diameter through this point. It is but fair to the builders of the wheel to say that the fractures showed uniformity of strength and of workmanship, since there was hardly a member or a joint which did not fail in one part or another of the wheel.

One thousand seven hundred and seventy-five revolutions per minute means a linear speed of rim 22,300 feet per minute, or 372 feet per second. This is not as great as the probable speed of a solid cast-iron rim of good design, but it is greater than the speed of any sectional or jointed rim which has been tested. The tensile stress due to the centrifugal force at this speed is 13,800 pounds per square inch. This shows that the joints were much weaker than the solid rim. On the whole, the test of this particular wheel was disappointing, since its strength was not sufficient to repay one for the expense of the design.

It is interesting to compare the kinetic energy of the rim of the wheel at the recorded speed with the work of destruction. Assuming the rim with its lugs, flanges, etc., to weigh 300 pounds, which is a reasonable estimate, the kinetic energy at a speed of 372 feet per second would be 645,000 foot pounds. Further assuming that none of the energy was dissipated in heat, and that the combined mass of wheel and casing projected into the air weighed 1,500 pounds, we find the height of projection to be 430 feet. It is good cause for congratulation that four-fifths of the energy *was* dissipated.

STAYBOLTS, BRACES AND FLAT SURFACES.

December, 1904, Meeting A. S. M. E.

In a paper upon staybolts, braces, and flat surfaces, Mr. R. S. Hale compares the various rules for working stresses in staybolts, pointing out that in short bolts a bending action occurs which is more destructive than in the longer bolts. He also compares various rules for the strength of flat surfaces, and gives a table containing figures upon cases where bulges in boiler plate have occurred between staybolts. His general conclusions are as follows:

Stress on Stays.

Comparison of the various rules for working stress on stays and braces shows a general neglect of the difference between long and short stays. For the long steel stays, subtracting ⅛ inch from the diameter, and then allowing 12,000 pounds per square inch on net section, remaining gives results which apparently will be better than any of the present rules. For iron stays probably 10,000 should be used. For short stays, which are chiefly iron, where bending action comes in, empiric rules reducing stress as length of stay decreases may be used. Our knowledge of the bending stress is not sufficient to warrant the use of a more theoretic formula

Pitch of Stays and Thickness of Plates.

Comparison of the working pressures for pitch of stays and thickness of flat plates shows that the complicated formulas of some of the rules do not give as good results as the simpler formula $P = C \frac{t^2}{p^2}$, C being taken as 100 to 115 for riveted stays, 140 for stays nutted or crowfoot stays riveted on, and a higher value up to 200 or 250 for the use of washers or channels or angle bars riveted on; P = steam pressure; p = pitch of staybolts in inches; and t = thickness of plate.

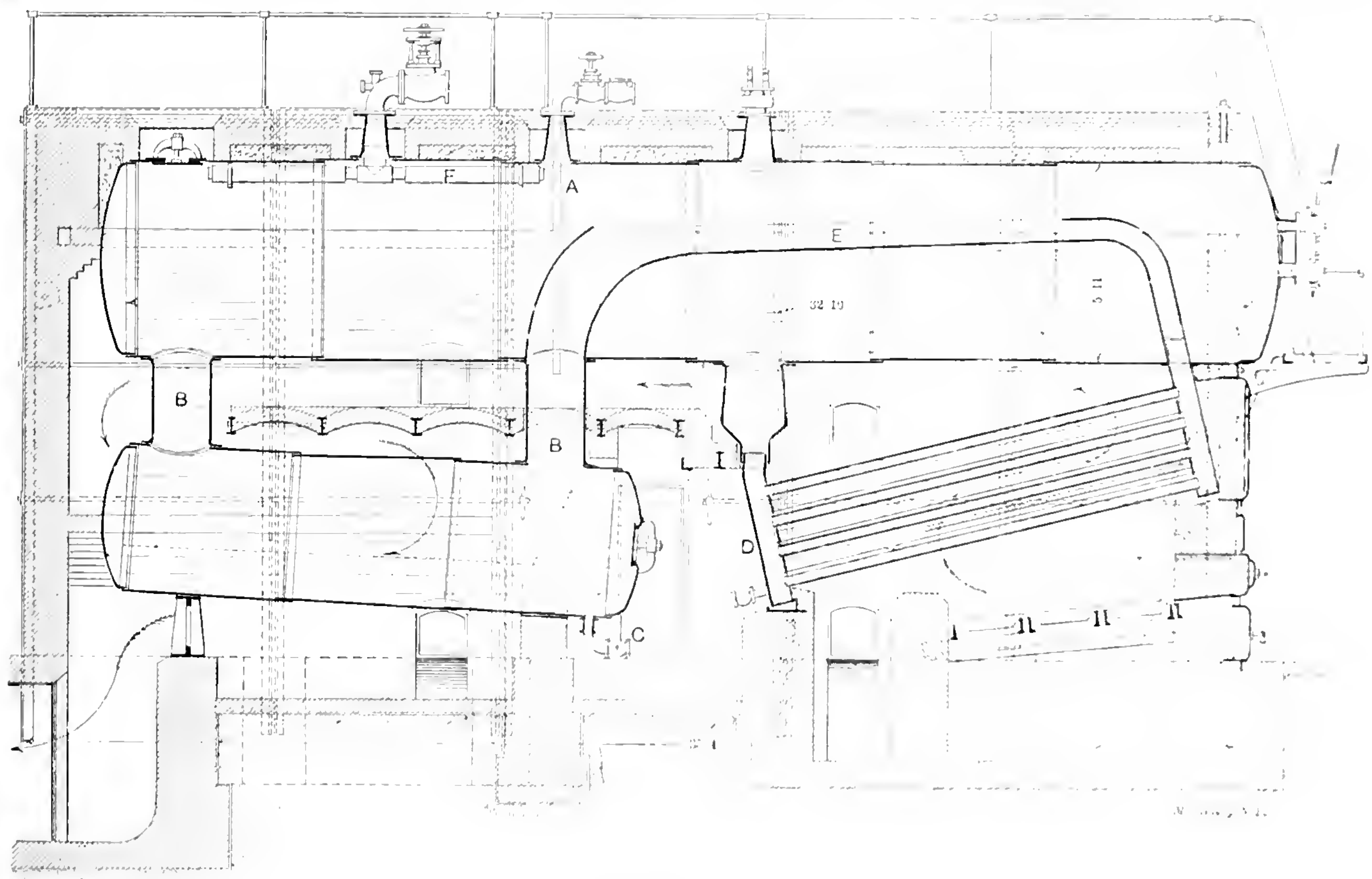
If the pitches differ by less than 20 per cent use the surface instead of p^2. If the pitches differ by more than 20 per cent it is a special case. Special cases and unusual construction must always receive special consideration.

The above constants give results indicating the probable safe pressure for a year or so, until the next examination. In designing a boiler for a long life the constants should be reduced by some 20 per cent or so, just as a factor of safety of 4 can sometimes be used temporarily for the shell of a new boiler, while 5 should be used in designing a [illegible] to be run for a number of years without reduction of pre[illegible].

LARGE WATER-SPACE WATER-TUBE BOILER.

Der Praktische Maschinen Konstructeur, July 7, 1904, p. 106.

This boiler, which is exploited by the Rhenish Steam Boiler and Machine Works, has a claim of extra high efficiency of evaporation given it by its builders. The accompanying illustration shows that it is a compound of water-tube and cylindrical types with a special circulating apparatus. The water tube section is at the front and closely resembles the Babcock & Wilcox type. At the rear of the rather long shell there is a mud drum placed beneath and in the passage of the gases as they come from the furnace. This mud drum is connected to the upper shell at two places and at the forward end it leads into a trough extending along the upper surface of the water to which the front header of the water-tube section also leads. This is intended to facilitate circulation. The course of the gases of combustion is up through the water-tubes, thence back beneath the water drum to the rear where they turn forward to pass over the top of the mud drum to finally turn back beneath the latter and escape at the flue



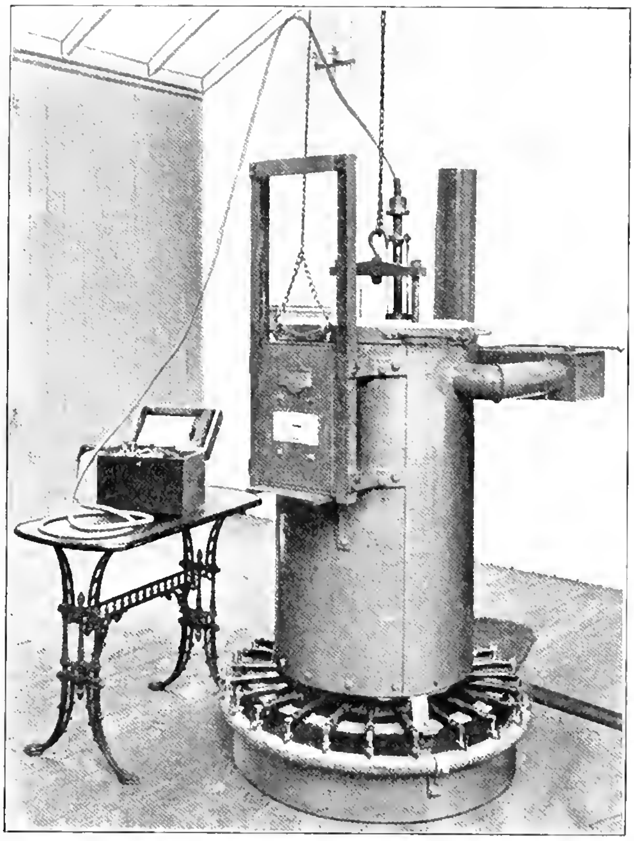
Large Water Space Water-tube Boiler

The circulation of the water is as follows: The feed is introduced through the top of the upper shell by means of the pipe A, which leads down to near the bottom of the same and over the forward connection of the mud drum. The water, on leaving this feed pipe, sinks down through the connection into the mud drum, where the blow-off cock C is located, and there it flows back to the rear end of the drum. Having become somewhat heated by the spent gases in the flue it rises through the connection B into the upper drum, where it is still further heated. In this condition it flows down through the connection into the back header of the water-tube section D, and streams from there out through the nest of tubes. Here it is partially evaporated and the mixture of steam and water issues from the front header through a connection, as shown, into the trough E, where they are separated. The water again drops down through the connection B' into the mud drum while the steam is stored above the water level. When the throttle is opened and the steam is drawn off, the trough F serves as a sort of steam separator. G. L. F.

A NEW HARDENING FURNACE.

A hardening furnace with a number of features of interest has been in operation at the New York offices of Geo. Nash & Co., dealers in iron and steel. It is a furnace made under the Brayshaw patents, the United States rights for which have been secured by this company, who are now in a position to place the furnace on the American market.

The contention made by the inventor is that the treatment of tool steel cannot be accurately regulated in an open furnace. In order to know what is being done it is necessary to immerse the steel in a liquid the temperature of which can be accurately determined. Mr. Brayshaw has experimented extensively with lead, but he considers a salt bath to be superior, and has patented a composition for such a bath. The operation of the furnace is based upon the well-known laws of the heating and cooling of steel, which are in no way a secret, but on the contrary well understood by metallurgists. If, for example, a piece of tool steel is gradually heated, the



Hardening Furnace and Pyrometer.

heat being supplied at a uniform rate, a point will be reached called the absorption point, at say 725 degrees C, or thereabouts, where the rise of temperature will be more gradual for a few minutes. After that point is passed the rise will then continue at about the same rate as before. In cooling, the temperature will drop regularly until the point of recalescence is reached, when the temperature for a few minutes, will not only cease to drop but will actually rise a slight amount. After passing this point, however, the drop in temperature will gradually resume its former rate. A peculiar fact is that this point of recalescence is lower by several degrees than the absorption point. In the specific case mentioned above it is about 700 degrees C, instead of 725. Mr. Brayshaw finds that it is impossible to harden steel at any point below the absorption point. For good hardening the temperature must be raised so that the absorption of heat is complete; but when this has been done the temperature may be lowered very considerably, so long as recalescence does not begin. In the case mentioned above, if the steam is first heated to above 725 degrees C, and then is allowed to cool down to nearly, but not quite, 700 degrees, it will still harden perfectly. He also finds that by adopting this method of heating carefully to a point above the absorption point, and then lowering the temperature, it is possible to harden steel at a very low point.

The object in designing the furnace was to take advantage of the above principle. A crucible is hung inside of the furnace for holding the liquid bath. The gas flames, coming from the Bunsen burners beneath pass up and around the crucible and heat it, and also the bath and the inner lining of the furnace, to a temperature determined accurately by a pyrometer, which is always in the bath. The pyrometer is read by means of a Whipple temperature indicator which operates on the principle of Wheatstone's bridge. The perforated metal tray can be raised and lowered inside the furnace, and pieces of the work placed inside the tray can thus be dipped into the bath or raised out of it without subjecting them to any change in temperature since the walls of the furnace are substantially at the temperature of the bath. Obviously, since it has been desirable to work between such narrow limits of temperature the heat of the furnace must be regulated carefully and this is done by watching the recording instrument and by adjustment of the main supply pipes for the Bunsen burners. In case of complicated cutters and other tools they can be heated up gradually in another furnace, if desired, before dipping in the bath, so the thin parts of such cutters will not be suddenly heated up to a high point before the heavy parts are heated. When placed in the bath the temperature is allowed to rise to what is known to be the correct point, assuming that any particular brand of tool steel is fairly uniform in character, and then the temperature is allowed to drop until the point is reached where the work is to be removed and plunged in the cooling bath. It is claimed that most complicated work can be hardened with little or no trouble by this means, and that results are very uniform.

THREAD DRAWN FROM MELTED QUARTZ.

The investigations of physicists generally require apparatus of the greatest possible refinement, and oftentimes it must be developed to a degree of sensitiveness hitherto unknown. Some years ago it was found imperative to discover a fiber for the suspension of certain parts of a bolometric apparatus used in the determination of the amount of heat received from the stars, that should possess properties found in no material then available. The fiber or thread required was to be used in supporting part of the apparatus subjected to very minute torsional force. Fibers of silk or steel or any known substance did not fill the requirements, inasmuch as they are unstable and do not possess the absolute perfect springy qualities necessary to return the needle to zero every time it is displaced. Moreover, it was necessary to find a fiber of the utmost tenuity which possessed the required qualities. Professor Boys experimented and discovered that melted quartz could be drawn into fibers of extreme tenuity, having an almost perfect torsional elasticity, if the operation could be done quickly. This requirement was satisfied by spinning the molten quartz from the pot by attaching it to an arrow which was propelled from a pine bow. Thus apparently one of the most unpromising substances for the support of delicate deflecting apparatus proved to be an almost ideal material. Lately it has been discovered that soapstone when highly heated can also be drawn into fine fibers possessing all the qualities of elasticity and resistance to chemical action characterizing the quartz fibers.

WALTER KIMBALL, OF RICHMOND, VA.

Last month an individual writing under the name of Walter Kimball, from Richmond, Va., with a letter-heading giving his business in machinery and tools, inserted an advertisement in this paper offering a number of standard machines at absurdly low prices, which caused considerable inquiry among the trade; several orders having been sent, and in one case a remittance made to cover the purchase. None of these orders was filled, and careful search in the city of Richmond failed to discover any person of that name in the machinery trade in that city. Further investigation shows that on November 26, last, he rented a room in a private residence at 315 E. Main Street, Richmond, where he roomed until the 14th of December, when he left without notice to the lady of the house, or giving any information concerning his whereabouts.

JIG AND MILLING FIXTURES WITH OPERATION SHEET.

B. P. FORTIN.

The accompanying drawings show jig and milling fixtures, and the operation sheet, Figs. 1 and 2, is also included as being of interest in connection therewith.

In my article of August, 1904, I described some of the obstacles to be met with in jig designing. Now some of these same difficulties are encountered in milling fixture construction—in fact, all of them except the need for lightness of fixture. First, as with drill jigs, they must be so designed as to be easily cleaned of chips, and to prevent possibility of work being put in in the wrong way. Another very important thing is the springing of work. Rough castings give the greatest trouble, and it often requires considerable thinking to design a fixture to clamp a delicate casting without springing it. Milling fixtures should have ample stock in the right place, to insure stiffness and a smooth cut. The cutter used should be as small as possible and close to the spindle, unless supported by the overhanging arm.

The operations for the job were gotten out in this manner: The name of casting to be operated on is called "gear rack take-up," and this name was printed on the outside of a double sheet of paper, 9 inches by 6 inches, Fig. 1. The name can be written or printed, but the best plan is to have the sheets typewritten on bond paper, and the prints taken from them. The sheets can then be placed in some commercial cover; one that is arranged so the sheets can easily be changed whenever a change is made is the best. Each cut or hole has a name. On the inside of the sheet, on the left hand side, Fig. 2, are the names of different cuts and holes, and on the right-hand side, opposite each operation, are the names of the jigs or fixtures and the tools used; also the kind of machine that they should be used on. The extreme right gives the sheet number of drawing and stock tools.

The drawing room and the manufacturing department each have a set of these sheets. Whenever a new job is started, by consulting the operation sheet, it is easily found whether the particular machine wanted for the job is in use. After finding this out, we next look at the operation to see what tools are wanted, and in making our wants known to the toolroom keeper, all the tools pertaining to this job are handed out. Each jig or fixture, with its tools, is kept in separate bins and is easily found.

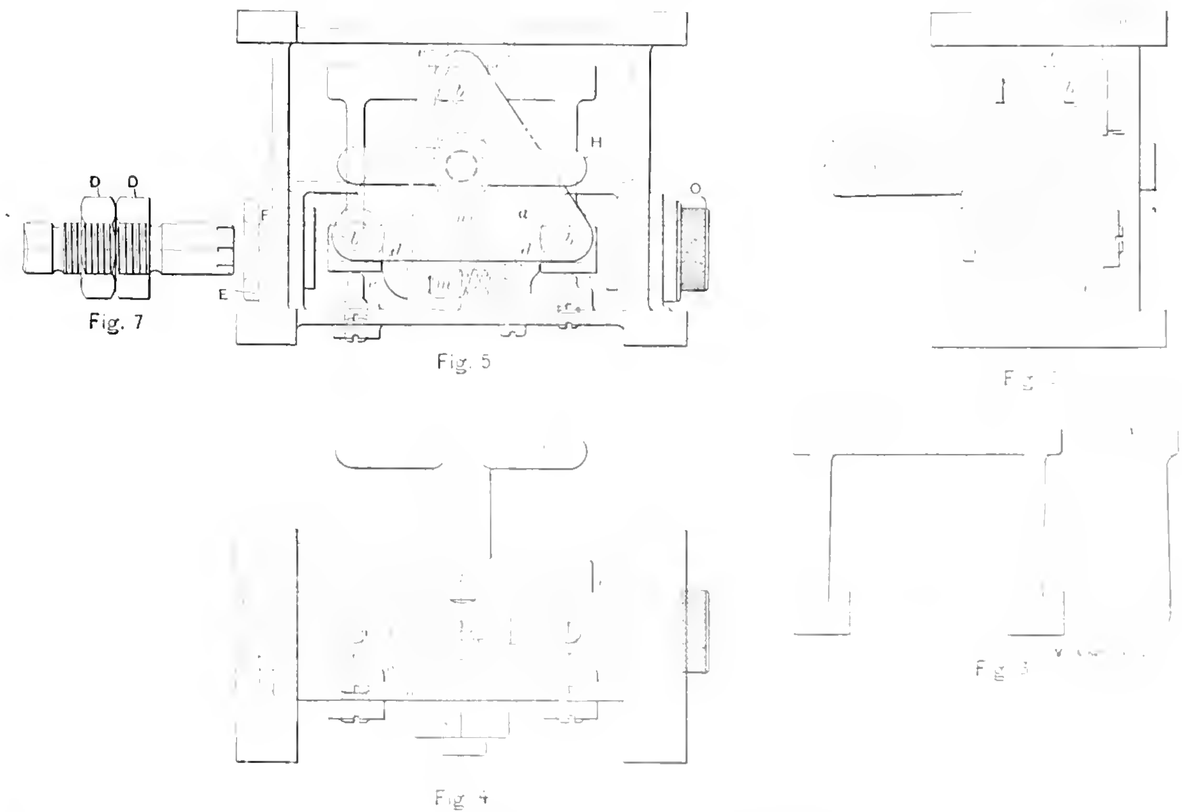
Fig. 2. Operation Sheet



Jig with Equalizing Clamping Device for Rough Castings

In this particular case the drilling was found to be the most convenient operation to perform first. Fig 3 shows the casting with a ¼-inch reamed hole through opposite hubs, and milled at the points indicated by f. Figs. 4, 5 and 6 show side, plan and end views of the jig with the work therein. The casting rests on the rigid gage point b and two adjustable points b^1 b^1, and is pushed against the two adjustable gage points c c, Fig. 5, by the spring c; d is a rigid gage point sideways, which takes the thrust of drilling, and the end mill. d^1 is a spring pin which pulls the work against the rigid point d, and it also takes the thrust of drilling and end milling. The clamp a has three pins h, h^1 h^1 which are in line with gage points b b^1 b^1, for clamping points. Stud j extends through the bottom of jig into the strap k, which takes the pull of the hand nut l. Strap k rests on a solid seat, on one end, and the other end rests on the pin m, which is in direct line with the spring pin d^1. The upper end of m has a slight angle to prevent the slipping of d^1. Therefore, by screwing down the hand nut l the force is transmitted through strap k to pin m, and thus clamps the work and the spring pin d^1 simultaneously. O is a slip bushing, which is also used on the opposite side; n is a pin extending through a to prevent the turning of the clamp when screwing the hand nut l; Fig. 7 is the end mill for facing the hubs; and D D are adjustable nuts used as a stop against O. As the distance from one finished surface of hub to the other had 0.01 inch limit we had no trouble in getting them inside of that figure.

The milling fixture is shown in views Figs. 8, 9 and 10. This fixture is designed for two positions at right angles, or in other words, there are two separate operations to be performed, one from each base A and B, Fig. 10. The reason for this is that when the fixture is set up on machine platen, on base A (as will be seen in operation) a gang mill is used which furnishes surface a and b, Fig. 3, and roughs out the slot for the dovetail. Now, if this operation were performed in the other position B (B is the base the fixture stands on when finishing dovetail slot) it would be necessary to make these cuts do the same amount of work that is done with the gang mill in one; therefore it is readily seen that it makes considerable difference in cost of piece what kind of cutters are used. The casting is located from the shaft hole by the stud C and spring pin D. The idea of a spring is that it has a certain pressure not great enough to spring the casting, but sufficient to push the pin into the hole and the work against the shoulder on C. The casting rests on rigid gage point E which has the same relative position to fixture as d, Fig. 5, has to jig. The center clamp F forces the work against the rigid gage point E; the two end clamps G and H are made to float and locate to casting and are locked in place by J and K. M is a gage for setting the cutter. The numbers on the screws indicate the order in which they are to be screwed up. Fig. 11 is the bevel cutter for finish-milling dovetail slot or rack seat.

MAKING DROP FORGING DIES.

C. W. SHELLY.

Young machinists, who have never seen drop forgings made, may be interested in the following general description of the work:

The dies are made of .45 to .60 carbon steel, and are, usually, from 5 to 8 inches thick. Fig. 1 gives a general idea of their appearance when finished. They are marked T and B (top and bottom) to prevent their getting mixed up in the laying out. The front and left-hand sides are squared up, and from these sides the center lines of the impressions are laid out and the dies set up when ready for use. The edger, or breaking down impression, is on the right-hand side of the die. It is for breaking down the rough heated stock into something like the shape required, before it goes into the finishing die. Sometimes a separate breaking-down die is used. The heaviest part of the forging is always nearest the front. In deep dies, shapes which show parallel sides on the drawing, are given from 5 to 7 degrees taper on each side, to prevent the forging from sticking in the die. For machining the forging 1-32 inch is usually allowed, and for shrinkage, .012 to .015 per inch. When the dies are finished a

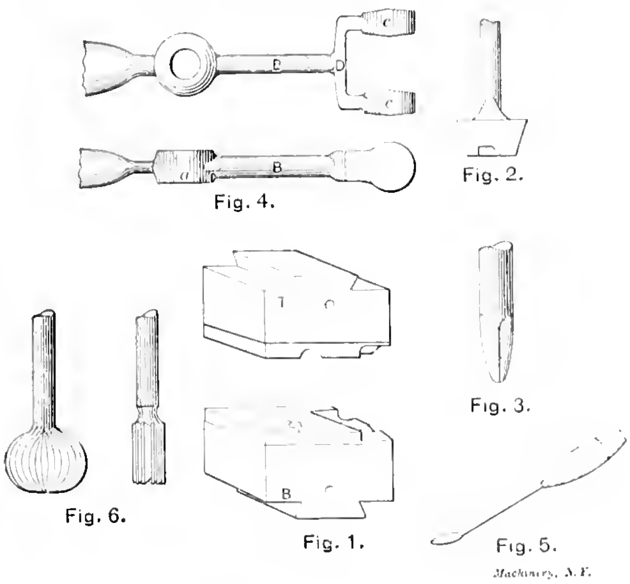
Milling Fixture for Rough Castings.

C. W. SHELLY was born at Berlin, Ontario, Canada, 1879, and received a Canadian high school education. He served an apprenticeship with the Canadian General Electric Co. at Peterboro, Ont., and has since worked for the General Electric Co., in Lynn, Mass.; the Richmond Electric Co., the Stanley Electric Co., the Hope Mfg. Co., J. H. Williams & Co., etc. He is a tool, die and jig maker, and is now working as a die-sinker on ornamental work.

specimen casting of lead is made in them for ascertaining whether or not they will give the desired result.

The round portion of the impression is sunk first. Swinging the die blank in a lathe, when there is much stock to remove, is a convenient method. In J. H. Williams & Co.'s drop forge shop a cast-iron bolster, for the lathe faceplate, is used. This bolster has a web on its back, which fits the slot in the faceplate. The face of the bolster has a dovetail slot, which is identical with those in the hammer, and is at right angles to the web on the back. By this means a circle is quickly trued up. When the round portion is under $1\frac{1}{2}$ inches in diameter, a profiling machine is better adapted for the work, using the half-round cutter shown in Fig. 2 to finish with, after roughing the stock out with a two-lipped cutter similar to Fig. 3. The half-round cutter is very useful, being strong, easily made, and is easily ground by hand. The one illustrated in Fig. 2 leaves a point in the center of the impression, for spotting the center of the boss on the forging. A die for forging a ball is sunk with a two-lipped spherical cutter. If there is to be a large hole drilled in the forging a plug is left, when sinking, or is afterward inserted in the die to lighten the forging at that point, as is shown at *a*, Fig. 4. This plug should have a taper of 15 degrees on each side, and the top well rounded. In making the dies for forging the piece illustrated in Fig. 4, the round portion, *B*, can be machined out after the part, *D*, is sunk. This may be done with a spherical cutter. In one shop in which I worked a patented attachment for the die-sinker is used, by means of which a cutter can be sunk to its center in the work. The cutter is held in the fixture on a short arbor between half-round centers, around which the cutter is rotated by means of a rawhide gear. The teeth of gear engage the back of the teeth of the cutter. This is only used for finishing. Parts *c c*, in Fig. 4, could be done with this device. It saves time, makes an accurate, clean job and does work that would have to be typed out, *i. e.*, sunk by hand. Some circular impressions are sunk in the milling machine, using one long half-center, and a forming cutter with a small shank, a groove being first cut to clear the shank. The parts *c c*, Fig. 4, would have to be typed in most shops. A type is a hardened steel template, of the size and form that the impression is to be, with the top left soft to prevent the steel from flying when struck with a hammer. Portions of the die that cannot be machined, owing to their irregular shape, or the lack of shop facilities, must be sunk by hand. This requires especial skill with the hammer and chisel, scrapers and gravers, as well as a good eye for judging form. The chisels must be ground to the proper angle on the cutting edge, for chipping the curved surfaces and awkward corners. Scrapers may be made of various shapes, to suit the requirements of the work. One of the most useful is the three-cornered scraper, with two edges rounded; the third, being the cutting edge, is left sharp and is curved toward the point. Another handy one is shown in Fig. 5. It is leaf, or heart-shaped, and is convenient for getting at small curves and corners, especially those at the bottom of the impression. The type is covered with a thin coating of Prussian blue or red lead, and driven into the die from time to time, as the work progresses, and the high places worked down until the correct form is produced. For the fillets and small corners, a graver or scraper is made from Stubb's steel drill rod, of the desired radius. To save room in the tool-box, a 3-16 or ¼-inch rod may be threaded on one end, and these scrapers fitted to it. A hole is drilled in the cutting end to save time in grinding. The scrapers leave small ridges in the work, which are filed out with riffles, or bent files. Some impressions are polished with a soft pine block and powdered emery, but this is not the usual practice. When the impressions are worked out to the lines a lead casting is taken to see where they need matching or evening up. The lead is tested for size, and if all right, a half-lead is taken from the top die, to be used as a template in laying out the trimming dies, that is, in shops where sheet metal templates are not used. If the lead is overheated, or is heated too often, it will not flow freely and chills before the impression is filled. Powdering the impression with chalk causes the lead to flow freer.



Making Drop Forging Dies.

The edger, or breaking down form, on the right of the die, is made from 1-16 to 3-16 inch smaller than the horizontal cross section of the forging, and has no abrupt shoulders or curves. The idea is to get the heated stock smaller in width than the finishing impression, so that the bottom of the impression strikes the stock first, and spreads it to the sides, filling the die. Cast-iron dies are also used for breaking down heavy work.

The flash, which is a recess .015 to .025 inch in depth, and about ⅞ inch wide, milled around the outline of each impression, allows the surplus stock to escape from the die. This surplus is afterward trimmed off in the trimming dies. The top die, also, has a groove about 1-16 inch in depth, milled around the impression, ¼ inch from the edge. The gate for clearing the stock tapers gradually toward the front from the impression so as not to weaken the die at that point.

In dies for making small forgings in large quantities there are several impressions sunk, one of which is used for a rougher, and should be about 1-32 inch narrower and deeper than the finishing impression. Some dies have to be interlocked when difficult shapes are to be forged, that is, the faces have to be shaped to suit the offset in the forging. Care must be taken to have the interlocking parts high enough so that the dies will not glance off when striking the stock, and making an imperfect forging. When the face of the dies is curved special cutters are made, similar to those in Fig. 6, for surfacing and flashing. As a guide for machining curved impressions, some mechanics transfer the lines to the side of the die blank and lay out the curve there, then clamp a surface gage to the profiling machine, and with the needle set to the face of the cutter, work out the stock by following the lines with the needle point. Dies for forging gears, or similar work, are finished with a broach having the teeth machined in it, which is then driven into the die.

Drop forge die-sinking, on the average, pays better than toolmaking or machinist's work. It requires, I think, more manual skill and, often also, more "jackass" power, but not such a general mechanical knowledge as is necessary in tool making. If one becomes expert in sinking dies for drop forgings, and has a taste for the artistic, he can easily work himself into ornamental die-sinking and steel engraving. To follow this up, and become expert at it, requires time and patience, but it holds out the prospect of better wages and better conditions than ordinary tool work.

* * *

A dispatch from Boston says that two fifteen-year-old boys of that city have established a wireless telegraph connection between their homes half a mile apart. This recalls the fact that thirty days after the appearance of the first published accounts of Bell's invention of the telephone, two New York boys had built and were successfully operating an experimental telephone system of their own. These two boys have since achieved distinction in the electrical field, and have for many years been allied in business. They are Prof. Frank B. Crocker, of Columbia University, and Dr. Schuyler Skaats Wheeler.

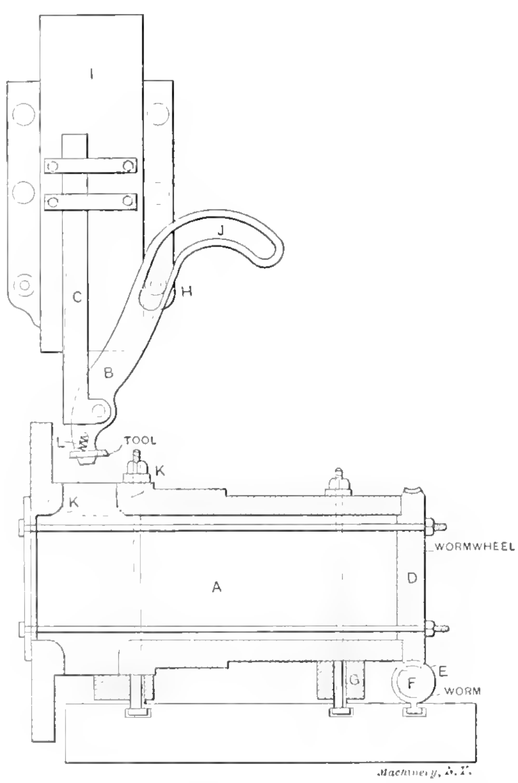
LETTERS UPON PRACTICAL SUBJECTS.

RADIAL SLOTTING ATTACHMENT.

Editor MACHINERY:

I send you a sketch of a radial attachment for a slotting machine that I made for cutting the arcs marked *K* in the breech bushings of the 15-inch coast defence "dynamite" guns made by the Dickson Mfg. Co., Scranton, Pa., for the government. The first bushings were made of bronze and in these the arcs were cast in, but after trying the guns it was found the metal in the bushings would not stand the test, and they were replaced by the best gun steel. In these the openings were cored straight through, as shown by dotted lines. When the bushes were turned and faced it was found the parts *K* could not be chipped or cut to the required radius by any means at hand in the shop. I then devised the attachment here shown.

A is the bushing, *K* is the part to be cut to a radius of about 2 inches, the openings being about 5 inches by 2½ inches wide. Both ends of the slots had to be cut as shown, and there were about ten slots in the circle. *G* shows wooden blocks made to fit the outside diameter, with a piece of sheet iron tacked on the inside so the bushing would turn freely when screwed down with the clamps. *D* is a wormwheel made fast to the back end of the bushings, and a bracket marked *F* is screwed on the table to hold the worm in place. The worm *E* was turned by means of a hand wheel, not shown, to give the circular motion



Radial Slotting Attachment, Working on Dynamite Gun Bushings.

while the cut was fed in by the screw in the table. The bar *C* was forged from machine steel about 2 inches square and was milled out at the bottom to fit the radial bar *B*; it was also cut out as shown by the dotted lines above, so the bar would fold into it when at the bottom of the stroke. The slot *J* is formed so as to give the proper radius to the cutting tool when rounding *K*. The bar *B* was made about ⅞ inch thick by 3 inches wide and the cutter was ⅝ inch by 7-16 inch with a 5-16 inch pivot pin. The slot in the bar was made so that the tool could relieve itself coming back by compressing spring *L*, which forced it again into position. *H* is a stud with a roller, nut and washer put in place of one of the bolts in the head of the machine; when the holes on one side were finished, all that had to be done was to change the stud to the other side, turn the attachment over and proceed as before.

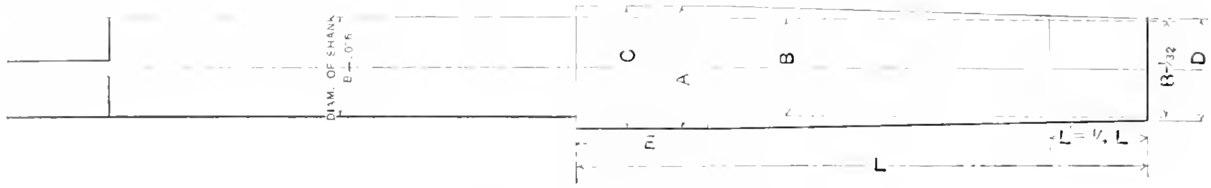


Diagram of Acme Tap illustrating Factors used in Table.

I think that the description and sketch will make the scheme plain and simple to every mechanic, but would add that, of course, a right and left tool was used to cut out the corners.

Plainfield, N. J. D. LINDSAY.

ACME TAPS IN SETS.

Editor MACHINERY:

The table given herewith, on Acme taps in sets, is one which I think will be very much appreciated by many of your subscribers. The formulas, I believe, are correct both as regards theory and practice. I have tried several sets of Acme taps made as per these instructions, and they have given me more satisfaction than any other set of Acme thread taps I have ever tried.

No. of Taps in Set.	Tap.	*C*	*D*	*E*
2	1st	$B + (A - B)\ .65$	$B + .01$	.125 *L*
	2d	A	*C* on 1st tap − .003	.25 *L*
3	1st	$B + (A - B)\ .45$	$B + .01$	.125 *L*
	2d	$B + (A - B)\ .8$	*C* on 1st tap − .003	.17 *L*
	3d	A	*C* on 2d tap − .003	.25 *L*
4	1st	$B + (A - B).4$	$B + .01$	.125 *L*
	2d	$B + (A - B)\ .7$	*C* on 1st tap − .003	.17 *L*
	3d	$B + (A - B)\ .9$	*C* on 2d tap − .003	.20 *L*
	4th	A	*C* on 3d tap − .003	.25 *L*
5	1st	$B + (A - B)\ .37$	$B + .01$	.125 *L*
	2d	$B + (A - B)\ .63$	*C* on 1st tap − .003	.125 *L*
	3d	$B + (A - B)\ .82$	*C* on 2d tap − .003	.17 *L*
	4th	$B + (A - B)\ 94$	*C* on 3d tap − .003	.20 *L*
	5th	A	*C* on 4th tap − .003	.25 *L*

Table giving Proportions of Acme Taps in Sets.

Referring to the cut, the length *L* is indeterminate, as it is governed by four factors, which vary according to the work, viz.: diameter of tap, pitch, length of nut to be threaded, and the material to be tapped. But whatever length of *L* is chosen, if made according to the formulas given, every tap in the set will have the same proportion of work to do as the others; the user will have a well divided set of taps no matter how long or how short the length is made.

A = actual diameter = nominal diameter + 0.02 inch.

$$B = \text{root diameter} = \text{nominal diameter} - \left(\frac{1}{\text{no. of threads}} + 0.02 \text{ inch}\right).$$

The values of *C*, *D*, and *E* are given in the table. The length of *L'* is ¼ *L*, and this refers to the first tap only. The end of the first tap is reduced in diameter, as indicated by the dotted lines, so that it will catch the thread without reaming, which

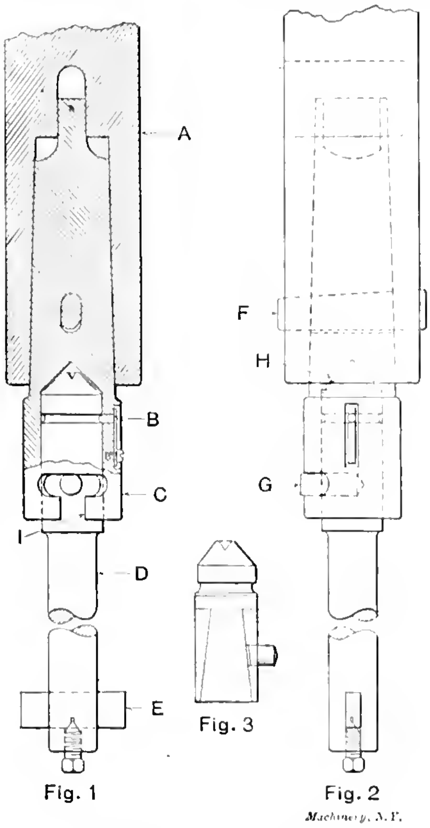
is always the trouble otherwise. With the other taps of the set, of course, this is unnecessary, as the first tap makes the thread deep enough for the following or second thread to catch the lead. In other words, the first tap of the set is made taper in the grooves at the root of the thread for a length of about ¼ *L* to prevent reaming and make it catch the lead easier than would otherwise be the case. A. L. VALENTINE.

Hartford, Conn.

FACING BAR HOLDER.

Editor MACHINERY:

The facing bar holder shown herewith is one of my own design and I believe is new. I find it very good for certain work. The work that I designed the tool for is back-facing boring mill housings, which have to be drilled bottom side up. Its advantage over the ordinary bar with retaining key slot is that the straight bar, *D*, is much cheaper to make, and much easier to change. On a job which requires a variety of bars to face different size holes, considerable time is saved in not having to knock out the retaining key, *F*. Instead bar *D* is disconnected by turning it backward a short distance and



Facing Bar Holder for Drill Press.

slipping it endwise. Again it has the advantage that in case the bar is broken and another one has to be made, the drill press does not have to stand idle while the toolmaker is fitting a new bar in the socket and to the key *F*. The reason for the bar *D* being pointed at the upper end at *H* is to lessen the cost of making; an ordinary drill can be used to drill the socket, and the recess does not have to be squared out in the bottom with the taper end on the bar. The spring and plunger *B* is merely to hold the bar up in place in case the driver pin *G* should become turned backward, so as to be over the center of slot *I*, as sometimes happens when the drill press spindle is reversed.

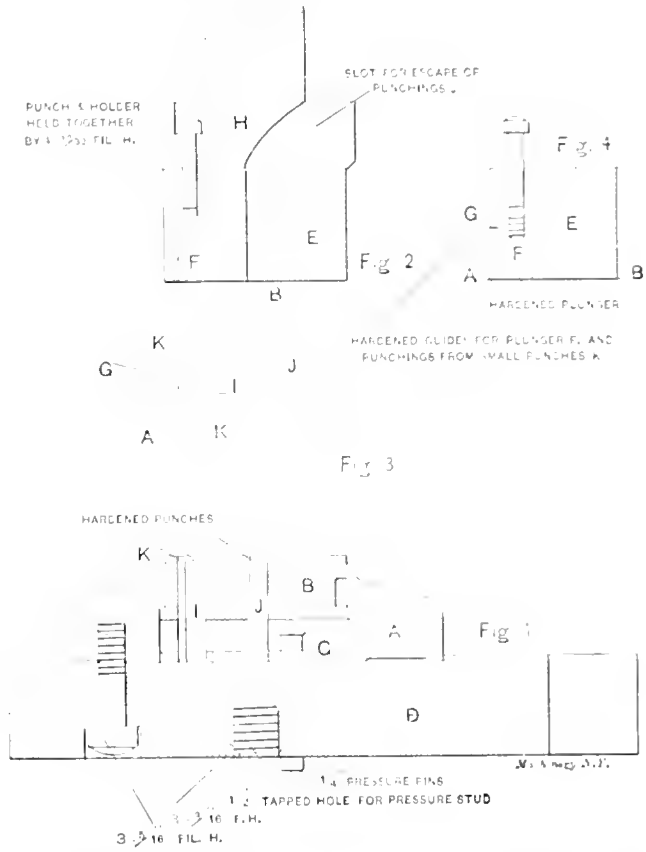
The device is made still more effective for drilling and back-facing holes, say 1½ to 2 inches in diameter, by using straight shank drills with the shanks finished in the same manner as the boring-bar holder. These drills can be exchanged with the boring bars without removing the taper collet. Or in case that is not desirable, collets like that shown in Fig. 3 may be made and used with the drill, the drill and collet being disengaged together. All parts are made of machine steel except the driver pin, *G*, which is made of drill rod hardened and temper drawn to a pale blue. B. M. WELLER.

Franklin, Pa.

PUNCHING DIE FOR MAKING LABELS.

Editor MACHINERY:

Being obliged to get up a set of tools for the cheap manufacture of labels, Fig. 5, I built the following illustrated compound punch and die, one of the requirements having been the use of a single-action press and the production of the piece, Fig. 5, in one operation. As will be seen in Fig. 5 it was necessary to cut the blank, pierce three holes and split the stock between two of the smaller holes on a 5-32-inch radius



Punching Die for Making Pasteboard Labels in Single-action Press

to allow the enclosed material to be deflected for the insertion of an endless loop. The flap was then bent back into place and secured by a small gummed label pasted over the juncture.

Fig. 1 shows the die, the first part to finish being the cutting ring, *A*. The corrugated cutting edge was made by dividing the circumference into an equal number of parts and drilling every other one, the remaining stock being filed up, with

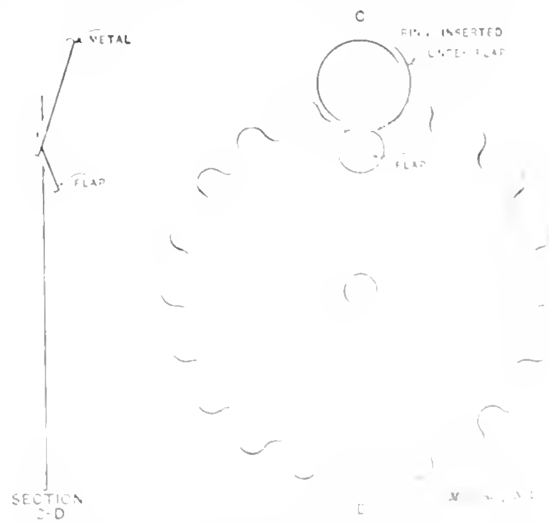


Fig. 5. Label showing Method of Attaching Ring under Flap

hardly any clearance, to an arc of a circle having the same diameter as the drilled holes, thus producing the outline as seen in Fig. 3. The cutting ring was then hardened and ground on the base (which was slightly recessed) and up a short distance on the outer circumference where it fits the

cast iron die plate, *D*, Fig. 1. It was also ground on the cutting edge, which was beveled about 15 degrees.

The main punch, *E*, Fig. 2, was now worked up and finished by shearing it through the cutting ring, *A*.

Pressure plate, *B*, Fig. 1, was turned up with a 5/8-inch annular groove 1/8 inch from the lower edge and deep enough to clear the inside points of cutting ring, *A*. It was then inserted from below into *A*, and cutting edge scribed off and worked up.

Punch holder, *C*, a 1/2-inch steel disk, was next clamped to the plate, *B*. The two largest holes were drilled and reamed through both and then it was used for a drilling jig on the punch, E, after which the largest hole was plugged with same quality of steel, to prevent drill running, and holes drilled for the two smallest punches, *K*. The pressure plate, *B*, was now used to drill the small holes in the punch, *E*, which had also been plugged the same as plate, *B*. The short plug used in the pressure plate, *B*, was used as the plunger, *F*, Figs. 2 and 4, and the plug used in the punch, *E*, Fig. 2 is the long punch, *I*, in Fig. 1, with the top faced off on an angle to enter the main punch, *E*, which acts as a die, splitting the stock to the small holes previously punched by punches, *K*. Plunger, *F*, is faced off to the same angle as punch, *I*, but not quite up to the edge of the small holes which form the piercing dies. The punchings are expelled through the side of the punch, *E*, by the agency of beveled guides, *G*, Figs. 3 and 4.

Plunger, *F*, Fig. 4, was kept from turning by two right-angle guides, *G*, set into small holes above the discharge holes in the punch body, *E*, from the inside, the plunger when in place keeping them from working out. The guides, *G*, were beveled to facilitate the expulsion of the small punchings from *K*, Figs. 1 and 3.

The punches, *K K I J*, were riveted over in punch plate, *C*, Fig. 1, the tapped holes of which were spotted by using die-plate, *D*, for a template.

Allowing the punchings from *J* and *K* to work up through the punch is a decided advantage, since there is no need of cleaning out the scrap from the finished punching, as happens when using strippers, which force the stock back into place. This saves considerable time in assembling on this class of work.

What may be new to some readers is the use of compressed air for carrying away the work after punching, in lieu of gravity, as on the inclined presses. It was successfully made use of in producing the above article on the upright press. The air was compressed on the down stroke and allowed to strike the face of the die on the up stroke, thus carrying the article, which was light, aside. PAUL R. WERNER.

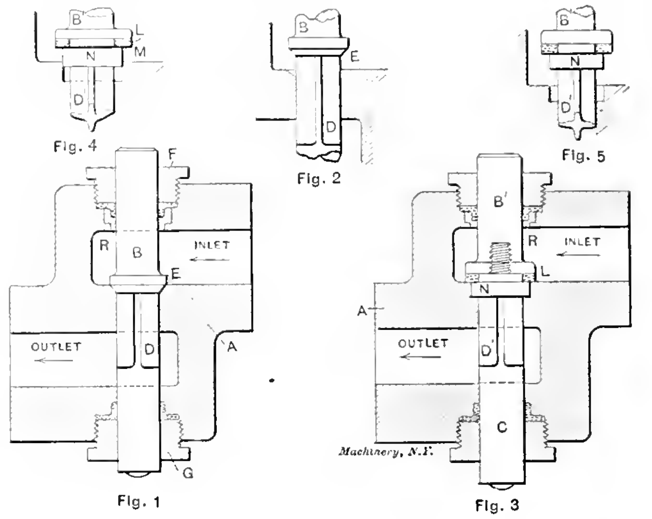
Philadelphia, Pa.

HYDRAULIC VALVE IMPROVEMENT.

Editor MACHINERY:

The illustrations herewith show a hydraulic valve improvement which has proven very satisfactory. The metal-seated valve usually, or rather, I might say, often employed, is shown by Fig. 1. The inlet and outlet are marked, and *A* shows section of the valve body. *F* and *G* are the stuffing-boxes which hold the leather packing rings in place. *B* is the stem cut away to leave only cross ribs at *D*, thus providing water passages when *B* is raised off of the seat *E*, as shown in Fig. 2. As shown, the valve seat is made solid with the body of the valve, but in actual practice this would be separate in order to cheapen repairs. Valves of this style are used in our present installation with water under a pressure of 1,500 pounds to the square inch, and in spite of extreme care taken to keep grit and dirt from the water by filters, etc., we experience more or less trouble continually from the cutting of the seats. The velocity of the water, of course, is at times very high when the valve is open a small amount. Dirt and rust on the pipes, etc., will then quickly groove and destroy a ground brass seat.

To do away with the necessity of grinding the seat and reduce or rather eliminate the leakage when seats become worn or grooved, the style shown in Fig. 3 was adopted. The only change in the design was directly at the valve seat. A leather ring *L* was inserted, which covers the seat joint when the valve is closed. The seat in the body of the valve was then recessed, and the valve stem made to fit fairly tight, as at *N*. Fig 4 shows the valve stem slightly raised and illustrates the use of the part *N*, which as shown, tends to practically keep the valve closed until the leather ring *L* is far enough removed from the edge of valve seat of body to be clear of the cutting action of any dirt carried by the water. As the part *N* does not exactly fit the valve body, a certain leakage will take place as soon as the leather ring is lifted at all, but this amount is so



Hydraulic Valve Improvement.

slight that there is no serious wear on the leather, and its life is, under average conditions, equal to the regular valve seat shown in Fig. 1, and, in addition, has a further advantage of being easily and cheaply replaced.

R is a loose ring which can be removed to allow the larger part of stem *B* to pass. W. T. SEARS.

Harrisburg, Pa.

ACCURATE JIG MAKING.

Editor MACHINERY:

There seems to be a misunderstanding between Messrs. Shailor and Gordon regarding accurate jig making and if you will allow me the space I will express my views on the subject.

In the first place, I infer from Mr. Shailor's article that his description was intended solely for very accurate jig making. On the other hand it appears to me that Mr. Gordon's method of jig making was intended for jigs such as are used in the average shop. If such is the case it simmers down to a simple misunderstanding between above named gentlemen. But if Mr. Gordon really places the drill-press plan on a par with the button method as described by Mr. Shailor, I have a few words to say regarding the method. The subject is an interesting one; in this case the argument should be carried to the end, for the benefit of the younger readers who accept a statement as truth because it appears in a mechanical magazine.

I have knocked around the country quite a little and have made jigs for producing the recognized standard watches of the country but was compelled to use a more accurate machine than a drill-press. Mr. Shailor enumerated ten chances of error that are presented when employing the drill-press plan, but any toolmaker accustomed to fine work can enumerate ten more chances. Therefore a toolmaker using Mr. Gordon's method stands but one chance in twenty of producing an *accurate* jig. I have in mind a watch factory where the limit on the finished product of a jig is 0.0001; it is obvious that the jig must be almost absolutely correct. For an illustration let us suppose that a jig is assigned to a toolmaker, said jig to produce the plates of a stop-watch. For the benefit of the readers not acquainted with the movements of a stop-watch I will say that there are three wheels in each watch about 0.3 inch diameter that operate the split-second hand. The teeth on said wheels are so fine that they can barely be observed with the naked eye. Let the reader imagine that the job was assigned to him and then seriously consider the drill-press plan for producing the jig!

Mr. Gordon admits the chances for errors are in evidence and proceeds to explain how they can be overcome, but we all know the fact remains that the chances are there. The more chances there are for error the more cautiously a workman must proceed and a greater number of obstacles must be overcome before the workman can make one cut on the jig. It needs no argument on this point to convince the reader that the best method is the one that has the least number of chances for inaccuracy to creep in. Mr. Gordon has the assurance that the drill continues straight clear through the work owing to his long practice. He says if it were not possible to drill straight that we would not have gun barrels, etc. For the enlightenment of Mr. Gordon, would say that gun barrels are not drilled straight through the bar. But the hole is drilled through a large bar and the barrel is then turned to size, using the hole for centers. After turning to size the barrel is straightened by skilled workmen with a hammer in the same manner that we would straighten a crooked nail. Mr. Gordon also states that if a drill is started straight and is not crowded and encounters no blow-holes or uneven density of metal it will continue straight. This remarkable statement is equivalent to telling a teacher that if a person had two dollars and spent one there would be one dollar left. The facts are that blow-holes are encountered, the drill is crowded and uneven density does cause the drill to change its path. Mr. Gordon closes with the statement that he can exactly duplicate jigs on the drill-press plan. I claim he can not and am of the opinion that all thinking toolmakers will agree with me.

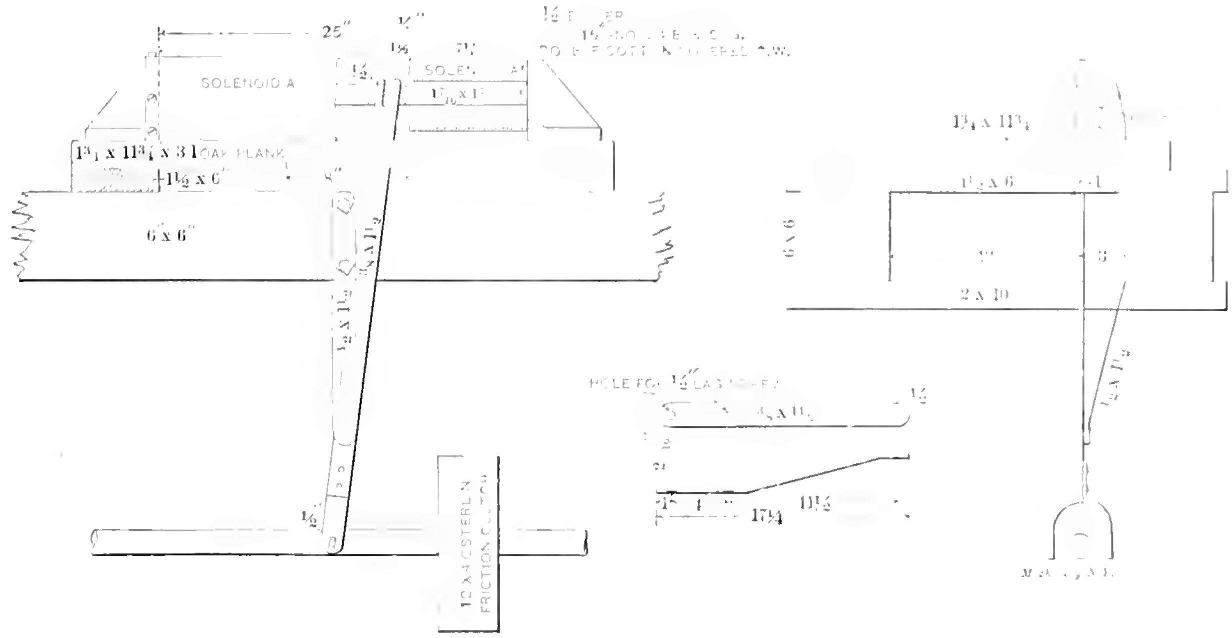
JIG MAKER.

MAGNETIC CLUTCH SHIFTER.

Editor MACHINERY:

The cuts, Figs. 1, 2 and 3, show a magnetic clutch shifting device, and the switch used for operating it. It is used to operate a 4 x 12-inch friction clutch which is belted to the feed of a 36 x 15-inch Gates crushing rolls used for crushing rock. The feed must sometimes be stopped, and it was inconvenient to have an ordinary clutch shifter about, so solenoids were used to throw the clutch instead. The solenoids are operated by a 250-volt lighting circuit and are controlled by the double-throw gravity switch shown in Fig. 3. To start the feed the ball lever is moved to the left to the position marked "feed on" and held there about a minute, and then allowed to fall to its vertical position. To shut off the feed the ball is moved to the right to the position "feed off," and then allowed to fall back to its normal position. One terminal of each solenoid is connected to the same feed wire and the other terminals are connected to the double-throw switch at C' and C''. The middle terminal C connects to the other feed wire. Hence when the ball handle is thrown in one direction solenoid A, for instance, is operated, and in the other solenoid A'. In the middle position no current flows through either solenoid. A number of these double-throw switches are located near the rolls or near other points where trouble may require the stoppage of the feed. The device has been in use for some time and works very satisfactorily.

Desloge, Mo. HERBERT S. GLADFELTER.



Figs. 1 and 2. Magnetic Clutch Shifter.

HERBERT S. GLADFELTER was born in St. Louis, Mo., April 7, 1882. He has worked for the Curtis & Co. Manufacturing Co., the American Arithmometer Co., the Laclede Gas Company, the St. Louis Smelting & Refining Co., and others. He is a draftsman and machine designer.

COMPOUND PUNCH AND DIE FOR STEEL RANGE WORK.

Editor MACHINERY:

I show herewith a punch and die which I designed recently for punching rivet holes in the strips which make the top of a steel range stove. I am of the opinion that this die is con-

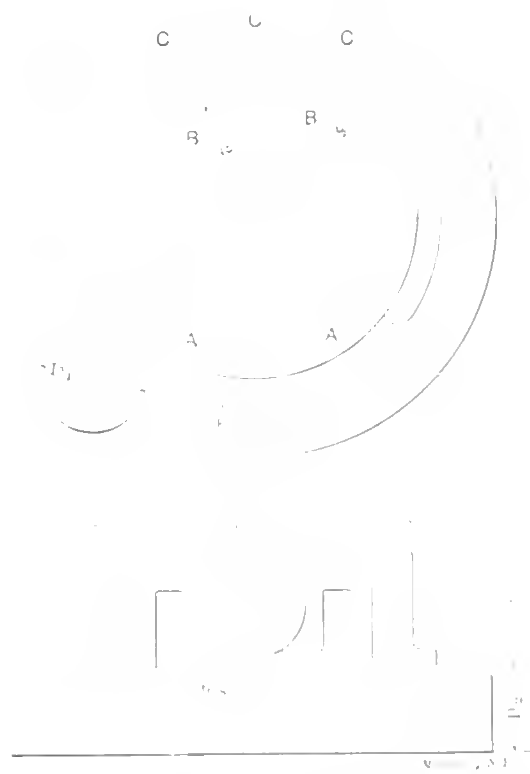


Fig. 3. Switch for Operating Magnetic Clutch Shifter.

structed and built on different principles than any I have seen in the columns of MACHINERY. If one is looking for cheap production and modern methods, I think this tool will do the

business, for it does in one stroke of the press what would require three separate operations, if done one operation at a time. The die is what I would call a twin die, and punches either right or left as the case may be, and in making the die this way I found that it saves three handlings of the work.

Before I describe the tool I would like to say a few words in regard to this tool and what it will do. Of course, everything is done piecework in the shop, and I am figuring this on a piecework basis. We will say there are 1,000 stoves to be made, which means there are 4,000 strips, for it takes four

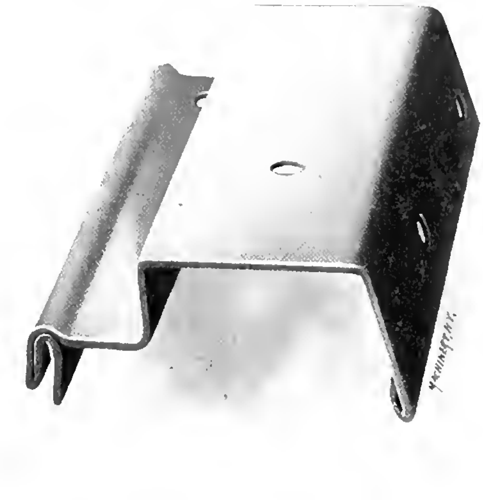

Fig. 1. Sample of Work done on Compound Punch and Die.

strips to each stove, and 20,000 holes to be punched in these strips, and if it were to be done one operation at a time, it would take a man about three days to do the work. This would cost $6.00 and keep the press tied up thirty hours. But the tool I show herewith will do the work in ten hours at a cost of $2.40, and give us twenty hours more use of the press and two days more use of the man for something else. These prices are figured at three cents a hundred holes, and for the tool I show six cents a hundred strips, which makes a difference of

make them more rigid, so there is no chance for them to shift and change the alignment with the punches *J*. The punch holders *D* are made of machinery steel, and are made a nice working fit in the pieces *G*. It will be noticed in the sketch that I have left a small tenon on the pieces *D* for the purpose of giving more stock for the setscrews *P*, which hold the punches *J* from pulling out. The vertical punches *I* are four in number and are held in place by means of the setscrews *O O*.

This die was made for a press having a 1¼-inch throw, and the side punches *D* have ½-inch travel; while the ram of the press is traveling 1¼ inches, the side punches move in ½ inch, being operated by the slotted pieces *A*. The pieces *A* are of machinery steel, and casehardened, and are fastened to the piece *E* with ⅜-inch cap screws *L* and two 5-16 inch dowel pins *N* in each piece. The die block *F* is mortised to guide and support the four pieces *A*, and at the highest point they project about ¼ inch into the die block. In this way they are well supported when taking the thrust of the side punches *D*.

After having determined the location of pins, *H*, the slots, *K*, were laid off, giving a horizontal traverse of ½ inch in the diagonal portion which of course gave me the right amount of travel for the side punches. The pins, *H*, are of tool steel, hardened and drawn to a dark straw color, and held in place, as shown in the sectional sketch. The sizes of the holes punched are No. 1 and No. 6 respectively Brown & Sharpe gage, and the material is No. 16 gage. There is also a stripper fitted to this die, which strips the stock from the punches, and acts as an end gage, not shown. There are also two pieces of rubber placed between the punches *I*, which force the work down on the piece, *C*, holding it firmly so that every one is punched alike.

I have tried to show this die as plainly as possible, in the sketch, and also to make the description clear to the readers. In conclusion I wish to say I, for one, would be pleased to see more dies of this nature described, and I hope this may be the means of bringing forth from the readers of MACHINERY a great many tools constructed along these lines.

Lorain, O. W. VAN ORMAN.

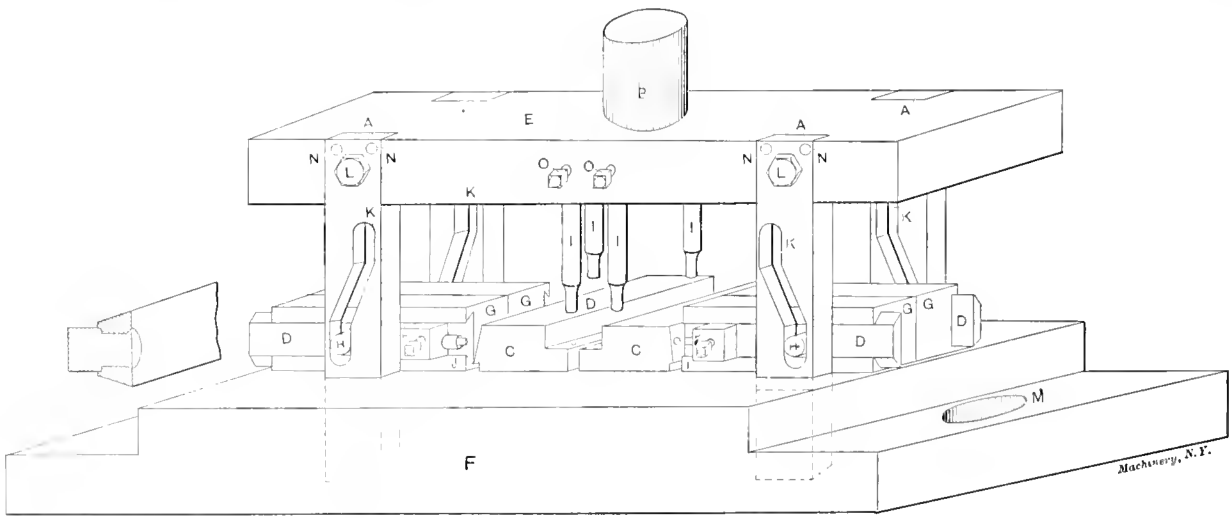

Fig. 2. Compound Punch and Die for Steel Range Work.

$3.60 on a thousand stoves, besides having two days more use of the machine. Since writing the above, 600 strips containing 5 holes each, or 3,000 holes total, have been punched in one and one-fourth hours at a cost of five cents per hundred strips.

The punch holder, or upper half of the die *E* is of cast iron and is mortised out to receive the four pieces *A* which operate the side punches *D*. The shank *B* is of machinery steel and is made a driving fit in *E*. The bolster plate *F* is of cast iron and is fastened to the bed of the press by bolts through the holes *M*. The four pieces *G*, which hold the sliding punches *D*, are of cast iron and are dovetailed; each piece is fastened to the bolster *F* by means of two ⅜ inch fillister screws and two 5-16 inch dowel pins from the under side, which are not shown. The pieces *C* are also of cast iron and are made to conform with the shape of the strip to be punched; they are held in position the same as the pieces *G*, being doweled to

SPRING STRIPPERS CONSTRUCTION.

Editor MACHINERY:

I send you sketches of two spring strippers for use on small punches. Fig. 1 was designed to avoid broken punches caused by the spring in the ordinary form (with spring on the inside of stripper shell), getting in under the punch occasionally, and "putting it out of business."

In Fig. 1 punch *A* is fitted into the punch head and fastened by a setscrew as usual. Bushing *B*, is a shell, the upper end of which is a "drive" fit on punch *A*, and the bottom end is a sliding fit over stripper *C*; it has holes for pin, *E*, about ¼ inch from the lower end as shown. Stripper *C*, is a nice sliding fit over punch *A*, and has a shoulder on lower end to retain the spring, *D*, which is of the ordinary coil type. At the top it has slots through which pin *E* slides, forming a stop and also preventing stripper, *C*, from turning around on

punch, *A*. To set up, remove pin, *E*, stripper, *C*, and spring, *D*. Set up the punch in the die; then when the ram is up place the stripper and spring again in position and fasten with pin, *E*. I have used this construction for two years with satisfactory results.

Fig. 2 is for stripping piercing punches consisting of more than one punch in a single head. I drill four holes (one in each corner) in the punch head as shown, counterboring

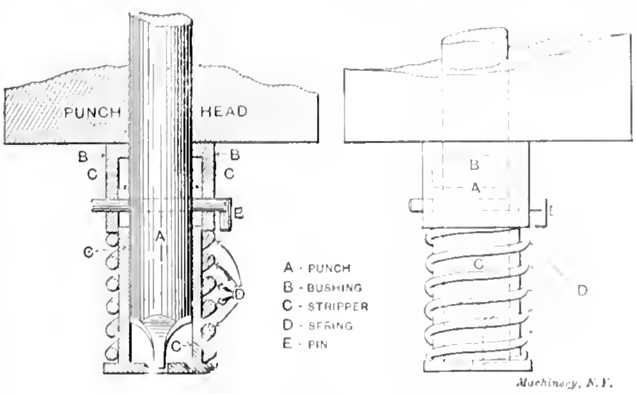

Fig. 1. Sectional and Side Views of Spring Stripper.

nearly through from the top. I insert into each hole a plunger, *A*, and spring, *E*, holding spring, *E*, in position by pin, *D*, and insert a bushing, *B*, in each corner through the holes corresponding to those in the punch head. Now set up punch and die in usual manner, raise ram of machine and place stripper plate, *F*, in position. Plungers, *A*, fit into holes in corresponding bushings, *B*, and are fastened by means of the pins, *C*, as shown. The advantages of this stripper are that it is easily and quickly adjusted, the springs are always

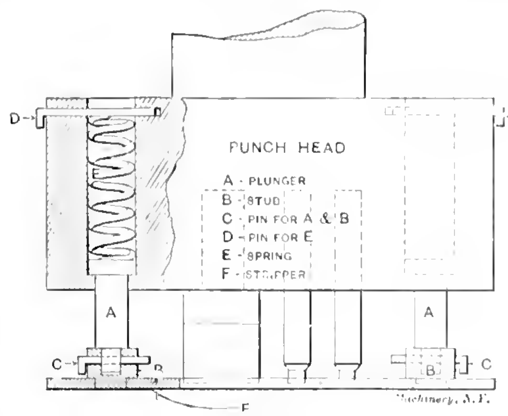

Fig. 2. Stripper for Piercing Punches

in position and out of the way, and the operator does not have to work against the tension of the springs as he does in the usual form. It is substantial, efficient and a time and profanity saver in setting up, as the operator simply takes it off, sets up the punch, and puts it back again. We have used this design for nearly a year, and have discarded the others.

Belvidere, Ill.

SOME HINTS ON BENDING DIES.

Editor MACHINERY:

The illustrations herewith show two styles of bending dies for curling the hinge shown in Fig. 5. Tools and appliances for the making of hinges are about as numerous and vary in design as much as the hinges themselves; they range from the simple punches and dies for blanking and curling in separate operations, to the complicated automatic machines and press attachments, for producing the hinge, complete, with the two parts and pin assembled. The writer has worked on the machines which perform this last-named operation, or multiple of operations, as well as on several types of dies for the same purpose.

The exact design of a die for making a hinge or any other difficult piece of work cannot be selected arbitrarily, but must be governed by conditions. Of course a style of die should be decided upon whose first cost is not out of proportion to the amount saved by its use. The two dies here shown and described are for curling both parts of the same hinges and are merely two differently designed tools for doing the same job. While the diverse plans are for the same requirements it may be interesting to state that the ratio of production between the two dies was about 5 to 7 in favor of Figs. 3 and 4. This was noted as they were being used at different times in the same press and by the same operator, the press being run at as high a speed as is consistent with good practice. Although these dies are simple in design and construction, there are several points in each where close work is essential to accurate and uniform production, *i. e.*, accuracy of the parts which curve the metal; smooth finish on these parts and care in hardening; to have them as hard as possible, as there is considerable wear at this particular point from the friction of curling. Care must be exercised in the setting up of the dies, to insure perfect alignment with the punch so that when the V on the lower side of the latter engages the upper edge of the blank, it will be held in line with the slot

Fig. 1

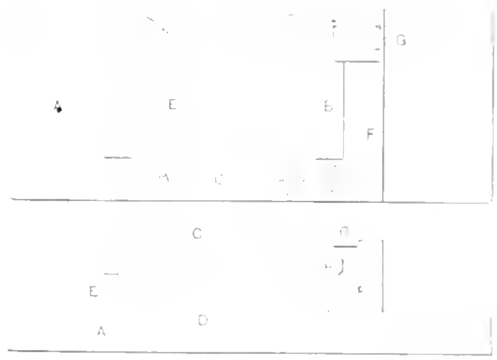

Fig. 2

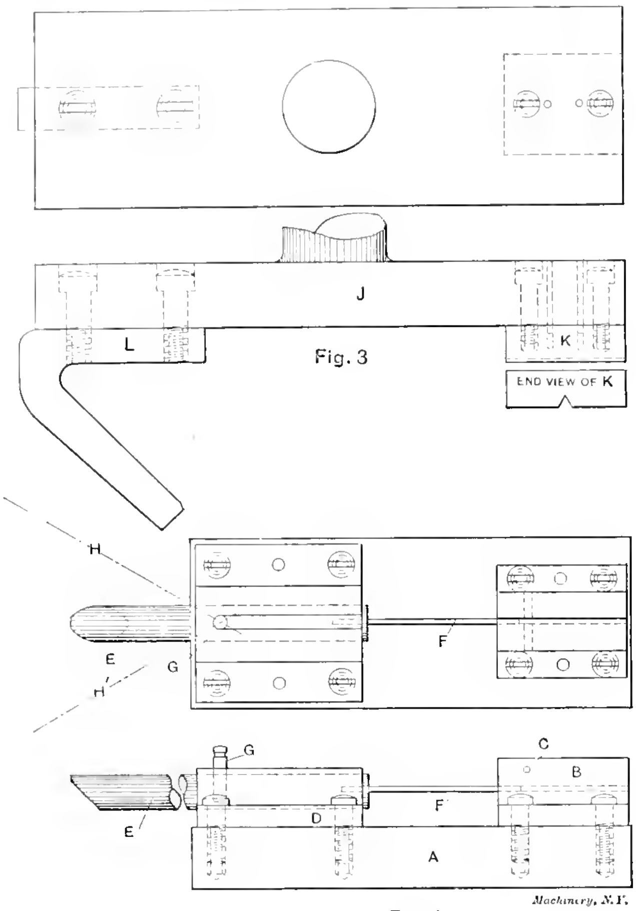
Figs. 1 and 2. Design of Punch and Bending Die for Curling Hinges No. 1

in the die that receives it, otherwise the work will have a tendency to buckle. Moreover, carefully adjust the stroke of the press, to allow it to descend just far enough to complete the curl, and no more. If it comes down too far the work will jam in the die, and difficulty will be experienced in removing it without injury to the die. It is essential that the proper lubricant be used on the blanks according to the metal employed, and also, that every blank be dipped to eliminate unnecessary friction in the curling action. We have observed from the action of hinge dies of this character, for small work, that there is a very narrow margin between the development of a good and a bad curled hinge, and that it takes very little deviation from the ordinary conditions to make the latter.

When dies for turning out the work under consideration are made of the above types and properly constructed, the results will be all that can be desired. They work well and rapidly and turn out the maximum amount of work before requiring repairs or renewal. It is important for the successful running of these dies that there be no pronounced

burrs on the blanks, and especially so in regard to Figs. 3 and 4; prominent burrs would preclude the use of this type altogether, as the opening to receive the work can only be about .003 inch wider than the thickness of the blanks, consequently, the piercing and blanking die must do good work in order to show final results.

The die, Fig. 2, consists of seven parts: The holder or body *A*, of cast-iron; the slide, *B*, of tool steel, hardened and finished



Figs. 3 and 4. Design of Punch and Bending Die for Curling Hinges, No. 2.

by grinding; the cast-iron cap *C*, secured to *A* by four screws, and holding in place the slide *B*, yet permitting it to have a free lateral movement; the spiral spring *D*, which is for the purpose of moving the slide outward on the upward stroke of the press, by the pressure against pin *E*; the tool steel die *F*, which curls the blank, forming the hinge, and *G*, which is the gage to locate the blanks, and prevents the operator from putting them too far back in the die.

The punch, Fig. 1, consists of the holder *H*, finished top and bottom with one end slotted to receive the cam *I*, which is secured by a cap-screw. The working face of this piece is polished and made as hard as fire and salt water will permit, and engages the corresponding angle on the outer end of the slide *C*, in Fig. 2. Secured by two screws to the opposite end of the punch holder, is the punch *J*, having a small V planed in its lower face to engage the upper edge of the work.

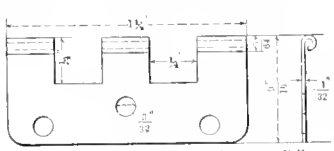


Fig. 5. Sample of Hinge Curled.

When in action the blank is placed in position between the inner end of the slide and the die proper; the punch descending, forces the slide firmly but lightly against the side of the work, and the continued downward movement of the punch performs the operation. On the up stroke the slide is pushed out to its limit by the spring, permitting a free removal of the finished work and the insertion of a fresh blank.

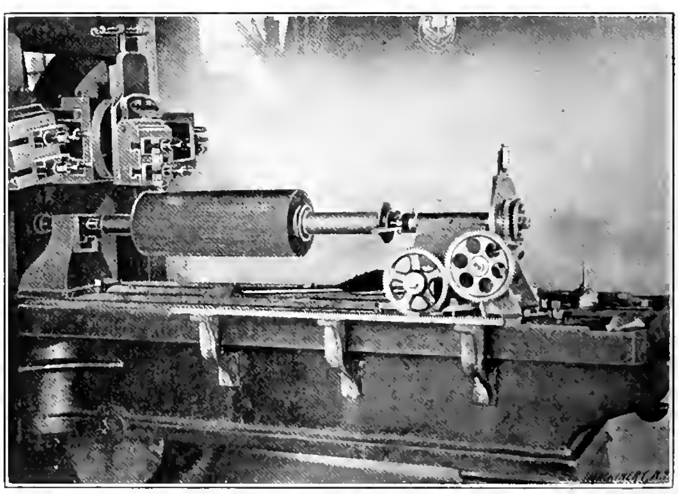
The sketches, Fig. 3 and Fig. 4, illustrate the second die. *A*, Fig. 4, is the cast-iron base, *B* is the die, and *C* is the stop pin. The die is fastened to the base by screws and dowel pins. Mounted in the rear of the die *B*, and fastened to *A* by screw and dowel pins, is the bracket *D*, carrying the sliding shaft *E*. Inserted in the forward end of this shaft is a piece of Stubb's drill rod *F*, the outer end of which is hardened, and fits in the hole in the die. Driven into shaft *E* is a spring post, *G*, to which are hooked two closely coiled springs, their opposite ends being fastened to pins located in the bolster, in such a position as to line the springs at about the angle indicated by the dotted lines *H H'*. On the down stroke of the punch these springs hold the shaft in the position in which it is drawn. The object of the angular arrangement of the springs is two-fold: permitting the cam *L*, Fig. 3, to pass between them, and also, minimizing the possibility of an accident. Should one spring break, the other is sufficient to do the work. The punch, Fig. 3, consists of the holder *J*, steel die *K*, and angle or cam piece, *L*. When in operation the punch descending allows the stripper shaft *E*, Fig. 4, to be withdrawn, by the springs, in time to clear the blank as it is forced down and curled. On the return stroke the shaft is positively advanced, by contact with the angle piece on the punch, ejecting the hinge from the die. This tool had to be, of necessity, operated in a press of the proper stroke to prevent the angle piece *L* raising entirely clear of the end of the shaft *E*. This stripping arrangement permitted a continuous feeding of the blanks to the die, increasing the output over the other punch and die in about the ratio above referred to. C. H. Rowe.

Worcester, Mass.

PLANING SPIRAL CORRUGATED ROLLS.

Editor Machinery:

We recently had some corrugated chilled cast-iron rolls, all belonging to a feed grinding mill, come into the shop to be re-corrugated or sharpened. If the flutes had been straight, this would have been a simple matter, but as they were in the form of a spiral extending around the roll 1-42 of a revolution per foot in length, or 8 4-7 degrees per foot, they presented somewhat more of a problem. Each roll weighed about 400 pounds, and we mounted it on a pair of Fay & Scott's 20-inch planer centers. On the outer end of the head spindle was keyed a disk carrying an index pin. Outside of the disk and loose on the spindle was a worm gear to which was fastened the index plate.



Planing Spiral Corrugated Rolls.

To prevent undue strain on the index pin when the roll was being revolved, binder bolts were passed through the worm gear extending into a circular T-slot in the disk, and it was of course, necessary to loosen them when revolving the roll by hand to the next corrugation. For revolving this work to obtain the spiral, a horizontal shaft extended out to the side of the planer platen on which was mounted a gear. This gear running in a stationary rack fastened to the bed of the planer gave the proper speed to the roll when the platen was in motion. The extra intermediate gear shown was to change the direction of revolution of the roll, as we happened to have a left-hand worm which was used in place of a right-hand, which would have given the right direction without use of the intermediate gear. We found it necessary to slow the planer down

to about one-third speed, and then tried several makes of high speed steels before we found one which would cut this chilled iron in an economical manner. W. L. FAY.

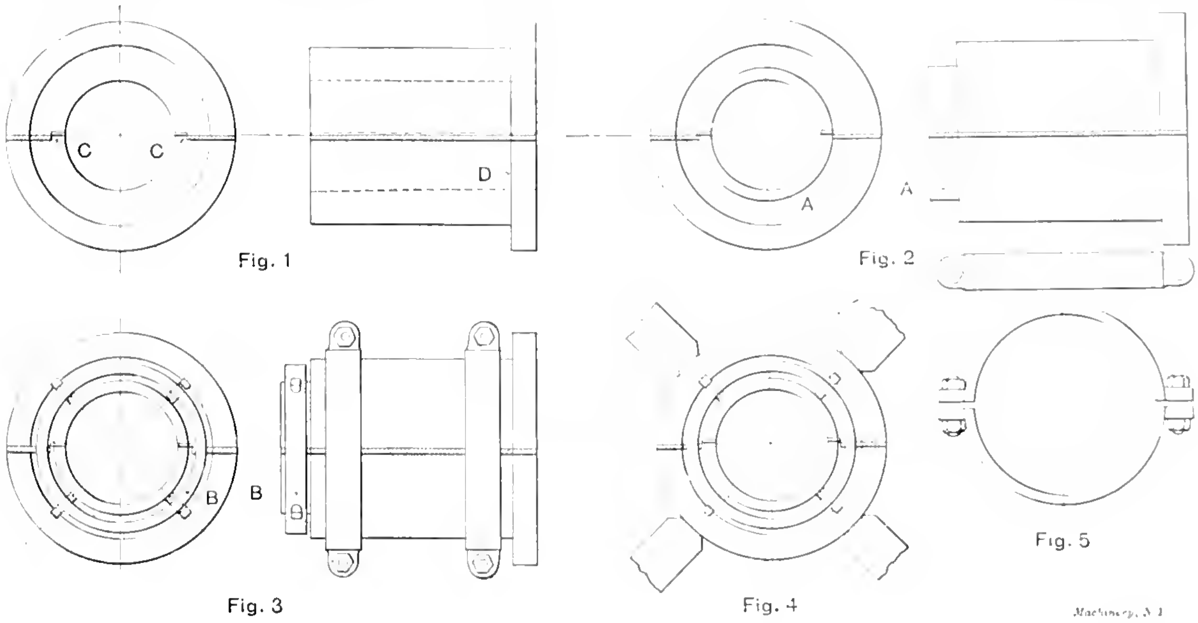
Dexter, Me.

METHOD OF BORING AND TURNING A CAST IRON BUSHING IN HALVES.

Editor MACHINERY:

Some time ago in the shop where I am employed the question came up as to how we could bore and turn the cast iron bushing shown finished in Fig. 1. The bushing is in halves, and is used in the end crank bearings of a two-cylinder vertical gas engine. After some figuring we decided to do the job in the following way:

First, the bushing was cast with the projected ring on the end as shown at *A*, Fig. 2. The halves were then planed in



Method of Boring and Turning Cast Iron Bush in Halves

the usual manner, with the shoulders *C C* in Fig. 1. Next we made a steel ring with setscrews as shown at *B*, Fig. 3. The halves of the bushing were then placed together with the proper size shim between; the steel ring was next placed over the projected ring of the bushing and the setscrews tightened. The work was placed in the lathe chuck and centered as shown in the end view of Fig. 4. It was bored and turned and the edge, *D*, in Fig. 1 faced. While still in this position in the lathe two clamps like the one shown in Fig. 5 were slipped on the bushing and tightened as shown in the side view of Fig. 3. The bushing was then taken out of the chuck and slipped on a mandrel. The flange end was turned and the projected ring turned off, this being the last operation and finishing the job. This method of boring and turning the bushing makes all of the surfaces perfectly true with each other.

Dayton, O. A. J. BRUTSCHE.

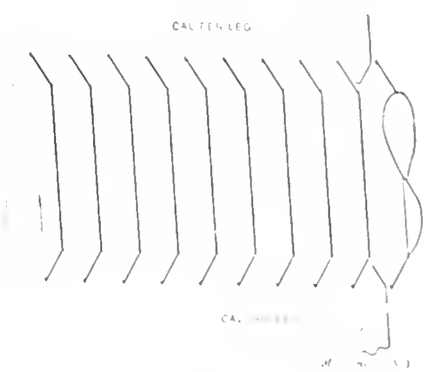
CALIPERING THE FIT OF A SCREW THREAD.

Editor MACHINERY:

The fit of a screw with V-threads is on the incline face of the thread only, and not at either sharp point top or bottom; but I find it to be decidedly common practice among machinists to use a thread caliper which is sharpened to a thin sharp point. This is a mistake, for the reason that in case the thread tool should crumble the least bit or get dull at the extreme point, it leaves a little fillet at the very point at which the caliper is indicating, and then the man is at sea as to the thickness of the thread.

To remedy this evil, I would advise him to take a pair of ordinary outside calipers and file the points to fit a thread tool gage, leaving a slight space flat at the extreme point as indicated by the sketch submitted herewith, thereby avoiding any chance of touching the bottom. Then when the caliper is tried over the work it will be found to fit on the flat incline surface of both sides of the thread, thereby calipering the work just where the bearing surface is. When the thread cutting tool is properly ground the extreme root of the thread will take care of itself. Some men advise making the points of the caliper points slightly round instead of a fit to the thread gage. By using the above described style of caliper points the lathe man is able to vouch for the accuracy of the fit he is making, just as well by the calipers as he can after he has tried the pieces together. I have found the scheme efficient, as will be seen by relating a circumstance which occurred when I was working on the night shift in an engine shop.

When I came in to work in the evening I found standing beside my lathe, nine piston rods to be finished to size (the piston head had been put on and riveted solid). They were $2\frac{1}{4}$ inches diameter by 30 inches long, and were to have a thread cut up on the end $3\frac{1}{2}$ inches long with 8 threads per inch, which had to be a perfect fit to the cast steel crosshead. The entire rod and head weighed about 150 pounds, while the crosshead weighed 110 pounds. They were the high-pressure heads for a 12- and 22- by 12-inch compound engine. I used the sort of thread caliper above described, in fitting the threads, and found each rod to fit perfectly the first time I tried them into the crosshead. At 12 o'clock at night I had the entire lot



Calipering Screw Thread

completed, every one of them stood their test, and passed the inspection O. K. Previous to the time I introduced these thread calipers, it had usually been one hour's job to fit each thread alone, to say nothing of the finishing cut on the blank or straight portion of the rod. H. E. WOOD.

Pearl River, N. Y.

A COMBINED CUTTING, DRAWING AND KNURLING DIE.

Editor MACHINERY:

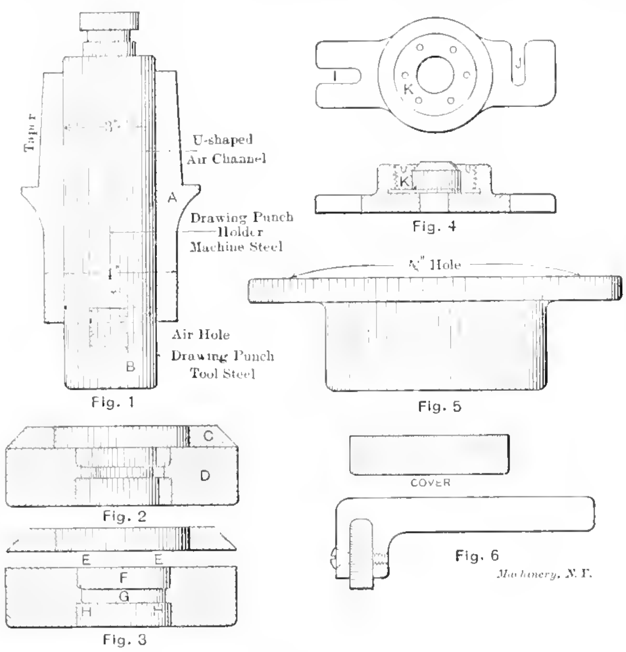
The cut shows a set of cutting and drawing tools used in a double-acting power press for cutting and drawing a so-called knurled cover, in one operation; also a die bed or bolster which is quite a time-saver, and is used in connection with

this set of tools. These tools cut and draw a brass cover 3 inches diameter and ½ inch long—thickness of metal 0.050 inch—which is used on a cylinder-shaped metal box, the outside of the cover being ribbed or milled for convenience in screwing on or off the box.

Fig. 1 shows the cutting punch, *A*, which is 4 inches diameter at the cutting part. It has a taper shank and is made a driving fit in the punch holder, Fig. 5, which is held in the press by two ⅝-inch screws.

The drawing punch, *B*, is made in two parts. The drawing part is made of tool steel and is 3¼ inches long and has a 1-inch tapped hole in the end where it screws on the punch-holder. The punch is hardened and ground, and is lapped smooth to size. The air hole shown not only makes it easier to draw up the shell or cover, but it enables the cover to be more easily stripped from the punch. The drawing punch holder is used for different sizes of drawing punches, and is held in the press by a yoke key, or as some diemakers call it, a U-shaped key, which fits the nipple on the upper end of the holder.

The die is made in two parts, namely, the cutting part and the drawing part. The cutting part is made of tool steel, and is hardened and ground on the top and bottom; it is beveled



Combined Cutting, Drawing and Knurling Die.

on the side to correspond with the bevel on the threaded collar shown in Fig. 4 at *K*. The 4-inch hole is ground and has very little clearance, for the reason that if too much clearance is given it will cause the blank to shift from side to side after it is cut, thereby causing the cover to be uneven in its length.

The drawing part is made as shown in Fig. 3. *F* and *G* are the parts that draw up the ribbed cover after the blank is cut. The mouth of die is rounded, as shown at *EE*, thereby making it easier to force the blank through the die. The diameter of *F* is made 0.020 inch larger than *G*, and it draws up the cover before it is ribbed by *G*. The diameter of *G* is made a trifle smaller than the required size, as the cover expands slightly after having passed through the die. The corners, *HH*, are made sharp and strip the cover from the drawing punch on the upward stroke of the press. Part *G* is ribbed or milled with the knurl shown in Fig. 6.

Fig. 4 shows the bolster for holding the die. The die is held in position by the threaded collar, *K*, which is screwed down upon it by the aid of a spanner wrench having two pins which engage in the holes shown. This bolster differs from the one most generally used inasmuch as it has the slots for the screws running at right angles with each other. When taking the bolster out of, or placing it in the press, the screws need never be any more than just loosened up, while with the other style, one screw must be taken out entirely before the bolster can be removed. When placing this bolster in the press, the slot, *I*, is engaged with the screw on the left, after which the bed is swung to the right until the slot, *J*, engages the screw.

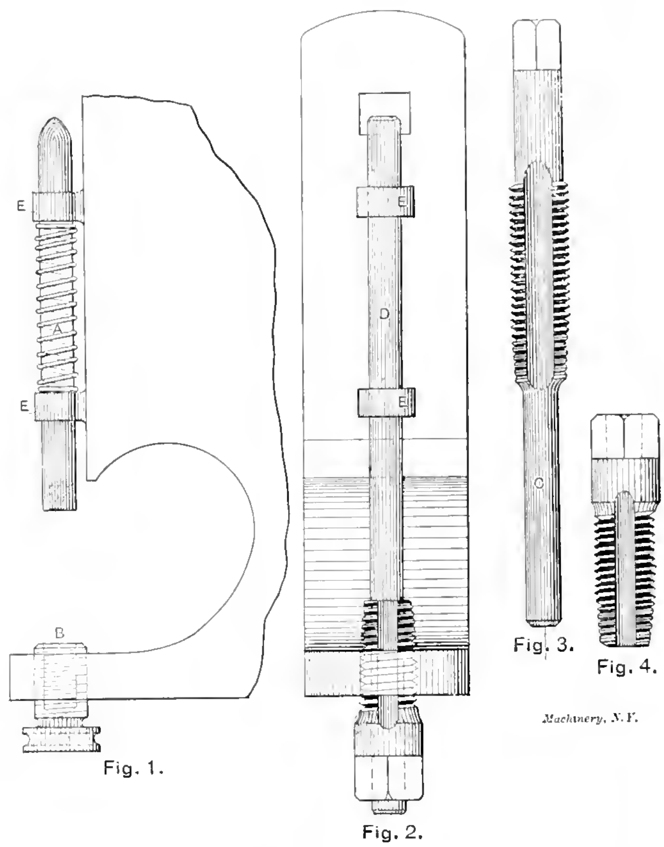
The arrangement used for guiding of the metal, and the stripping it from the cutting punch is not shown, but is similar to those that have been described in MACHINERY from time to time and therefore needs no explanation. The covers are threaded after they leave the press; they are then cleaned and nickeled and are then ready for use.

C. F. EMERSON.

A TAPPING EXPERIENCE.

Editor MACHINERY:

In the accompanying sketch, Fig. 1 illustrates a portion of a machine for setting metal parts in a fabric. *A* is the ram, or plunger, and *B*, is the bolster. Both of these parts carry a die. In tapping the base for the bolster, *B*, we used the tap, Fig. 3, with a pilot pin, *C*, running up through the lug, *E*. It seems as though this should bring the plunger in line with the hole in the base, but it was found on examination



Showing use of Hollow Tap.

that it did not, some varying as much as 1-32 inch, which wrought havoc with the metal parts being set. So the foreman designed the hollow tap, Fig. 4. This tap was bored a snug fit for the bar, *D*, which passed through the lugs, *E*, *E*, and the hole to be tapped, the hollow tap was slipped over it and the hole was tapped. In this manner the tapped hole came in exact alignment with the plunger.

PEDRO RE.

* * *

An error occurred in Mr. L. S. Burbank's article "Table of Spur Gear Teeth Giving Diametral Pitch," in the December, 1904, issue. In the explanation of the table the statement: "As the products of , s and $\sqrt{\frac{2.51}{W}}$ (the loads and velocities) divided by 33,000 give the horse powers, etc.," obviously should have read: "As the products of the loads and velocities divided by 33,000 give the horse powers, etc."

* * *

A little kink in the lacing of belts is mentioned by the *Mining Reporter* which makes it easier to thread the ends of the lacing leather through the belt. The ends of the laces should be gently charred over a small flame, a lighted match, for instance, using care that the leather is not burned, and it will be found that the ends have taken a stiffness or rigidity sufficient to enable them to be readily pushed through the holes in the belt.

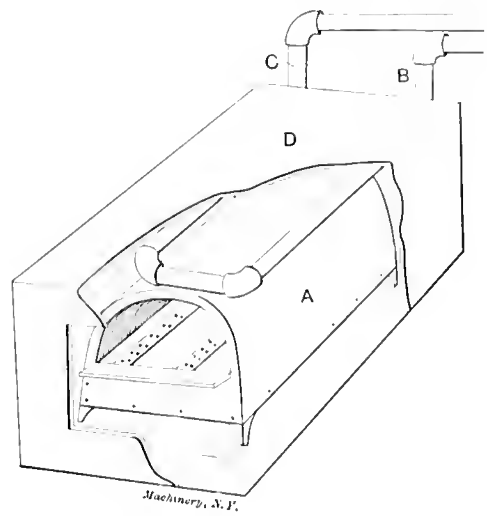
SHOP KINKS.

A DEPARTMENT OF PRACTICAL IDEAS FOR THE SHOP.

Contributions of kinks, devices and methods of doing work are solicited for this column. Write on one side of the paper only and send sketches when necessary.

HOT WATER FOR THE TIN SHOP.

Shops using soldering furnaces and not run by steam power, may have hot water in abundance by using this design. It is in practical use and furnishes us with abundance of water, scalding hot. An old style kitchen range outfit is used, that is, a regular galvanized boiler, and a coil of pipe. Referring to the sketch, *A* is the soldering furnace; *B* and *C*, the pipes to and from boiler; and *D*, a sheet iron (1-16 inch

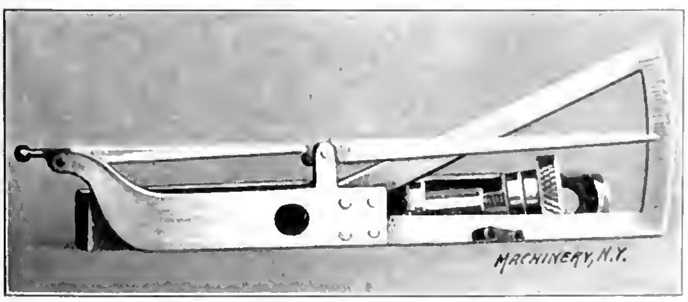


or ⅛ inch thick) covering, lined with thick asbestos paper or fire clay. The furnace is set about 4 inches back of the front of the covering. The bend of the pipes is over the front edge of the furnace, so as to catch the bare flame, escaping from the front end of furnace. All pipes used are 1 inch, except the pipe running from the boiler to hydrant, and this is made ½ inch. PARK B. SHILE.

Lancaster, Pa.

A SIMPLE INDICATOR.

The half-tone shows an indicator, for testing the truth of work, that I find to be very sensitive and reliable. It is so simple in construction that an apprentice can easily make one for his own use. It consists of a frame supporting two levers arranged in tandem and swinging upon hard steel pivots, a reading scale, a ball, a bolt with thumb-nut, and a holder for use on the lathe. With the bolt the indicator may be screwed to a surface gage, and the frame is of such a shape that it may be easily clamped against any flat surface. Since gravity, and not springs, is relied on to work the lever, the tool must



always be used in or near the horizontal position, but with some special attachments it may be used as a universal indicator, and I use none other in the shop. The ball shown in place is used in truing up work by a hole, a button, a prick punch mark, etc. When truing work by the prick punch mark we use a "wiggler," which is made in two parts, one telescoping the other and provided with a spring for holding them apart. This is preferable to a solid wiggler, because it can compress as the prick punch mark nears the center. The small attachment shown in the illustration is used instead of the ball to test lathe centers, faceplates, large shafting, and all work of a similar nature. The first or short lever is 2.1 inches long over all, the distance from the center of the ball to the pivot being 0.25 inch, and from the pivot to point of contact with second lever 1.75 inch. The long lever is 2.65 inches long over all, the distance from the contact with the first lever to the pivot being 0.11 inch, and from the pivot to pointer end 2.47 inches. The distance between the pivots is 1.86 inches, and the total length of the tool is 4.77 inches. The short graduations on the scale represent 0.0002 inch, and the long ones 0.001 inch. The graduations were marked off from actual measurement on the ball point of the first lever.

Great Barrington, Mass. J. MATHIEU.

PIPE CENTERS—KEYSEATING BAR FOR SHAPER USE.

Figs. 1 and 2 show male and female loose head pipe centers for lathe use. The head *A* may be made of either machinery steel or cast iron. The hole is bored taper, and the stem *B* is fitted, and driven in tight enough to allow it to be used as an arbor for turning the head, thus making it true. When finished, two or more steel buttons are made to fill

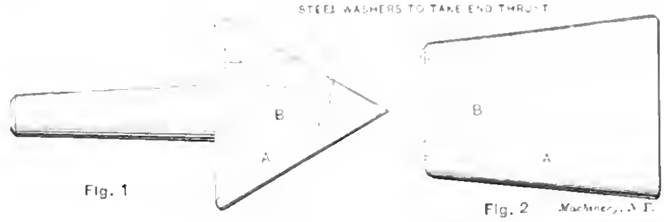


Fig. 1 Fig. 2

the end of the small hole and act as a step bearing to take the end-thrust when the center is in use. Enough buttons should be used to hold the head in position on the stem so there will be no lost motion and still have it turn freely. The pipe center is a tool which is almost indispensable, where all kinds of work are done, to hold pieces being bolted to the face plate, to hold and turn any piece with a hole in it, and many other jobs.

A handy bar for use in a shaper for key-seating may be made like Fig. 3. The tool-post of the shaper having been re-

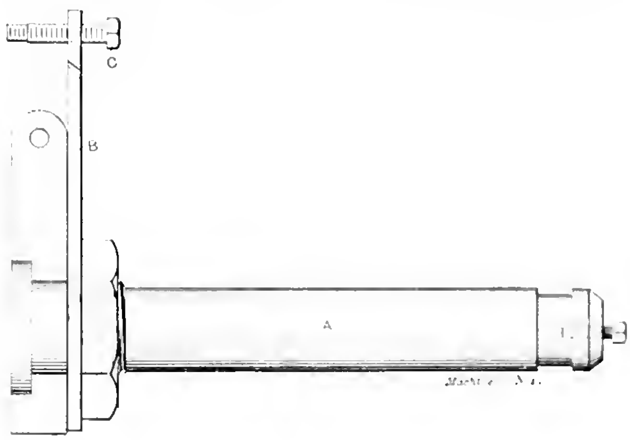

Fig. 3

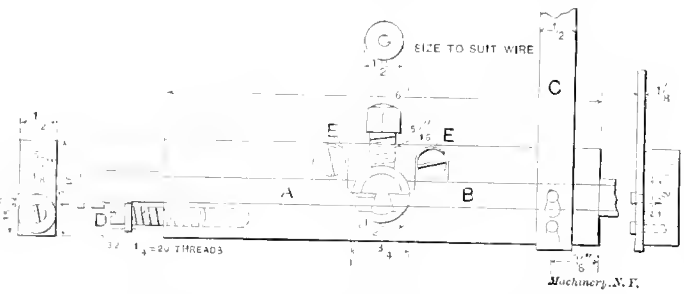
moved, the key-seating bar *A* is placed in the clapper block and a piece of spring steel *B* about 3-16 to ¼ inch thick and from 2½ inches to 3 inches wide is bolted under the nut. The steel spring has a hole a little larger than the diameter of the thread on the bar, and extends high enough to reach a good resting place for the tension screw *C* at the upper end. The outer end of the bar has a hole about ½ inch square for the tool, which is held in place with a setscrew. I made and used a bar of this description in one repair shop, where it is still in use for light key seating. J. T.

"BOSTON TOOL" FOR MODEL WORK.

The drawing shows a little tool which I made some years ago for an odd job of model work, which was this. I wanted a shaft 9 inches long, 3-32 inch diameter, with bearing on each end ½ inch long and 1-16 inch diameter—rather an awkward job for a 16 inch lathe. So I made the "Boston tool" here described, which I found very satisfactory for the purpose, and I have since made others in different shops where they have

been accepted as the "proper thing" for making little pieces, such as special screws, counterbores, dowel pins, cores, etc., from drill rod and round stock. The large bushing is hardened and ground and may be used on ½-inch work, and bushings fitting it for smaller work. Tool *A* is a regular side tool and *B* is a cut off tool, operated by the lever *C*, which can be detached by pulling up so the pin heads may pass through the large holes at the lower ends of the slots in the lever. The



collar on the feed screw *D* turns in slots in the bottom of the tool *A*. The tools are made of ¼-inch by ½-inch stock and are an easy fit in the holder; they are gibbed at *E E*. For the convenience of any reader of MACHINERY who may wish to make himself one of these tools I have put the principal dimensions on the drawing. L. E. MUNCY.

Syracuse, N. Y.

* * *

HOW AND WHY.

A DEPARTMENT INTENDED TO CONTAIN CORRECT ANSWERS TO PRACTICAL QUESTIONS OF GENERAL INTEREST.

Give all details and name and address. The latter are for our own convenience and will not be published.

The following queries are referred to the readers:

22. A. R. B.—What is the specific heat of soapstone?

---

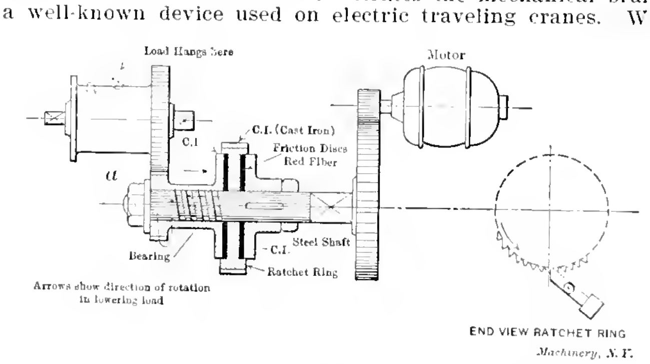
23. H. L.—What is the shrinkage coefficient of plaster of paris from liquid to solid state, at ordinary temperatures? What is its expansion coefficient for heat when in the solid state? At what temperature is the "water of crystallization" driven off?

---

24. T.U.V.—What is the reduction of strength in ordinary brass when subjected to temperatures higher than normal? For instance, how much thicker is it necessary to make a brass globe valve for superheated steam at, say, 600 degrees F. than for saturated steam at 350 degrees F. in order to secure the same factors of safety, the pressures being the same in each case?

---

25. R. A. G.—The sketch illustrates the mechanical brake, a well-known device used on electric traveling cranes. Will



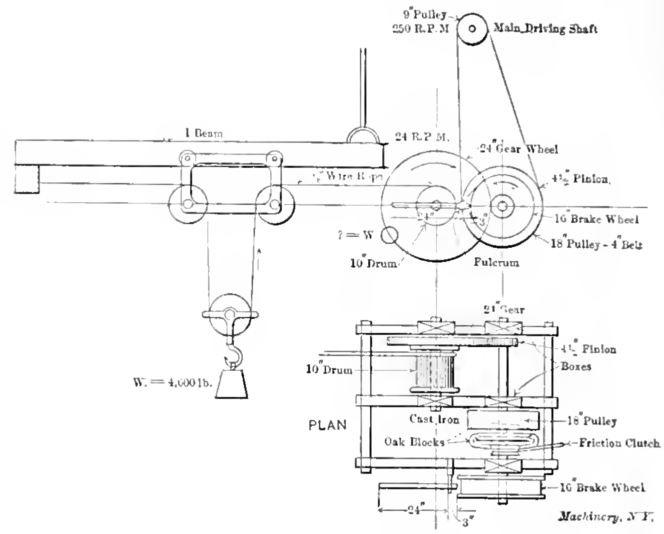
you kindly tell me how to figure the pitch of the screw *a* to hold the load; also the proper pitch which shall require the minimum amount of power to lower the load.

Answer to Question No. 16.

In reply to the inquiry in the December issue for a compound that will coat zinc black for template work, L. M. writes: "Paint will not adhere directly to zinc, as owing to a chemical action, a fine white powder or scale is deposited on the surface of the zinc, causing the paint to peel off. This can be prevented by preliminary treatment, and I feel sure that the following formula will work well: Dissolve in 64 parts of water, 1 part chloride of copper; 1 part nitrate of copper; 1 part sal ammoniac. Add to the above 1 part of commercial hydrochloric acid. Brushing the surface with this preparation will give a dead black coat, and the zinc will be ready for painting in 24 hours."

---

26. A. P. M.—Kindly give a demonstrated formula for finding the necessary weight to be placed upon the lever of the power hoist so as to sustain a weight of 4,600 pounds with the band brake. The brake is fitted with oak blocks of the usual V-shape working in a grooved cast-iron brake wheel. The load is lowered by gravity, and must be retarded and brought



to rest gently by the action of the brake, because of the delicacy of the work handled, being cores for the foundry. With the mechanism now in operation, I find a weight of 20 pounds on the lever enables us to handle a load of 2,000 pounds nicely and without the slightest jar. A formula submitted by another journal gave the weight of 3½ pounds to sustain the full load of 4,600 pounds.

Answered by Mr. C. F. Blake.

A. This problem cannot advantageously be put into formula shape as requested, but the solution is as follows: The first thing to be obtained is the efficiency of the machine. Formulas for this may be found in MACHINERY, Mar. and Apr., 1903. Lacking definite information as to sizes of pins and shafts, etc., we will assume 75 per cent., which will be quite near the truth if the machine is well built. We must also assume that the weight of the blocks and ropes at the lowest point is included in the 4,600 pounds, since nothing is said to the contrary. We then have 2,300 pounds on each rope, and $\frac{2,300 \times 10 \times 4.5}{24 \times 16} = 269$ pounds *net* on brake wheel. Including the frictional loss we have 269 pounds $\times$ 0.75 = 201.75 pounds, say 202 pounds on brake wheel at 75 per cent efficiency of machine. Formulas for band brakes may be found in MACHINERY for January, 1901, from which we have:

$$T = \frac{P\,b}{a\,(k-1)} \text{ in which}$$

T = weight required.
b = lever arm = 3 inches.
a = lever arm = 24 inches.
k = constant.

Data to obtain k is wanting in the sketch, but assuming the arc of contact to be 270 degrees and the coefficient of friction 0.3 we have $k = 4.11$. Then $T = \frac{202 \times 3}{24 \times 3.11} = 8.1$ pounds weight required. Owing to the variation in the coefficient of friction and the assumed efficiency of the machine it will be well to make the weight somewhat heavier than calculated, say ten pounds, and make it to slide on the lever and fasten with a setscrew, so as to be adjustable. You probably get the results described with the 20-pound weight, but you will also get the same results with a much lighter weight, since the lever and weight must be lifted to lower the load, and a man could lift considerably over-weight without losing control of the load.

MACHINERY AND TOOLS.

A MONTHLY RECORD OF NEW APPLIANCES FOR THE SHOP.

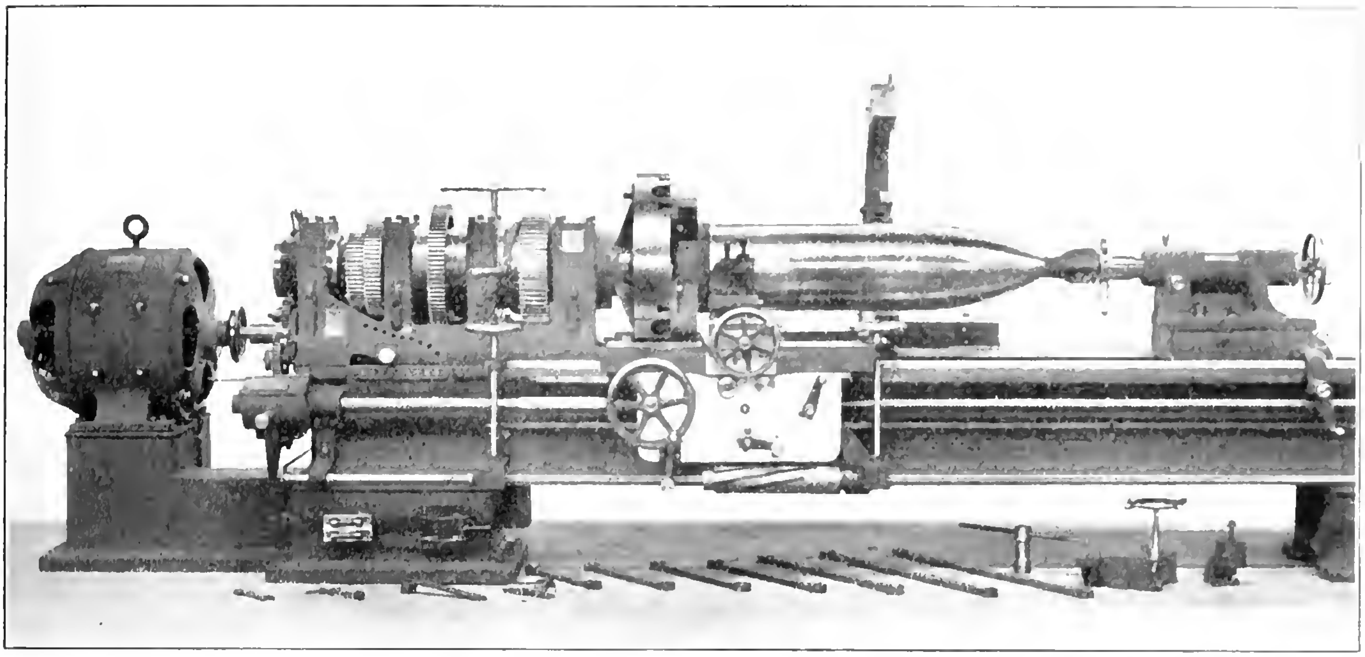


Fig. 1 Front View of Lathe showing Device beneath Carriage for Automatically Regulating Speed to Diameter

LODGE & SHIPLEY PROJECTILE LATHE.

The three half-tones herewith are illustrations of a new lathe recently brought out by the Lodge & Shipley Machine Tool Co., Cincinnati, O., which was built for them by a prominent projectile manufacturing concern. It is motor-driven, the motor used being a Ridgway 15 H. P., with speeds of 350 to 1,750. The controller has 20 speeds, and is operated from the carriage, or at the headstock. The ratio of back gearing in the head is 1.62 : 1 and 2.62 : 1; the ratio of the motor shaft to the live spindle is 7.48 : 1 and 15.1 : 1. All gearing in the head, that is, the main driving gears, has cast iron centers, with machinery steel rims of extra width. The sizes of the spindle bearings are: Front, 7 7/8 inches diameter by 8 3/4 inches; back, 7 1/2 by 5 5/8 inches. The spindle is of crucible steel .55 carbon; the hole through the spindle is 2 3/8 inches diameter. The lathe is designed at minimum speed of motor, to have a cutting speed for roughing on the body of the shell of 30 feet per minute, and for finishing of 60 feet per minute. It will be seen that the milled cylinder on the speed control shaft, immediately under the apron, provides an automatic mechanical and full electrical speed variation for varying diameters, so that the cutting speed may be continuous from 2 inches diameter up to the largest diameter.

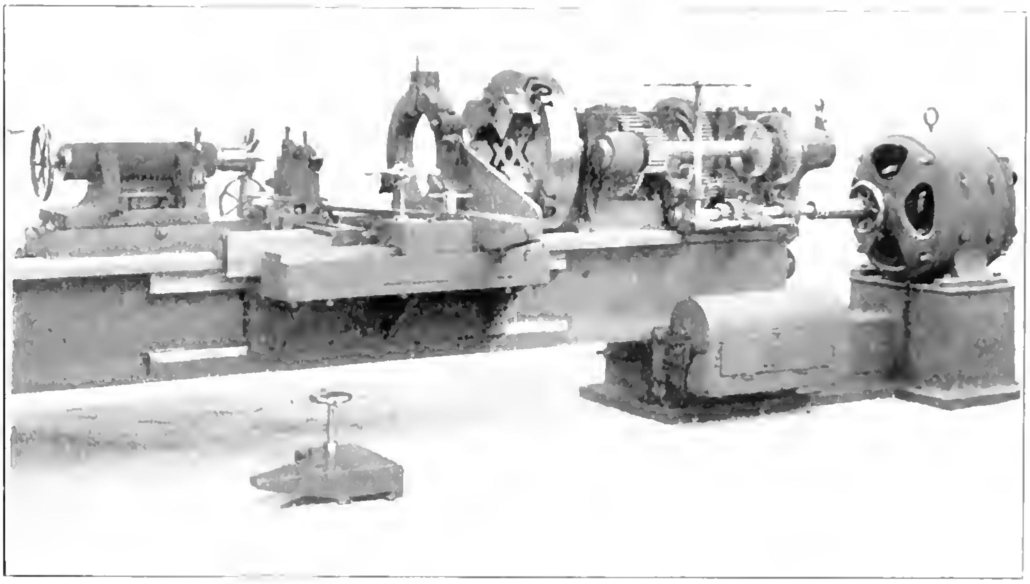

Fig. 2. Rear View showing Radius Bar for forming Points

The tool post is of steel. There is a special steady rest, which is quickly applied and removed, also the radial attachments for furnishing several desired curves. The chuck was made in the company's shop, and is of massive and substantial design. The diameter gages shown on the nose of the tailstock are great economizers of time.

The lathe here illustrated is of 27-inch swing and has a 11-foot bed, but the length of bed can be varied to suit requirements.

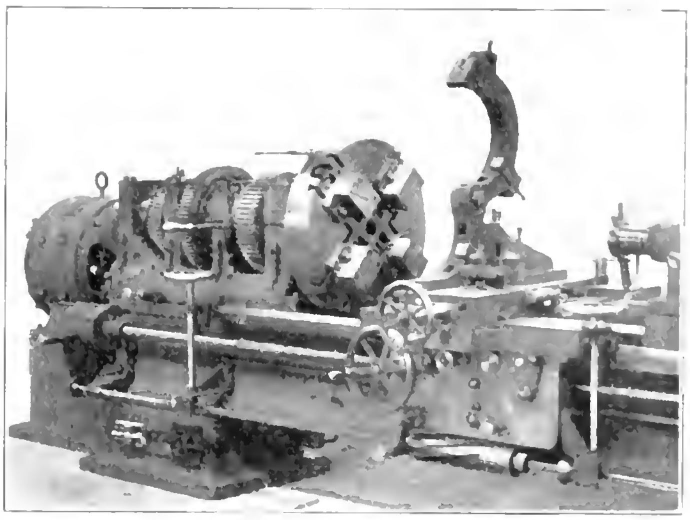

Fig. 3 Showing Massive Chuck and Special Steady Rest

MECHANICAL DRAFT APPARATUS.

The application of fans to induced draft work has made necessary many changes from the established standards of fan builders in order to avoid difficulties never met with in other lines of their work. Most fans are built with two or three spiders, and a comparatively short distance between the bearings. With this arrangement there is no deflection of the shaft and the fan wheel runs very smoothly, but when these fans have to be adapted to the handling of hot gases, the bearings must be removed from the path in which the

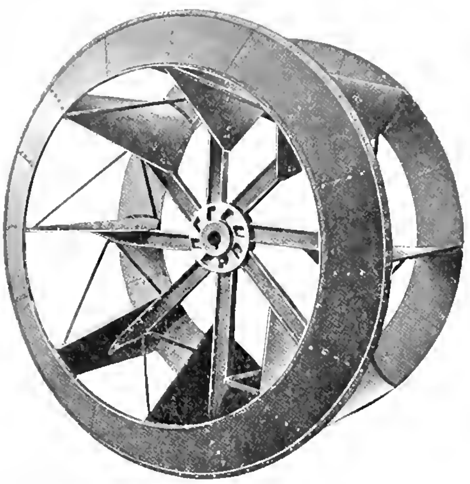

Fig. 1. Improved Fan Wheel Construction.

gases travel, as they become overheated. This necessitates either having an overhung wheel, or placing one bearing outside the inlet chamber built on the side of the fan. Unless the bearings are placed very close to the center of the fan, the overhanging will cause deflection which will work the keys loose and also cause the fan wheel to strike the housing, while the same is true of the two bearings far apart. Increasing the diameter of the shaft is not a relief, as it will deflect by its own weight. Again, the intense heat within the housing causes it to expand, and as the steel framework outside the shell is at a much lower temperature, the natural curvature is inward. Fig. 1 shows a wheel made by the American Blower Co., Detroit, Mich., with a view to overcoming these defects. The spider is made of "L" beams, which have

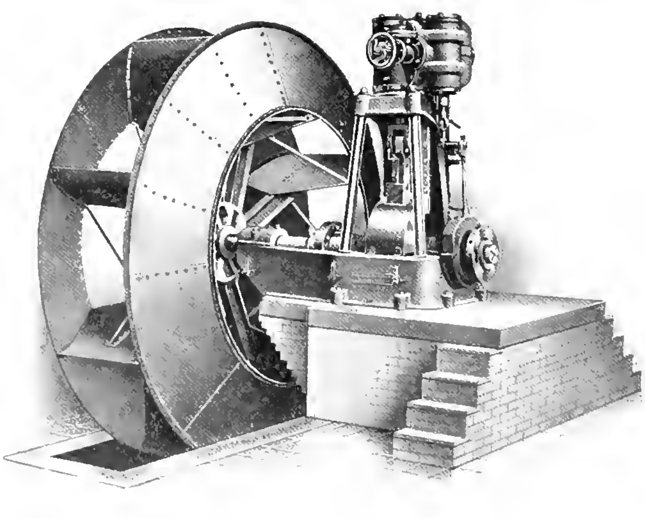

Fig. 2. Direct-connected Engine and Fan.

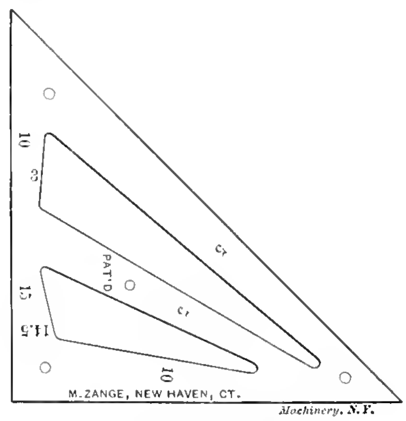
about three times the strength of a double set of tee arms as usually employed, and every blade is braced with bar iron braces from the outer rim to the center, thus overcoming any tendency to twisting. A very deep cone, reaching in close to the hub, is built in the side of the fan housing, while a special arm of heavy construction is built on the cantilever principle to carry the water-jacketed inner bearing, and placed at the apex of the cone. The distance from the end of the apex to the end of the projecting shaft seldom exceeds a foot. Fig. 2 shows a fan wheel mounted on a shaft with a direct coupled engine, though it is not always customary to make an extension of the base of the engine as here shown. In some cases an I-beam grillage is built into the brick foundation, the engine being set on the top of the outer ends of these beams and anchored down, and this makes practically a complete unit of the entire outfit.

IMPROVED TRIANGLE.

The illustration herewith shows a triangle made and sold by Max C. Zange, 417 Washington Avenue, New Haven, Conn. Besides the usual 90- and 45-degree angles there are two triangular spaces cut out of the triangle, the sides of which make definite angles, as indicated in the illustration. The angle between the two long sides of the lower triangle is 15 degrees, and between the sides of the upper triangle, 10 degrees. Starting at the bottom, the edge of the lower triangle makes 10 degrees with the base; and the upper edge, 25 degrees with the base. The lower edge of the upper triangle makes 30 degrees with the base, and the upper edge, 40 degrees. Turning the triangle around 90 degrees the short edge



Improved Triangle.

of the right-hand opening makes 14½ degrees with the base—an angle useful when drawing 29-degree threads on teeth. The short edge of the other opening makes 3 degrees with the base. Three small circular holes are ⅜, 5-16 and ¼ inch in diameter and are to be used in section lining, thus: Draw a section line on the 45-degree edge; put a pencil point down to the paper against one side of one of the holes and slide the triangle along the T-square till the other edge of the hole strikes the pencil; then make another line, and so on.

The triangle is provided with a small handle at the center which slides through, so that it may be used either side up and will rest flat on the paper.

STURTEVANT ENGINE.

The B. F. Sturtevant Co., Boston, Mass., have brought out a generating set consisting of a high-speed horizontal engine, direct connected to an electric generator, both of their own manufacture, and having a number of new features.

The reciprocating parts of the engine are counterbalanced with disks loaded with lead shrunk on to the crankshaft, which is a solid forging. All the main bearings are babbitted. The frame of the engine has a water sheet partition, which prevents water from the piston rod stuffing box from reaching the interior of the engine frame, and the oil on the reciprocating parts from being thrown out into the engine room. The frame is enclosed on both sides by removable plates, and the crank webs are enclosed by a cast iron hood, having two removable covers, one for the purpose of cleaning the crankpin box while it is in motion, and the other for removing the box without taking off the entire hood.

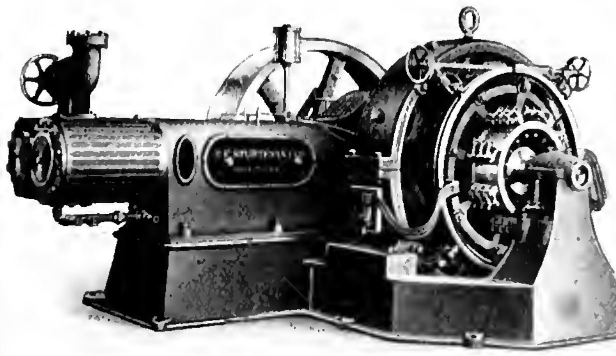
Provision is made for oiling either by the gravity or the forced pump system. In the former system, at each point where the oil is delivered are a glass gage and valve for regulating the flow at that point. With the pump, or forced lubrication system, a pump is located in the base of the engine and is operated by the crankshaft. Oil is delivered from this pump to the main bearings and from the main bearings through holes in the crankshaft and web to the crankpin. From this point the oil is conducted up through a hole in the connecting rod to the crosshead pin. A separate set of

pipes conveys the oil from the crosshead guides to the valve stem guides. The pressure of oil in the bearings under this system will vary from 12 to 13 pounds per square inch. The mechanical efficiency of the engine is so materially increased by this system of lubrication that its demand is rapidly increasing.

The engine is governed by a Rite's governor, giving very close regulation, and by adopting a modification of the Marshall valve gear an adjustment of the cut-off from zero to 70 per cent is attained.

The generator of this set is of the eight-pole type, capable of carrying momentary overloads of 50 per cent without any shifting of brushes or flashing of the commutator and an overload of 25 per cent for a period of two hours without undue heating. Before being shipped, the generator is given a breakdown test of 1,500 volts, alternating for sixty seconds between the conductors and the frame of the machine, to test the insulation.

The magnet frame is of high-grade cast iron, split horizontally. The pole pieces are of wrought iron with cast iron shoes or horns, and are secured to the magnet frame by through bolts. Any of the pole pieces may thus be removed to repair the field coils. The latter are wound up in two sections, with an air space between the shunt and series coils. The shunt winding is of double cotton-covered magnet wire with waterproof insulation. The series winding is of solid copper bars insulated in the same manner as the shunt coil.



Sturtevant Engine and Generator.

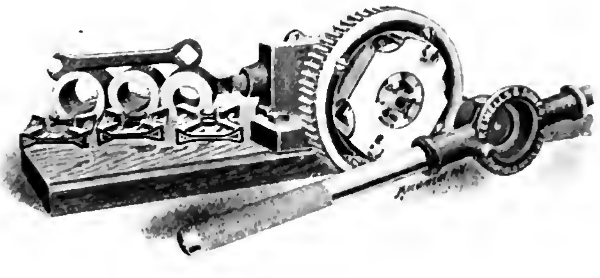
The armature is of the ironclad, form-wound, ventilated drum type, having a core built up of charcoal iron plates, japanned, mounted upon a cast-iron spider, and held by end flanges. The armature conductors are of copper bars.

In the construction of the commutator only drop-forged or drawn segments are used, these being secured in cast iron shells of spider construction and clamped in place with a steel ring. No cast segments are used. The brushes are of carbon and so proportioned as to allow at least one square inch of brush area to every 30 amperes carried. The brushes are held in holders so arranged that the entire set of brushes may be rotated completely around the commutator. Hand wheels are furnished for adjusting the brushes in position.

"WELLS" PIPE THREADING MACHINE.

The pipe threading machine illustrated herewith, for threading 1- to 2-inch pipe, is the product of the F. E. Wells & Son Co., 22 Riddell St., Greenfield, Mass. It is a very simple and compact little machine weighing about 45 pounds. It is used much like a hand diestock but it has gears to multiply the power, so that one man with this device can easily thread pipe that usually requires two with a hand stock.

The die is held in the large gear, which has a threaded shank screwing into the main frame and acting as a leadscrew to start dies. The pipe is centered by means of bushings, as in an ordinary die stock, and is prevented from turning by two vise jaws on the back of the machine operated by setscrews. All the gears are machine-cut, and the castings are of malleable iron, to save weight and yet have ample strength for the hardest usage. It can be bolted either to a bench or post, and the vise, which is a part of the machine, can be used in place of an ordinary pipe vise. With this machine the manufacturers furnish the "Economy" dies, made by them, but state that

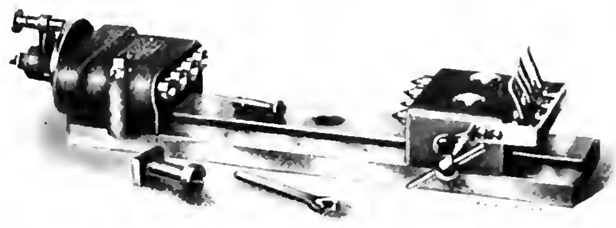


Hand Pipe Threading Machine

any standard solid square pipe die will fit. They further state that the moderate weight and small amount of work permit its being sold at a low price.

FOUR SPINDLE INDEX CENTERS WITH COLLETS.

The Garvin Machine Co., New York, have brought out a new line of multiple centers to supersede their style of centers illustrated in MACHINERY, April, 1903. For various manufacturing operations on small pieces, such at fluting, splining, flattening or squaring ends, etc., multiple centers are a valuable means of increasing production, as a number of pieces can be operated on in the same time and with the same attendance that would be required for one piece. The four-spindle center, with collet chucks, shown herewith, is for this purpose. The headstock spindles are hollow, so that work can be passed clear through, and are fitted with standard watch-lathe col-



Multiple Index Centers

lets, operated from the rear. The index dial is fixed and the spindles are indexed simultaneously by one handle. In tightening the collets, all strain is taken off the dial and pointer by locking the spindles by the binder bolt on the side. The tail-block is adjustable along the base and each spindle has an independent movement forward by a spring and is thrown back by a separate handle. The spindles are bound simultaneously by one handle. The center distance of spindles is $1\frac{1}{4}$-inch. A larger size, 2-inch centers, is also made.

NEW TOOLS OF THE THREE RIVERS TOOL CO.

The Three Rivers Tool Co., Three Rivers, Mich., have brought out several new tools for boring and drilling. One of these is the Matthews core drill, shown in Fig. 1, with blades of high-speed steel brazed into the body of soft steel. This is a modification of the Matthews reamer, described in our issue of July, 1904, but is designed for the removal of a large quantity of metal from the inside of a hole, such as a cored hole, and for this reason has deeper blades than reamers and is ground with a blunt cutting angle to prevent digging into the work, and with large grooves for chips.

This drill is made in different sizes to adapt it for the various classes of work to be done with such a tool. Since these drills are primarily for removing metal, and are followed by a reamer, they are made with a small number of flutes so that it is possible to grind them on an ordinary grinder and entirely used up. The composite construction of the drill gives all the advantages of high-speed steel at much less expense.

Core drills of this form have been used by the makers for many years, though of carbon steel, and it is found that the high-speed steel blades will render from five to six times the service of the others and at increased speed.

Another tool is a boring bar, such as has been designed and used by the Lodge & Shipley Co., Cincinnati, and shown in Fig. 3. In the description sent us the writer very pertinently calls attention to the annoyances caused by the ordinary form of boring bar and double-end cutter. Who has not had his patience sorely tried by the slot being crooked in the bar, the cutter not having a proper bearing, or, perhaps, by one of the little points used to center the cutter in the bar being broken off, or the failure of the key to fit properly? This bar has the following features, designed to overcome the usual objections:

The slot is finished complete in the machine and is central and square with the bar. The cutter has the back edge rounded to fit the slot and takes a true bearing against it. The thrust of the cut is taken against the solid metal of the bar, instead of against a key. The cutter is held to its bearing by a *transverse* key and thus avoids springing the bar; both key and slot are finished in the milling machine and the bearing in the bar is rounded like the back edge of the cutter. The transverse key serves also to center the cutter in the bar. The cutter may be sharpened until it is entirely used up without in any way affecting the centering of it, or its bearing in the bar. These cutters have been reduced to standard sizes for different diameters of bars, and may be ordered with the assurance that they will interchange. They are made of best high-speed steel.

Fig 1. New Core Drill.

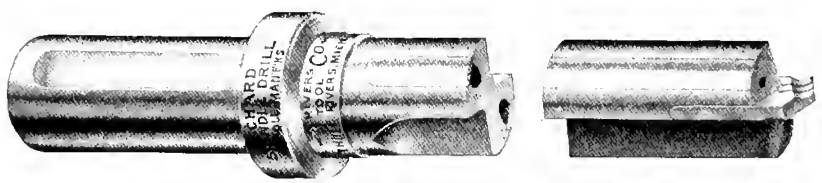


Fig 2 Deep Hole Drill

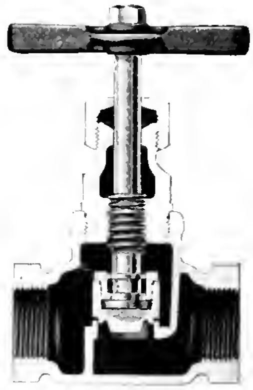

Globe Valve of the Hancock Inspirator Company.

Fig. 2 shows a tool, the outgrowth of the experience of N. D. Chard, superintendent of Lodge & Shipley Co., and used by them in drilling holes in their lathe spindles. This is being manufactured by the Three Rivers Co. It is a straight-grooved two-lip drill, provided with channels for conducting the oil or drilling compound to the point of the drill, to keep it cool and to wash out the chips. The body of the tool is of hard steel, being of unannealed tool steel in the longer lengths, to give greater stiffness. One advantage is the high-speed steel removable point, which may be changed when dull by simply knocking out a taper pin. These points are inexpensive, and the manufacturers of the drill make a small fixture for use in sharpening them. As an instance of what these drills will do, it is stated that the Lodge & Shipley Co. are drilling 1¼ inch holes in 22 spindles of 50-point carbon steel in ten hours. These spindles are 28 inches long, which makes an average of over one inch per minute for an all day's run.

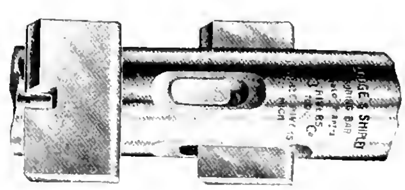

Fig 3 Boring Bar.

NEW GLOBE VALVE.

A new globe valve has been brought out by the Hancock Inspirator Co., 85-89 Liberty Street, New York, in sizes up to three inches. They are of a special composition, giving great strength and resistance to wear, and are made of the same proportions for all pressures to 4,000 pounds per square inch, and are tight under a water pressure of more than 1,000 pounds per square inch; and for 500 pounds steam pressure. The valve disks are of a special mixture not containing zinc, and the spindles are of Tobin bronze, working in a special composition bonnet, which experience has shown will not cut under high steam pressures. In this respect the experience gained in the manufacture of injectors has been made use of. Attention is called to the way in which the valve is guided upon the stem by two collars, thereby compelling the disk to sit squarely. The valve seat is flat and the valve disk has a projection on it which serves two purposes: It acts as a guiding ring when the seat is ground and prevents cutting of the seat by the wire-drawing of the steam when the valve is slightly opened. Also, as this projection is tapered slightly it allows the steam to blow out and clean the valve seat when the valve is opened.

The bonnet is made with a long thread and a narrow shoulder, by which means it is found easier to maintain a tight joint. A T-handle is employed and fits on the tapered end of the spindle, which has one side flattened to fit a taper hole of corresponding shape in the handle. There is thus no trouble from the handle working loose. When it is necessary to regrind the valve the bonnet is removed, the disk nut unscrewed and a piece of wood inserted in the disk, enabling it to be ground perfectly, as the projection on the disk guides it and no special regrinding tools are necessary.

DEVICE FOR TRUING COMMUTATORS.

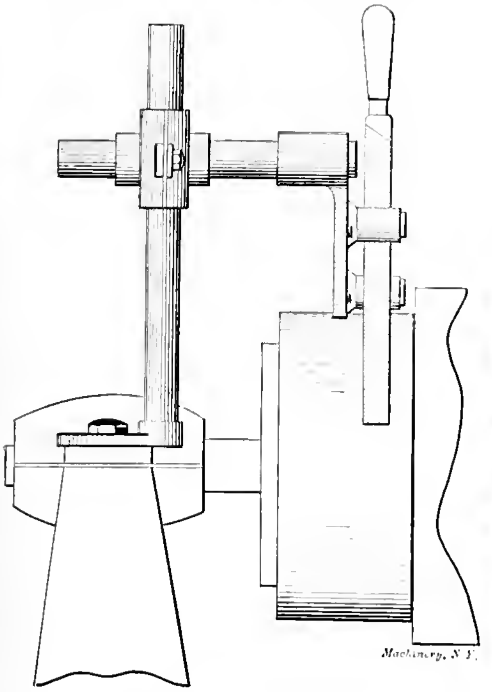
A device for truing commutators by filing has been brought out by the Excelsior Machine Works, Akron, O. The simple construction and method of attaching this device to the generator are clearly shown by cut on next page. One of its principal advantages is that no particular skill nor previous experience in truing commutators is required in order to insure satisfactory results, while the device is applicable to generators of all sizes.

The principal part is the standard, which is provided with a suitable foot by means of which it is securely attached to the generator by one of the cap bolts on the bearing. A horizontal bar is clamped at any height desired. This carries a file holder, which is moved along on the horizontal bar to meet the requirements of the commutator surface. The cutting tool is an ordinary file held in the proper position by means of the file holder. The pins, or file rests, one of which is slotted, are so located as to steady the file without the possibility of chattering.

The file, it will be seen, is moved back and forth over the commutator, and, being rigidly secured, similar to the cuttting tool in the ordinary toolpost, it cuts to a uniform depth, thus not only leveling the surface lengthwise, but restoring the true cylindrical form. Another feature is that commutators may readily be smoothed off as soon as the surface shows the first signs of becoming rough, and before it has become sufficiently uneven to warrant the removal of the armature or even the amount of metal that would ordinarily be taken off by means of a cutting tool. These little machines are manufactured at a low price.

HOLLOW HEXAGON TURRET LATHE.

The No. 3 hollow hexagon turret lathe illustrated herewith has been designed and constructed for the use of high-speed tool steels. It is made in three sizes by the Warner & Swasey Co., Cleveland, O. Fig. 1 shows a general view of the lathe and Fig. 2 an enlarged view of the turret and of the



Commutator Truing Device.

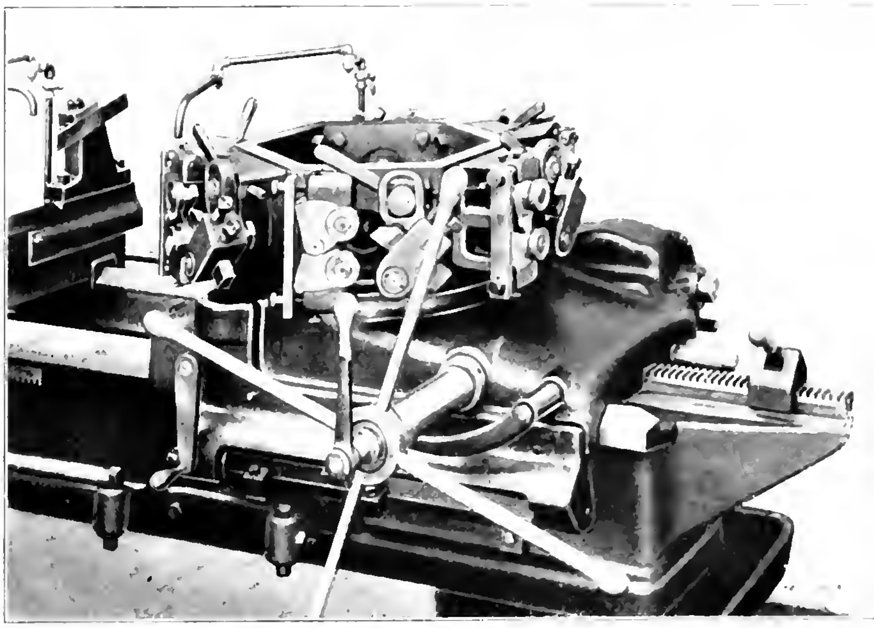


Fig. 2. Showing Turret and Tools of Hollow Hexagon Lathe.

universal turners. The head and the bed of this machine are cast in one piece. The bed is very wide and deep and the vees large.

The cone is geared 3½ to 1 and back-geared 13 to 1, the back gears being engaged and disengaged by friction clutches. There are twelve spindle speeds, ranging from 18 to 190, in geometrical progression, giving about 100 feet surface speed on diameters from 2 inches to 3⅝ inches.

The automatic chuck and the power roller feed, handle bar stock of any shape. The chuck is held in the head of the spindle, which is forged solid, thus bringing the chuck jaws close up to the front spindle bearing, with a minimum of overhang. The chuck is operated by the long lever in front of the head, working through a system of compound levers, which

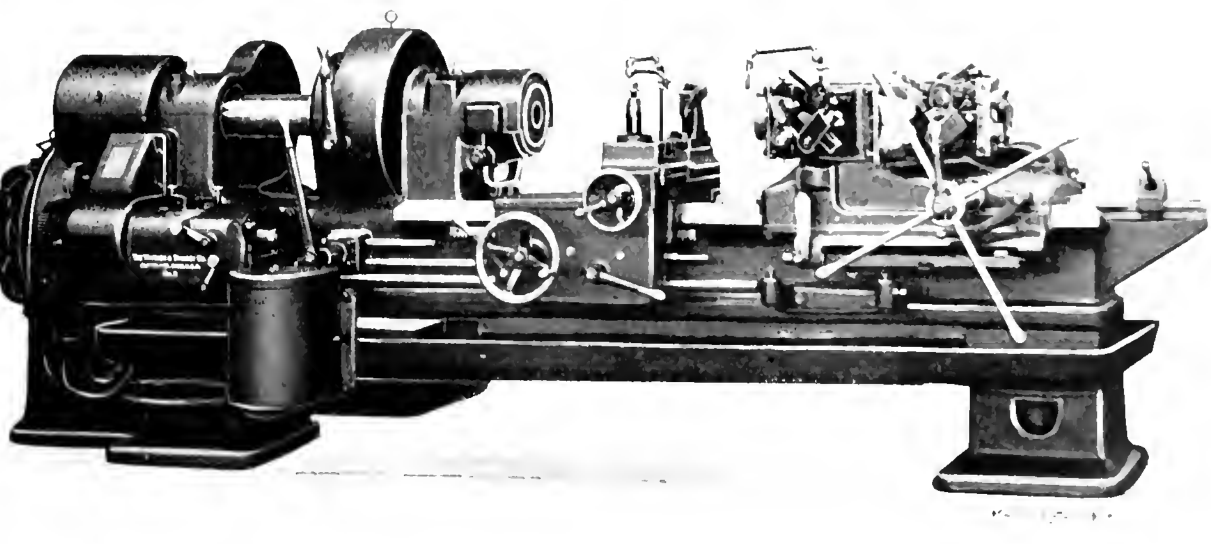

Fig. 1. Heavy Hollow Hexagon Lathe.

give a powerful movement for closing the jaws. The jaws are quickly changed for different diameters of stock and a single screw adjusts the roller feed and the guide fingers.

The turret saddle slides directly on the bed, eliminating all overhang. It is gibbed to the outer edge of the bed by flat gibs throughout its entire length. There are four changes of feed in either direction, varying from 20 to 100 (revolutions of spindle to feed one inch), and screw-cutting feeds for leading-on dies are also provided. The feed rack is located on the top of the bed, midway between the vees, as high up as possible, thus obviating the torsional strain in usual construction, where the rack is placed at the side of the bed. Power quick traverse in either direction is provided for the rapid handling of the turret, and for indexing, the movements being controlled by the lever in front of the turnstile. The independent adjustable stops for each face of the turret are located in front of the saddle, where they are easy of access for changing and adjusting, and at the same time are well protected from chips and dirt.

The hollow hexagon turret is 18 inches across flats, and has a broad bearing on the carriage. It revolves on and is kept central by a large taper bearing with ample provision for taking up wear, and its trussed form provides an exceptionally rigid support for the tools. The index is nearly the full diameter of the turret, and the lock bolt is placed directly under the working tool.

The tool equipment is adapted for a great variety of work, including thread-cutting. The universal turners are adapted for using high-speed tool steels, one of the special features of the tool being the roller back rest, which eliminates the excessive friction due to high speeds. The holder which carries the cutting tool swings about a stud, and can be accurately ad-

justed by means of a screw, while an eccentric lever provides means for quickly withdrawing the tool from the work.

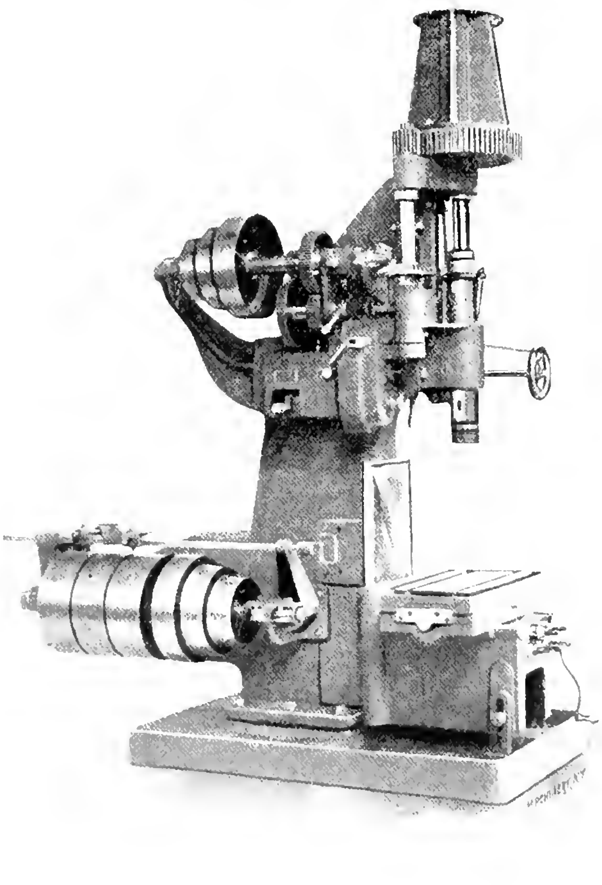
The carriage has 30 inches traverse longitudinally and 10 inches cross motion, both with four changes of feed in either direction. The longitudinal feeds vary from 24 to 120 and the cross feeds from 62 to 312 (revolutions of the spindle to feed one inch). Both feeds have adjustable automatic trips. There are two stops, with automatic trips, for the longitudinal travel; and the cross-feed screw is fitted with a graduated dial. The front of the cross-slide is equipped with a suitable toolpost for holding forming and turning tools, while the rear end carries a holder for cutting-off blades.

All the feeds are gear-driven, and are quickly and easily changed by simply shifting a lever in the feed box. The turret and carriage feeds are independent of each other. The pan and oil reservoir are large. A geared oil pump, operating in either direction, delivers a copious flow of oil to the cutting tools for both the turret and carriage, through two systems of piping. Gears and other revolving parts are covered by metal guards.

The machine shown in the photograph is electrically-driven by a variable-speed motor, direct-connected to the back gear shaft. For belt drive the spindle is equipped with a three-grade cone, and a triple friction countershaft. The net weight of this tool is about 12,000 pounds.

CYLINDER BORING MACHINE.

The half-tone herewith illustrates a new cylinder boring machine just placed on the market by Baker Bros., Toledo, O. The manufacturers call special attention to the time required to bore with this drill and give as an example a closed-end cylinder of 4⅝-inch bore, 11 inches long, upon which the time



Cylinder Boring Machine

for the roughing cut was 7½ minutes; for the second cut, 11 minutes and for reaming 3½ minutes, making the total time for the three cuts 22 minutes.

This machine is fitted with a compound table having 10 inches in and out adjustment, and 24 inches cross adjustment. The table screws are fitted with micrometers so that multiple cylinders may be accurately spaced. A gang of four of these machines has the advantages of a four-spindle machine and these machines have the same efficiency when boring out one-, two-, or three-cylinder engines that they have on four-cylinder engines. The time given above is for multiple cylinder engines where the bore must not only be perfectly true to size, but parallel besides. With independent cylinders, or with open-end cylinders, where a lower support for the boring bar is used, the time may be materially decreased.

Six changes of speed can be obtained and the machine is provided with positive geared feed, giving a range of feeds from ⅛ inch to .004 inch per revolution of spindle. It is also provided with open and cross belts and hand reverse for tapping, and with oil pump, piping and tank for receiving the surplus oil. There is an automatic stop, for stopping the feed when the spindle has reached the required depth, and all handles for operating the tables are in front, easily accessible for the operator. The main specifications of this tool are: Maximum swing, 23½ inches; diameter of spindle, 2¾ inches; vertical traverse of spindle, 4¼ inches; longitudinal movement of table, 24 inches; transverse movement, 10 inches; vertical movement, 24 inches.

NEW HENDEY-NORTON LATHE.

A lathe with special features in the way of improvements for increasing the production is illustrated herewith. It is the product of the Hendey Machine Co., Torrington, Conn.

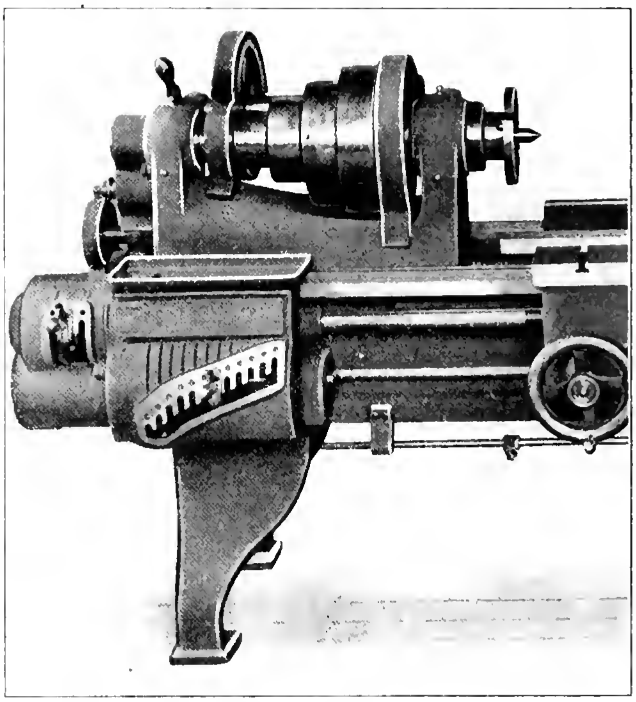


Fig 1. Headstock End of New Lathe.

Attention is called to the new compound gear box which is applied to all sizes of this lathe, from 12-inch to 20-inch swing. This combination gives a broad range of threads and feeds, approximating threads from 1½ to 80 per inch and

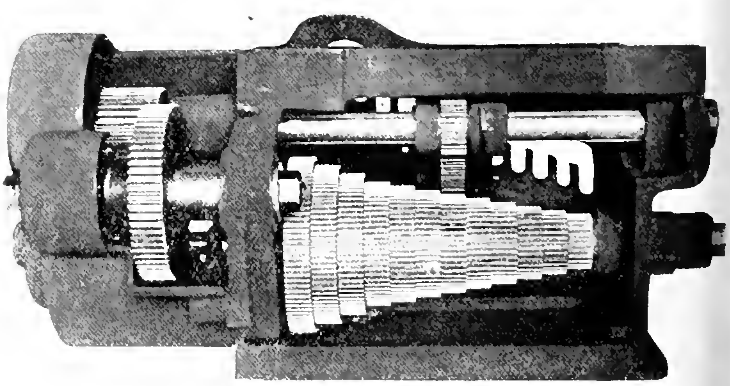

Fig. 2. Rear View of Feed Cone.

feeds from 7½ to 400 per inch. The threads available in this range are all standard pitches. Outside of this regular list of threads, the gearing on the sector of the lathe is so ar-

ranged as to be easily changed so that any special thread or threads not found on the index may be cut with special gear, which gear also works through the whole 36 combination, often cutting other useful threads.

The Hendey-Norton lathe head includes the taper bearing, self-oiling form of spindle construction with annular form of bearings carried in housings having large oil pockets in which a ring oiler for the bearing is suspended, furnishing constant lubrication to the bearings while in motion. The ample lubrication, and the rigidity of the bearings

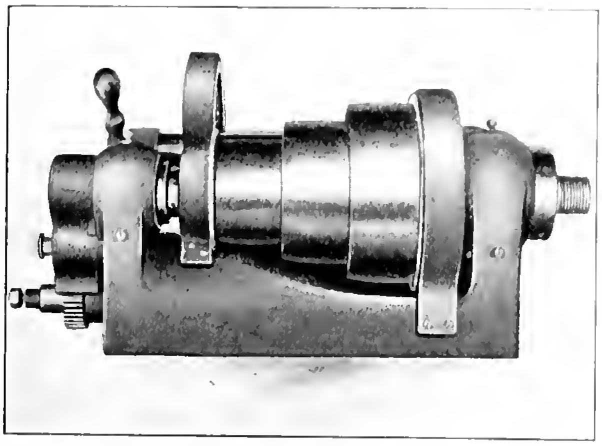

Fig. 3. Headstock Fitted with Three-step Cone for Wide Belt.

make these lathe heads long-lived in alignment and wear. The company state that an inspection and tests made of this lathe head with this form of bearing after six years' continuous service in their shops showed practically as good a bearing as when first assembled, and the alignment of the spindle was maintained with no perceptible change from the beginning.

The strength and rigidity of this lathe head make it possible to use three-step cones in place of the four-step at any time when it is desired to get more power in the spindle drive for high-speed steel work. It is to be noted that as all Hendey-Norton lathes run both belts from the countershaft in the cutting direction, the two countershaft speeds in connection with the three-step cones give 12 different spindle speeds, two more than are obtained with the ordinary type of lathe carrying five-step cones.

The addition of steel gearing wherever necessary, beds and parts made heavier than formerly, increased diameters of spindle noses for heavy chuck work, coupled with the improved features as mentioned, including the automatic stop and apron reverse for carriage, make this tool well adapted to all-around machine work as well as for tool room work.

* * *

FRESH FROM THE PRESS.

THE LAYOUT OF CORLISS VALVE GEARS. By Sanford A. Moss. Published in the Science Series by the D. Van Nostrand Co., New York. Price, 50 cents.

The basis of this little monograph is a series of articles on the lay out of Corliss valve gears contributed by Mr. Moss to the "American Machinist." It is intended as a manual for the drafting room and a complete discussion is given of the theoretical principles underlying the principles of the Corliss gear. This is followed by explicit directions for laying down the motions of a drawing board without resorting to rule-of-thumb methods. Both the single and double eccentric type of engines are taken up, although a complete theory of the latter type is not included.

LOGARITHMS FOR BEGINNERS. By Pickworth. For sale by D. Van Nostrand Co., New York. 47 pages. Price, 50 cents.

The purpose of this little book is to give a more detailed and practical explanation of logarithms and their various applications than is to be found in textbooks on algebra and trigonometry. The book is written in the clear and accurate style that has always characterized the work of Mr. Pickworth, and is to be recommended without hesitation to any one desiring to become proficient in the use of logarithms. A great many examples are worked out, both in the use of logarithms and of anti-logarithms, and there is also a discussion of logarithms having bases other than 10. It includes the treatment of hydraulic logarithms. The logarithmic tables contained in the book are quite brief and suited only to the working out of practice examples. The learner will need to have more complete tables of logarithms at his disposal.

SMOKE PREVENTION AND FUEL ECONOMY. By W. H. Booth and John B. Kershaw. Published by the Norman W. Henley Pub. Co., New York. 194 pages. Illustrated. Price, $2.50.

Mr. Booth, the well-known consulting engineer in England, has been a frequent and valued contributor to American technical journals, and his articles have been of such a character as to command the respect and attention of mechanical engineers generally. It is fair to presume, therefore, that this book will meet with just as much favor on the part of those interested in the subject of smoke prevention. The object in preparing the book was to bring before the fuel-using public a brief statement of the principles of fuel combustion, and of means for securing either complete combustion or smoke consumption, as the case may be. The book starts with the translation of the German work upon the subject by Ernst Schmatolla, and to this has been added considerable matter pertaining to both English and American practice. The treatise is brief and elementary, but apparently is comprehensive and explains methods for the examination of waste gases.

ELECTRIC FURNACES AND THEIR INDUSTRIAL APPLICATIONS. By J. Wright. Published by the Norman W. Henley Pub. Co., 132 Nassau Street, New York. 288 8-vo. pages. Illustrated. Price, $3.00.

The electric furnace is a comparatively new development in the industrial world and the magnitude of the industries that have come into existence through its use, at points like Niagara Falls where immense water powers are available, makes a study of such furnaces both desirable and necessary to those in any way connected with the manufacture of electro-chemical products. The following chapter titles will indicate the scope of the work: Arc Furnaces; Resistance Furnaces and Typical Processes; Calcium Carbide Manufacture; Iron and Steel Production in the Electric Furnace; Phosphorus Manufacture in the Electric Furnace; Glass Manufacture in the Electric Furnace; Electrolytic Furnaces and Processes; Miscellaneous Electric Furnaces and Processes; Laboratory Furnaces and Experimental Research; Tube Furnaces; Terminal Connections and Electrodes, Efficiency and Theoretical Considerations; Measurement of Furnace Temperatures.

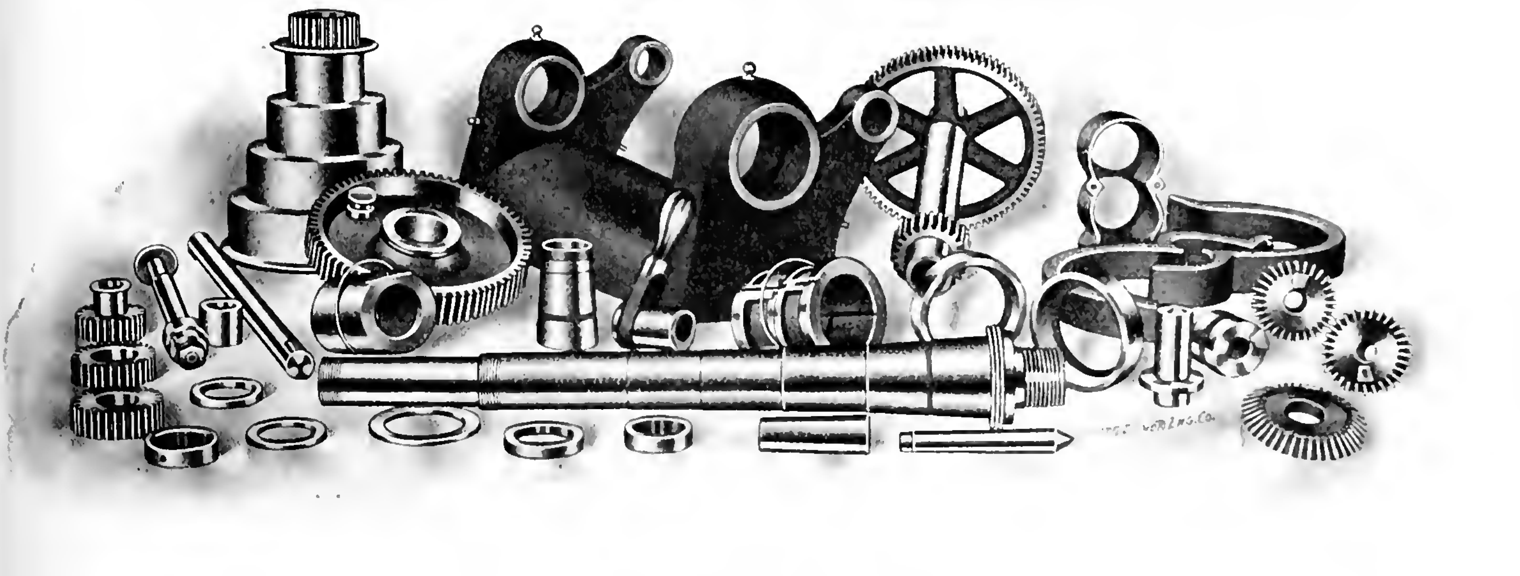

Fig. 4. View of Unassembled Lathe Head, showing the Various Parts.

STEAM BOILERS, THEIR THEORY AND DESIGN. By H. DeB. Parsons, B.S. and M.E. Published by Longmans, Green & Co., New York. 375 8vo pages. Illustrated. Price, $4.00 net. By mail $4.50.

Mr. Parsons is engaged in the work of consulting engineer, and delivers a course of lectures each year at the Rensselaer Polytechnic Institute upon steam boilers. This book covers the subject matter of the lectures and is intended to cover such points as in practical office work may be found to be perplexing. The book is largely descriptive, such mathematics as are used being extremely simple, and it treats of the subjects of combustion, fuels, boiler settings, chimneys, boiler auxiliaries, mechanical stokers, smoke prevention and superheaters, besides the treatment of the boiler itself and the materials entering into it. The illustrations are all made especially for this work and are unusually clear. They number over 150. The book is to be recommended to anyone desiring a complete but elementary treatise on the steam boiler. We are inclined to think it contains practically all the information that even the designing engineer would need to have at his disposal.

DIMENSIONS OF PIPE, FITTINGS AND VALVES. By W. D. Browning. Published by the Draftsman Co., Cleveland, O. 82 8-vo. pages. Illustrated. Price, 75 cents.

This little book is one of the most useful compilations of data for draftsmen that we have seen. It gives exactly the information that any one having to lay out piping would wish to have at his disposal. It is a compilation of tables on iron, lead and spiral riveted pipe, cast iron pipe, drain pipe, etc. These tables include dimensions and particulars in regard to the pipe itself, to their fittings, valves and

miscellaneous articles that go into pipe work. Not only the usual tables to be found in engineers' handbooks and catalogues of pipe manufacturers are here given but also dimensions such as draftsmen need, like for example, the principal dimensions of valves, elbows, tees and other fittings; boiler fittings, such as water columns, gages, injectors, etc.; also particulars in regard to laying out piping for steam-heating bath rooms, etc. It would be highly desirable to have more books of this sort upon other subjects, containing similar data for ready reference.

ELEMENTS OF MECHANICAL DRAWING. By Alpha Pierce Jamison, M.E. Published by John Wiley & Sons, New York. 226 8vo. pages. Illustrated. Price, $2.50.

This book has been developed at Purdue University for instructing first-year students in technical schools, and embraces those branches necessary to give the student such knowledge as will prepare him to pursue a course in engineering. It appears as though at this late day students in drawing would have no difficulty in securing text-books adapted to their needs. This is a well-written and carefully illustrated volume which becomes another addition to the many excellent treatises on drawing. The illustrations are unusually good and the subject matter is grouped under the following headings: Elementary Principles and Definitions; Letters, Figures and Lettering; Projection; Drawing Tools and Materials; Reproduction of Drawings; Patent Office Drawings; Gearing; Color Work; Sketching; The Mechanical Execution of Drawings. The chapter on lettering offers good suggestions; the one on projection is rather brief in its treatment, as is also the one on gearing. The chapter upon the mechanical execution of drawings takes up quite fully the characteristics of working drawings.

ELEMENTS OF GENERAL DRAFTING FOR MECHANICAL ENGINEERS. By C. E. Coolidge, assistant professor, and H. L. Freeman, instructor, in the mechanical department of machine design, Sibley College, Cornell University. Published by John Wiley & Sons, New York. Size, 9 x 12. 51 pages. Illustrated with 21 folding plates. Price, $2.50.

Messrs. Coolidge and Freeman have treated the subject of working drawings exclusively in this textbook, giving what we suppose to be the course of Sibley College upon this subject. As a treatise in the production of working drawings it easily stands as one of the most complete that has appeared. No attempt is made to include anything upon machine design, but rather to show by well-executed plates and suitable descriptive matter what conventional and mechanical drawing are, and how working drawings of different subjects are to be made. The plates include full details of a pillar shaper besides a number of engine parts, to show how machine details should be laid out. In addition there is a plate showing a lay out for piping, one showing engine foundations with templet for anchor bolts, one showing a plan of a building, one in isometric projection and a patent office drawing. The book describes the selection, use and care of materials and instruments for drawing, and the student is shown how to put in a definite form a standard drafting room system which has been worked out by the authors after careful study of many systems.

ELEMENTS OF MECHANISM. By Peter Schwamb, S.B., and Allyne L. Merrill, S.B. Published by John Wiley & Sons, New York. 264 8vo pages. Illustrated. Price, $3.00.

The main subject matter of this work was written nearly twenty years ago by Prof. Schwamb, and has since been used in the form of published notes for instruction in mechanism in the Massachusetts Institute of Technology. Inasmuch as calls were made for the notes from other schools, and it was decided to revise them, they are now brought out in book form. The book, as its name implies, deals almost entirely with elementary motions entering into the mechanism of machine parts. The treatment of the various elements follows closely the plan outlined many years ago by Prof. Reuleaux, but—and this seems to us a decided advantage—these methods have not been followed to the extreme position taken by many writers on mechanism who, in the attempt to be logical, treat the subject in a way that not only would not appeal to practical men who are largely responsible for the various mechanisms treated, but that would be positively confusing to them. The subjects of centroids, instantaneous centers, etc., receive proper recognition, but the book is not filled with such terms. The subjects of cams, parallel motions, crank motions, quick return motions, escapements, trains of gearing such as found in engine lathes, clocks, cotton machinery, etc., and epicyclic gearing appear to be treated very completely. The chapter on speed cones merely takes up the mathematical calculation of the length of belts without giving any of the recent graphical methods developed for laying out such cones. While the book professes to deal only with the elements of mechanism there is a chapter entitled "Aggregate Combinations" in which are shown a few combinations of moving parts, and the book would seem more complete if there had been included in this chapter some of the recent important mechanical movements that have been developed, such for example, as the speed cone arrangements so universally employed in machine tools. Following the treatment of mechanism are about 75 pages on the subject of gearing, showing how to lay out gear teeth. This part appears to be unusually complete.

MANUFACTURERS' NOTES.

THE GRAHAM MFG. CO., Providence, R. I., report that fire recently destroyed most of their stock (over 200 vises), but that they will be able to fill orders that come.

THE JACOBSON MACHINE MFG. CO., Warren, Pa., have just completed a line of patterns for an automatic gas engine in sizes from 5 to 200 H. P., of which they will be glad to furnish full description to any one interested.

THE RAND DRILL CO., New York, report that the United States Government have just purchased from them twenty-seven "Imperial" pneumatic hammers and drills, to be used in connection with the Manila harbor improvements.

THE NORTHERN ELECTRICAL MFG. CO., Madison, Wis., report the following orders recently received: A 200-K. W. Northern generator; Northern dynamos and motors for use in brewing work; three 150-K. W. slow-speed generators, etc.

GEORGE WILLIAM HOFFMAN, Indianapolis, Ind., announces that the "U. S. Metal Polish and Bar Keeper's Friend" received the highest award at the Chicago World's Fair in 1893 and also at the Louisiana Purchase Exposition this year.

THE STANDARD ROLLER BEARING CO., Philadelphia, Pa., have just doubled the size of their plant, have been running all night almost constantly for the past two years. They have just purchased a tract 300 feet by 20 feet for another addition to their foundry.

THE HAYES FILE CO., Detroit, Mich., have just purchased all the machinery and tools of the Simonetta File Co., which was organized in Detroit last May with a capital of $25,000 to manufacture files under a secret process. The Hayes File Co. expect to catch up with their orders as soon as they get the above machinery installed.

THE MASSACHUSETTS TOOL CO., Greenfield, Mass., are offering as a special bargain, from the first of the year till March 15, 1905, four tempered steel rules (one each) 2-inch, 3-, 4- and 6-inch, for $1.00. The accuracy of these rules is guaranteed, and they will be sent to any part of the United States on receipt of the above price.

THE WATSON-STILLMAN CO., New York, announce, with regard to their recent fire, that at present some of their tools are running and that through the courtesy of some of their friends, whose shops have been thrown open to them, they have been enabled to take care of their customers promptly.

THE STOW FLEXIBLE SHAFT CO., Philadelphia, Pa., report the following recent orders: A Halsey portable drill for a firm in Vancouver; an 18 foot flexible shaft and a large crankpin turning machine; also three complete electric hammer outfits, shipped to Italy, for use in the Government navy yards.

THE GARRY IRON & STEEL CO., Cleveland, O., recently shipped ten 30-ton pneumatic jacks, a hand power jib crane and a pneumatic jib crane to three customers. Their recent orders include a 3,000-pound revolving pneumatic crane, mounted on car, and six 1-ton buckets; a 5,000-pound revolving electric locomotive crane; a 15-ton hand power pillar crane; and one 6-ton hand power overhead traveling crane.

W. S. ROGERS, Supt. Philadelphia Bourse, Philadelphia, advises us that the following concerns recently rented space and placed their products on exhibition in the Bourse Exhibition: the Murray Iron Works, engines; the N. C. Lane Co.; Collins damper, regulators, oil filters, etc.; Germania Lamp Co., electric lamps; J. H. Lake & Vaughn Bros., gas and gasoline engines and launches; E. H. Godshalk Co., gas and gasoline engines and launches; Egry Autographic Registering Co., registers and the Egry merchandise systems; Philadelphia Gear Wks. (formerly Grant Gear Wks.), system of gearing; Novelty Tool Mfg. Co., Keystone combination tools, forge, drill, etc.; Pittsburg Fuel Saving Furnace Co., grate and smoke consuming furnace; Frank B. Smith, patent pneumatic despatch apparatus.

THE CROCKER-WHEELER CO., Ampere, N. J., who have recently become licensees of Brown-Boveri & Co., Baden, Switzerland, for their alternating current apparatus, announce the sale of three 4,000 K. W. alternators to the California Gas & Electric Corporation, of San Francisco. These are to be three-phase, 13,000-volt, 25-cycle, 83 R. P. M., revolving field alternators. They are to be driven by 6,000 H. P. gas engines built by the Snow Gas Engine Co., and will be the largest alternators ever built for gas-engine service. They are to furnish power for operating all the street railways in San Francisco and vicinity. This is the first important sale made by the Crocker-Wheeler Co. since acquiring the rights to manufacture apparatus under the Brown-Boveri patents.

NEW TRADE LITERATURE.

Manufacturers and others sending catalogues for notice are requested to address them to the Editor of MACHINERY, so that they can be kept separate from catalogues sent us for other purposes.

THE F. BISSELL CO., Toledo, O. Catalogue showing electric toys, motors and novelties, copy of which will be sent on request.

E. F. HOUGHTON & CO., Philadelphia, Chicago and Detroit. New catalogue illustrating the various methods of installing the Marck steam trap, for the economical use of steam, preventing freezing of pipes, and obtaining uniform heat at a minimum pressure. Mailed free to any one writing to their Philadelphia address, 240 W. Somerset Street.

THE COATES CLIPPER MFG. CO., Worcester, Mass. Bulletin No. 18 treating of the Coates flexible transmission. Herein are illustrated the unit-link, ball-bearing flexible shaft; also housed gear breast drills; the Coates drill press, made in three sizes; a magnetic hold-on; a die-sinker's engine, with Coates patent multiplier; a friction drive center grinder, etc., all using the Coates flexible transmission. Special attention is called to the Coates angle drive, which is new.

THE LUCAS MACHINE TOOL CO., Cleveland, O. Clever little pamphlet entitled "Why Does a Dog Waggle His Tail?" to which the answer is because "the dog is bigger than the tail," and the argument is put forth that raising and lowering a heavy piece of work in a boring machine is like "the tail wagging the dog," and that it is better to raise and lower the spindle; which is how it is done with the "Precision" boring, drilling and milling machine of this company.

THE CHICAGO PNEUMATIC TOOL CO., Chicago and New York. Catalogue, standard size, of pneumatic tools. Among these are listed the Boyer riveting hammers, chipping, calking and beading hammers, piston air drills, angle gears; the "Little Giant" flue-rolling, reaming and tapping machines; the improved "Chicago" air forge; rock drills, pneumatic motors and geared hoists, special air hoists, etc., etc. The catalogue appears to be very complete and will give a good idea of the products of this company. There are a large number of illustrations.

THE GISHOLT MACHINE CO., Madison, Wis. Illustrated catalogue, 8 x 10, of boring mills. A few sizes of the general line of vertical and horizontal mills are shown. A 34-inch vertical boring mill, with plain head and with swivel head; a 42-inch vertical boring mill with two swivel heads, and one with turret head; the 52-, 60-, 64- and 72-inch vertical boring mills; a horizontal mill; the "Gisholt" turret lathe and the "Gisholt" tool grinder. Brief descriptions accompany the very fine illustrations of each of these tools. The catalogue is printed on heavy coated paper and is a most creditable piece of work.

THE DERRY-COLLARD CO., 256 Broadway, New York. "Books and Things, No. 2," a pamphlet listing technical books. These treat of machinery, electricity, civil and steam engineering, pattern and foundry work, marine work, woodworking, plumbing and heating. There are also books on drawing and a list of the new books just out. Attention is called to the "D-C Book Club," by which plan one may buy any books or papers by paying $1, $2, $3 or $5 a month. The "Book Club Folder" explains this fully and will be sent to any one interested. This company also send on approval any mechanical book costing $1 or more, which may be returned if not satisfactory.

MISCELLANEOUS.

Advertisements in this column, 25 cents a line, ten words to a line. The money should be sent with the order.

MACHINERY.

February, 1905.

ROLLER CHAIN POWER TRANSMISSION AND CONSTRUCTION OF SPROCKETS.

A. EUGENE MICHEL.

A. Eugene Michel.

Machined chains and milled sprockets have but recently attained their present high standard. It is therefore not strange that the engineering literature of this country and Europe contains little valuable information concerning them. Ignorance and neglect of mechanical laws have resulted, and the users of chain drives have been subjected to difficulties, many of which may be eliminated by proper construction.

Steel chain of accurate pitch, high tensile strength, and good wearing qualities, possesses, when used within proper limitations, advantages enjoyed by no other form of transmission. It is compact, affords an absolutely positive speed ratio, and at slow speeds is capable of transmitting heavy strains. On short transmissions it is more efficient than belting, and will operate more satisfactorily in damp or oily places. There is no loss of power from stretch, and as it allows of a low tension, journal friction is minimized. The first cost is little more than that of belting for the same duty. Sprockets cost more than pulleys, but admit of great reduction in size and weight.

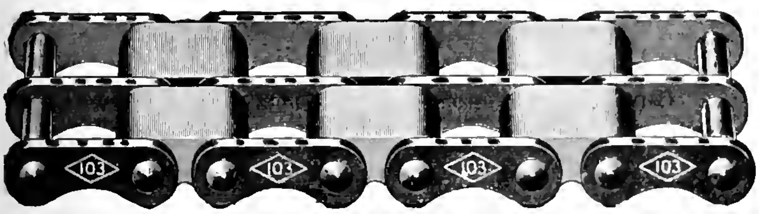

Fig. 1. Double-width Block Chain.

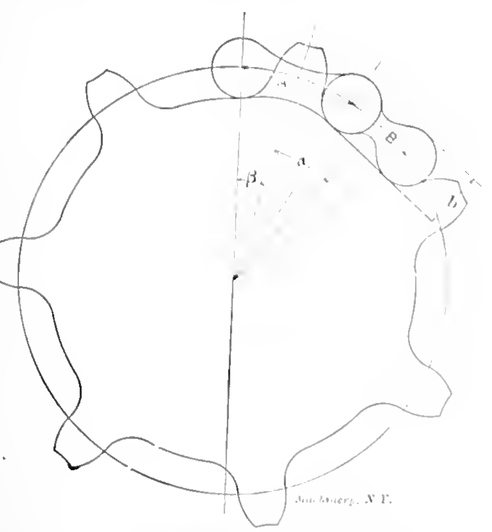

Fig. 3. For obtaining Pitch, Bottom and Outside Diameters of a Block Chain Sprocket.

Roller chain has been known to stand up at a speed of 2,000 feet per minute, and transmit 25 horse power at 1,250 feet per minute; but speeds of 1,000 feet per minute and under, give better satisfaction. Block chain is adapted to slower speeds, say 700 feet per minute and under, and is extensively used on bicycles, small motor cars and machine tools. Where speed and pull are not fixed quantities, it is advisable to keep the speed high, and chain pull low, yet it should be borne in mind that high speeds are more destructive to chains of large, than to those of small pitch.

The following table of tensile strengths, based on tests of "Diamond" chains taken from stock, may be considered a fair standard:

ROLLER CHAIN

Pitch.	Tensile Strength, Pounds.	Pitch.	Tensile Strength, Pounds.
1/2 inch	1,200	1 1/4 inch	9,000
5/8 inch	1,200	1 1/2 inch	12,000
3/4 inch	4,000	1 3/4 inch	19,000
1 inch	6,000	2 inch	25,000
BLOCK CHAIN			
1 inch	1,200 to 2,500	1 1/2 inch	5,000

It is a common fallacy that the safe working load of a chain is close to the ultimate tensile strength. The safe working load is dependent on the amount of rivet bearing surface, and varies from 1-5 to 1-40 of the tensile strength, according to the speed, size of sprockets, and other conditions peculiar to each case. The tendency now is to use the widest possible chain in order to secure maximum rivet bearing surface, thus insuring minimum wear from friction. In the last few years manufacturers have been making heavier chains than heretofore for the same duty. As short pitch is always desirable for high or low speeds, special double and even triple-width chains are now made to conform to the requirements when a heavy single width chain of greater pitch is not practical. Fig. 1 represents such a double chain having twice the rivet bearing surface and half again as much tensile strength as the similar single one.

Fig. 2. For Calculating Exact Length of Chain for a given Drive

The exact length of chain for a given drive is not so easily obtained as it seems at first sight. The following formula will be found useful: (See Fig. 2.)

All dimensions in inches.

D = Distance between centers of shafts.

A = Distance between limiting points of contact

R = Pitch radius of large sprocket.

r = Pitch radius of small sprocket.

N = Number of teeth of large sprocket

n = Number of teeth of small sprocket

P = Pitch of chain and sprockets.

$(180 + 2a)$ (see Fig. 2) = angle of contact on large sprocket

$(180 - 2a)$ = angle of contact on small sprocket.

$$a = \sin^{-1}\frac{R - r}{D}$$

$$A = D\cos a$$

A. EUGENE MICHEL was born in St. Louis, Mo. 1880. He is a graduate in mechanical engineering of the Rose Polytechnic Institute. Since graduation he spent two years in the engineering department of the Federal Mfg. Co.'s diamond chain factory. He resigned his position with this concern to take charge of the new testing department of the Ewart Mfg. Co., Indianapolis, Ind., and will there direct tests of the Renold silent chain and detachable link belting.

Length of chain required.

$$L = \frac{180 + 2\,a}{360}\,N\,P + \frac{180 - 2\,a}{360}\,n\,P + 2\,D\cos a$$

For *block* chain, the total length specified in ordering should be in multiples of the pitch. For *roller* chain, the length should be in multiples of twice the pitch, as a union of the ends can be effected only with an outside and an inside link.

PITCH DIAMETERS FOR ROLLER CHAIN SPROCKETS.

75	11.939	14.923	17.908	23.878	29.848	35.817	41.786	47.756

Wherever possible, the distance between centers of shafts should permit of adjustment in order to regulate the sag of the chain. A chain should be adjusted, in proportion to its length, to show slack when running, care being taken to have it neither too tight nor too loose, as either condition is destructive. If a fixed center distance must be used, and results in too much sag, the looseness should be taken up by an idler, and when there is any considerable tension on the slack side, this idler must be a sprocket. Where an idler is not practical, another combination of sprockets giving approximately the same speed ratio may be tried, and in this manner a combination giving the proper sag may always be obtained.

In automobile drives, too much sag or too great a distance between shafts causes the chain to whip up and down—a condition detrimental to smooth running and very destructive to the chain. In this class of work a center distance of over four feet has been used, but greater efficiency and longer life are secured from the chain on shorter lengths, say three feet and under.

Properly proportioned and machined sprockets are essential to successful chain gearing. Sprocket cutting is not difficult, yet strange to say, most American practice is bad. Hence the writer presents these formulas and data to enable any manufacturer to do this work correctly, and at little cost.

The important dimensions of a sprocket are the pitch diameter and the bottom and outside diameters. For block chain these are obtained as follows: (See Fig. 3.)

N = No. of teeth.

b = Diameter of round part of chain block.

B = Center to center of holes in chain block.

A = Center to center of holes in side links.

$$a = \frac{180^\circ}{N}$$

$$\operatorname{Tan}\beta = \frac{\sin a}{\dfrac{B}{A} + \cos a}$$

$$\text{Pitch diameter} = \frac{A}{\operatorname{Sin} \beta}$$

Bottom diameter = pitch diameter − b.
Outside diameter = pitch diameter + b.

For roller chain: (See Fig. 4.)

N = Number of teeth.
P = Pitch of chain.
D = Diameter of roller.

$$a = \frac{1}{2}\ \frac{360}{N}$$

$$\text{Pitch diameter} = \frac{P}{\sin a}$$

Bottom diameter = pitch diameter − D.
For sprockets of 17 teeth and over,

Outside Diam = Pitch Diam. + D.

The outside diameter of smaller sprockets are cut down so that the teeth will clear the roller perfectly at high speeds.

Outside Diam. = Pitch Diam. + D − E.

Pitch.	Values of E. 8 to 12 Teeth.	13 to 16 Teeth.
½ inch to ¾ inch	.062 inch	.031 inch
1 inch to 2 inches	.125 inch	.062 inch

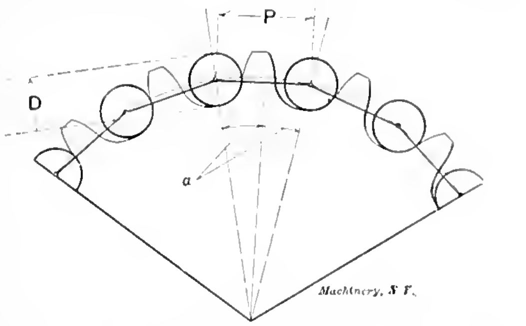

Fig. 4. For obtaining Pitch, Bottom and Outside Diameter of a Roller Chain Sprocket.

The tables of diameters on previous page have been prepared from these formulas.

Sprocket diameters should be very accurate, particularly the base diameter, which should not vary more than .002 inch from the value obtained from the tables. All sprockets should be gaged to discover thick teeth and inaccurate diameters. A poor chain may operate on a good sprocket, but a bad sprocket will ruin a good chain. Sprockets of twelve to sixty teeth give best results. Fewer may be used, but cause undue elongation in the chain, wear the sprockets and consume too much power. Eight-tooth sprockets ruin almost every roller chain applied to them, and ten and eleven teeth are fitted only for medium and slow speeds with other conditions unusually favorable.

Sprocket teeth seldom break from insufficient strength, but the tooth must be properly shaped. A chain will not run well unless the sprockets have sidewise clearance and teeth tapered at the ends. Fig. 5 is a practical shape.

Calling W the width of the chain,

$$A = \frac{W}{2}$$

$B = W$ − 1-64 inch when W = 1-4 inch or less.
$= W$ − 1-32 inch when W = 5-16 to 5-8 inch inclusive.
$= W$ − 1-16 inch when W = 3-4 inch or over.

Note that the curvature at the end of the tooth begins at the pitch line.

If the sprocket is flanged the chain must seat itself properly without the side bars coming into contact with the flange. The following values of C will be found safe:

Chain.	C not less than
1 in. P block, 1 in. P twin roller and ½ inch P block and ⅝ inch P roller	1-4 inch
1½ inch P block and ¾ inch P roller...	11-32 inch
1 inch P roller	1-2 inch
1¼ inch P roller	9-16 inch
1½ inch P roller	5-8 inch
1¾ inch P roller	13-16 inch
2 inch P roller	15-16 inch

The principal cause of trouble within the chain is elongation and this must, as far as possible, be eliminated. It is the result of stretch of material or natural wear of rivets and their bearings. To guard against the former, chain makers use special materials of high tensile strength, but a chain subjected to jars and jolts beyond the limit of elasticity of the material may be put in worse condition in an instant than in months of natural wear. If for any reason a link elongates unduly it should be replaced at once, as one elongated link will eventually ruin the entire chain. Such elongation frequently results from all the load being thrown on at once.

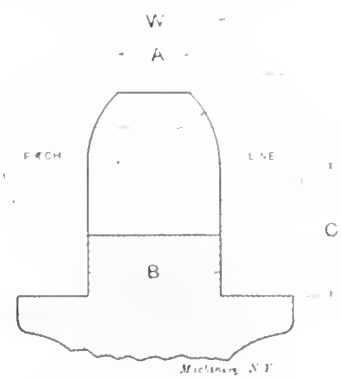

Fig. 5.

To minimize natural wear, chains should be well greased inside and out, protected from mud and heavy grit, cleaned often and replaced to run in the same direction and same side up. A new chain should never be applied to a much worn sprocket.

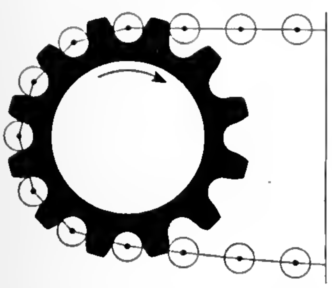

Fig. 6 A.

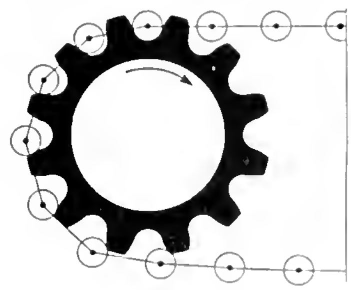

Fig. 6 B.

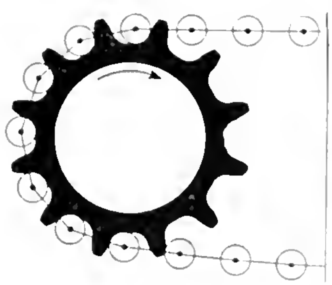

Fig. 7 A_1.

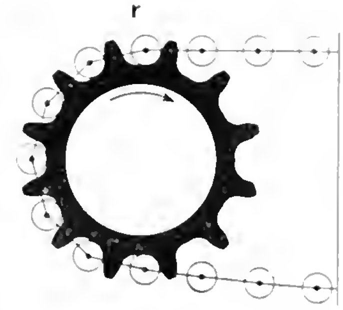

Fig. 7 B_1

The importance of pitch line clearances is clearly shown in Fig. 6, which represents a sprocket with no clearances.

The new chain, 6A, fits perfectly, but after natural wear, 6B the pitch of chain and sprocket become unlike. The chain is then elongated and climbs the teeth which act as wedges, producing enormous strain and disagreeable racket, and quickly wrecks itself.

Fig. 7 is the same chain on a driven sprocket, cut with clearances. When new, A_1, all rollers seat against their teeth. After long and useful life, B_1, the working roller, r, has shifted to the top, and the other rollers still seat with the same ease as when new. The chain may still be used until the stage indicated in B Fig. 6, is reached. B_1 also shows that the chain pull is taken by the one roller, r. Theoretically, all the rollers share the load in the case of A_1. This never occurs in practice, for infinitesimal wear within the chain causes *one, and only one*, roller, r, to bear perfectly seated against the working face of the sprocket tooth at any one time. In Fig. 8, A_1 shows the driver cut with clearance and with a new chain; B_1, the same chain after wear, which demonstrates that clearance alone on the driver will not provide for elongation. To operate properly the pitch of the driver must be lengthened.

which is done by increasing the pitch diameter by an amount dependent upon the clearance allowed.

In Fig. 9, A_3 is a new chain on a driver cut with clearance and increased pitch diameter. The working roller, r, is at the bottom of the sprocket. After the chain wears, B_3, the working roller, r, shifts to the top, and the chain is still good until the condition of B_2, Fig. 8, is reached.

This demonstration is quite true for a drive in which the chain pull is *always in the same direction*, and should be applied for such drives. The theoretical reasoning is intricate, so I shall refer those interested to "Roller Chain Gear," a treatise on English practice, by Hans Renold.

When the load reverses, and this is more frequently the case, each sprocket becomes alternately driver and driven. This happens in a motor car during positive and negative acceleration, or in ascending or descending a hill. In this event, the above construction is not applicable, for a driven sprocket of longer pitch than the chain will stretch it. No perfect method of equalizing the pitch of a roller chain and its sprockets under reversible load and at all periods of chain elongation has been found. This fault is eliminated in the "silent" type of chain; hence it runs smooth at a very much greater speed than roller chain will stand.

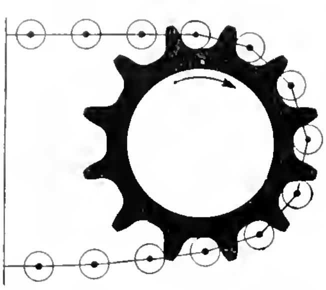

Fig. 8 A_2.

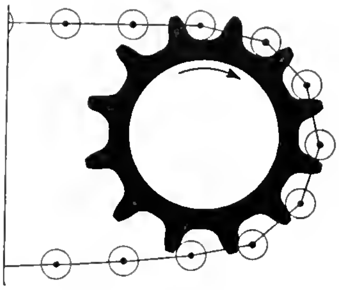

Fig. 8 B_2.

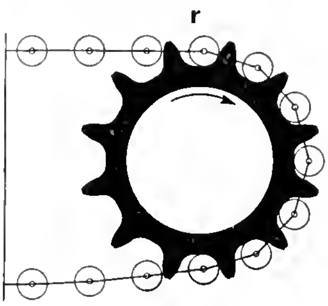

Fig. 9 A_3.

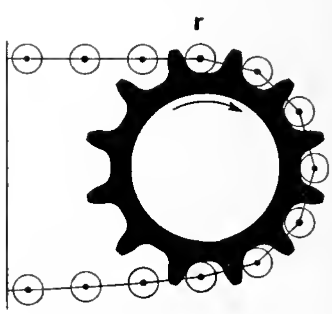

Fig. 9 B_3.

In practice there are comparatively few roller chain drives with chain pull always in the same direction, so manufacturers generally cut the driver sprockets for these with normal pitch diameter, same as the driven. Recent experiments have proven that the difficulties are greatly lessened by cutting both driver and driven with liberal pitch line clearance. Accordingly, chain makers now advise the following pitch line clearance (C in Fig. 10) for standard rollers:

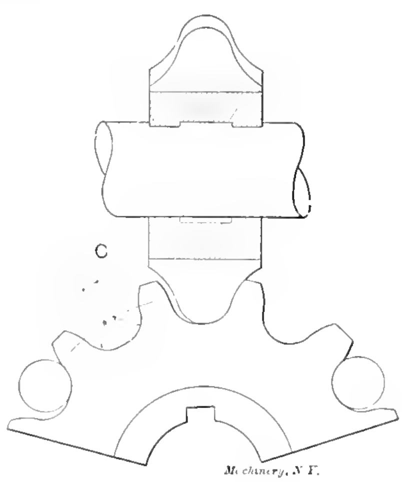

Fig. 10.

Pitch.	Clearance.
½ inch and ⅝ inch	1-32 inch
¾ inch	1-16 inch
1 inch	3-32 inch
1¼ inch	3-16 inch
1½ inch	7-32 inch
1¾ inch	1-8 inch
2 inch	5-32 inch

Cutters may now be obtained from B. & S. with this clearance, but their former cutters have only from .015 inch to .030 inch or none at all. To obtain the proper clearance with the older cutters, mill the sprocket, as usual, revolve it a sufficient amount to make the clearance conform with the above table, measuring on the pitch line (Fig. 10) and take an additional cut around. The base diameter should remain as figured from the pitch tables.

The above clearance table is figured for American and English standard size rollers, and will not apply to the Whitney standard. With this latter, it is not possible to obtain so much clearance on the 1, 1¼ and 1½-inch pitch without weakening the tooth beyond a safe limit.

There is yet much to be learned about roller chains and the pitch line clearances of their sprockets, but the hints herein given should enable chain users to obtain better results from their drives.

* * *

The use of nickel steel is becoming more and more extensive. In a report on the subject of steel hardening metals by Mr. Joseph H. Pratt, in the United States Geological Survey, it is stated that over 11,000 tons of nickel steel rails were manufactured in 1903. These rails were used on the Pennsylvania, Baltimore & Ohio, New York Central, Erie, Chesapeake & Ohio, and Bessemer & Lake Erie railroads. They are largely used on sharp curves where their value was first demonstrated by the Pennsylvania R. R. on the famous Horse Shoe Curve, near Altoona, Pa. From experiments made on this curve, it appears that nickel steel rails will outlast four ordinary steel rails. Nickel steel is also being extensively used where a non-rusting metal of high tensile strength is required. Nickel steel containing from 25 to 30 per cent nickel resists rust to a remarkable degree. It is being used in mines, for torpedo defense netting, umbrella wire, corset stays, condenser and boiler tubes, and many other purposes where steel is subjected to dampness. Not the least important feature of these nickel steel alloys containing a high percentage of nickel is the remarkable decrease in the coefficient of expansion. In fact with the alloy known as invar, the coefficient of expansion is nearly zero. By varying the proportions of nickel and steel the coefficient of expansion may be changed to agree with that of other metals, as for instance, platinum. Hence it is being substituted for platinum, which is very expensive, in the manufacture of incandescent lamps. Platinum happens to have practically the same coefficient of expansion as glass, which makes it possible to use it for the terminals which must pass through the glass. With other metals having a different coefficient of expansion the glass will crack, or the terminals will be loose, thus allowing leakage of air and destroying the high vacuum necessary to the success of the incandescent lamp.

* * *

A device known as the de Forest wireless ship localizer, the aim of which is to warn ships of their nearness to dangerous points, will be given experimental trial shortly on the Great Lakes. Ships so warned will have to carry wireless telegraph apparatus. For the tests on the lakes it is intended to install 52 automatic stations at the points of greatest danger to ships. These stations will operate continuously upon the approach of fogs or storms, and their effect will be felt for about six miles. Each will have its own characteristic call, so that an operator at a wireless instrument on shipboard hearing such a call will know that he is within six miles of the given locality. The intensity of the call increases as it is approached. The instrument on board ship for receiving the call is equipped with a long flat screen, pivotally mounted, in place of the antennæ wires usual in wireless telegraphy. By constantly turning the screen while the signals are being received, the direction from which the call comes may be indicated.

A REVIEW OF STEAM TURBINE PATENTS.—4.

Richard Schultz, 1900.

This invention, shown in Fig. 53, cannot be regarded other than as a modification of Pyle's turbine of 1895. Steam passes longitudinally through the wheel several times, as indicated in the engravings. *A* and *B* are two wheels attached to the shaft; *C* is an intermediate stationary disk with guide

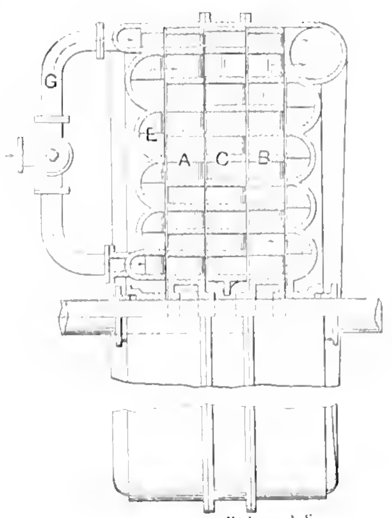

Fig. 53. Schultz Reversing Turbine.

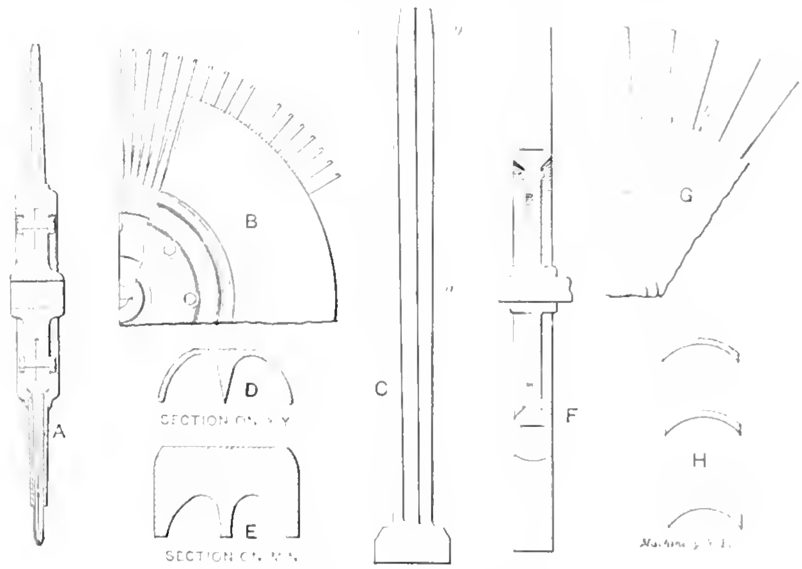

Fig. 54 Wheels Patented by Zoelly

passages, and *E* and *F* are stationary castings for reversing the direction of flow of the steam after it has passed through the passages of the wheels and guides, and directing it back through the next series of passages. In addition, he provides for a series of vanes for reversing the direction of motion against which steam flowing through the pipe at *G* impinges.

Zoelly, 1900.

The group in Fig. 54 shows certain features of construction for turbine wheels covered by two patents issued to Heinrich Zoelly, Zurich, Switzerland, one in 1900 and the other in

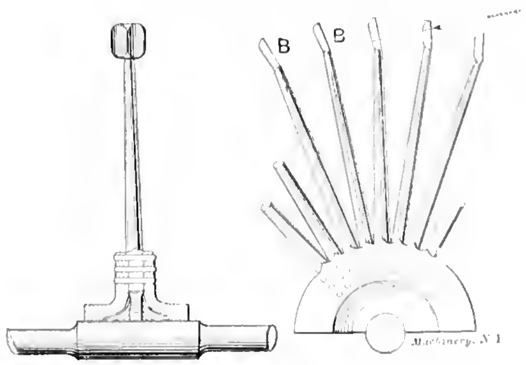

Fig. 55. Richards' Pelton-type Wheel.

1903. The inventions relate to wheels with radial arms, the outer ends of which serve as vanes for the wheel. These arms decrease in cross-section as they approach the periphery of the wheel and thus are proportioned to resist centrifugal force in such a way as to produce a uniform stress per square inch throughout their length.

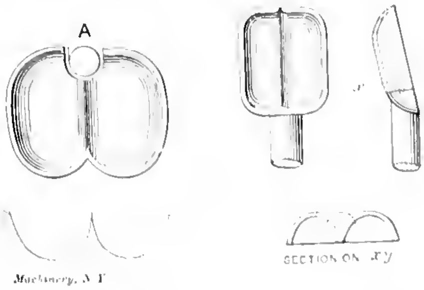

Fig. 56 Buckets proposed for Richards Wheel

The patent of 1900 is for a design of turbine blades suited to the Pelton type of wheel in which the stream is projected against the faces of blades which have a central rib to divide the stream and cause it to turn through nearly 180 degrees and discharge on each side of the wheel. The first claim of this patent is for "the combination in a turbine wheel of radial buckets separated from each other for a part of their length, each bucket having its receiving face channeled for the greater portion of its length, and a pair of flat disks inclosing said buckets from their inner ends for a greater portion of the length of the channeled part of the buckets." In Fig. 54, *A* and *B* are two sectional views of the wheel, *C*, an enlarged front view of one of the blades, and *D* and *E*, enlarged sections of the blade on the lines x y and m n respectively. At *F* and *G* are details of a wheel now used in the Zoelly turbine and already described in MACHINERY. In this type, the steam is directed against the blades on one side of the wheel and escapes on the other side. Sections of the blades are shown at *H*. The first claim is for a "turbine blade constructed with a gradually increasing longitudinal thickness and a longitudinal cavity of substantially uniform depth." Some of the other claims relate also to the method of clamping the blades in position, and the use of spacing blocks, *b b*, between them.

Richards, 1902.

The idea presented in the Zoelly patent of 1900 is carried a step further in a patent issued to J. Richards for a Pelton type of wheel, Fig. 55. The wheel consists of buckets, *B*, light in weight and drop forged on the ends of radial arms, which are attached to a central nave by pins inserted between the arms, as indicated in the illustration. The buckets are spaced

Fig 57 Buckets and Guides for Stumpf Turbine

further apart than is usual in turbines, because they are designed to be concave and reactive through a considerable angle of rotation, and thus will absorb the energy of the jet sufficiently throughout this range. The arms of the wheels are not covered by plates at the sides, as in the Zoelly design, the intention of the inventor being that the inside of the turbine casing shall be machined smooth, and the steam allowed to rotate with the wheel within the casing. The claim is in substance for a wheel having a single hub, of a diameter within the zone of disruptive centrifugal strain, with equidistant radial sockets formed therein; strong radial stems fastened in the sockets; and concave reactive buckets integrally formed on the extremities of the stems.

Stumpf, 1903.

The Pelton type of wheel devised by Prof Stumpf contains double U-buckets with a dividing ridge, milled out from the solid rim of the wheel and taking the form shown in the plan and sectional views of Fig. 57. He proposes to use a series of guide passages having the general contour of the dotted line shown at *A*, which gather up the steam after it has issued from the two sides of the wheel and return it in a single, solid stream at the center, where it impinges a second time against the blades of the same wheel. In Fig. 58 is shown a modified form of the guides having partitions extending in the direction in which the steam flows, for the purpose of insuring equal division of the steam jet over the whole breadth of the return buckets, with a view to preventing choking of the steam at the point where it strikes the wheel vanes.

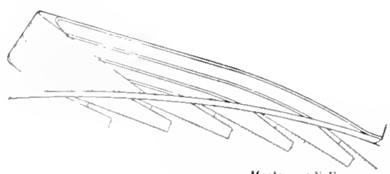

Fig 58 Modified Form of Guides for Stumpf Turbine.

It is pointed out by Prof. Stumpf that steam, in reversing its direction of flow in a turbine wheel, acquires sufficient centrifugal force to increase its pressure, frequently by a considerable amount, so that in leaving the vanes there is a sudden explosive expansion of the steam, causing a scattering of the jets. By catching the steam in the return buckets as it leaves the wheel, and bringing the streams together in a solid jet again at the center, he aims to overcome this action and to produce a more efficient type of compound turbine. His claims are broad ones, applying to the combination of admission nozzles, a turbine wheel with double buckets and double return buckets.

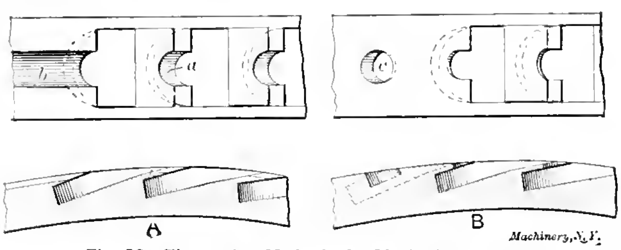

Fig. 59 Illustrating Methods for Machining Buckets.

In connection with the Stumpf patent, one issued in 1904 to Kaufhold and Hoffmann, and assigned to the manufacturers of the Stumpf turbine, relates to the process of cutting out the buckets. In order to insure a change in direction of the fluid of 180 degrees it is necessary that the grooved portion of the recess should complete a full half circle, and this is easiest accomplished by means of a disk milling cutter. In using such a cutter, however, it is necessary to cut out a circular portion of the rim, to allow room for the cutter arbor, as indicated at *a* in Fig. 59. One method of doing this is to use a stepped milling cutter, one part of which cuts the larger recess and the other part the smaller recess for the arbor. The methods covered by the patent, however, consist first in turning a groove, *b*, in the rim of the wheel before milling the recess, which obviously will accomplish the desired end. The other method is to drill holes in the rim, as shown at *c*. The inventors prefer either of these methods to the use of the stepped cutter method.

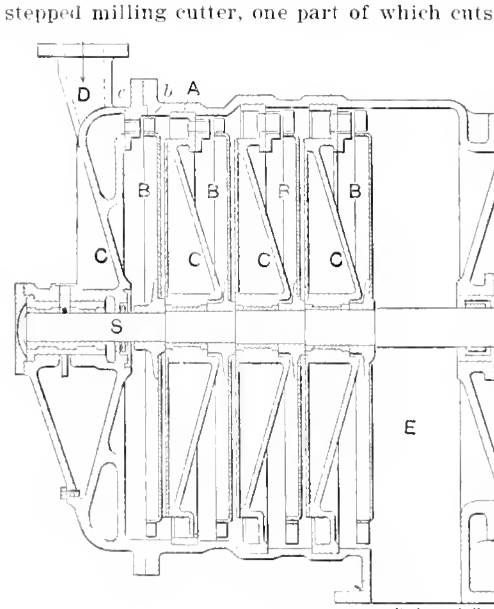

Fig. 60. Section of Rateau Turbine.

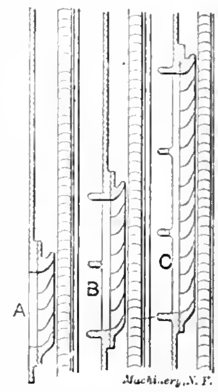

Fig. 61. Arrangement of Guides in Rateau Turbine.

Rateau and Sautter, 1903.

The Rateau turbine, the main principles of which are covered by this patent is, like the invention of Moorhouse, 1887, an impulse turbine consisting of a number of wheels upon which the steam acts in succession, each wheel being in a separate compartment. In Fig. 60, *A* is the turbine casing, *B B*, etc., are the rotating wheels attached to the shaft, *S*, and *C C C* are diaphragms forming the separate compartments. Steam enters through the intake pipe at *D*, passes between a series of guide vanes at *c*, where it is directed against the vanes, *b*, of the first wheel. It then passes through the guide vanes in the next diaphragm and impinges against the next wheel, and so on, until the exhaust space, *E*, is reached. The depth of the guide blades and wheel vanes increases progressively from the inlet to the outlet, to allow for the increasing volume of the steam.

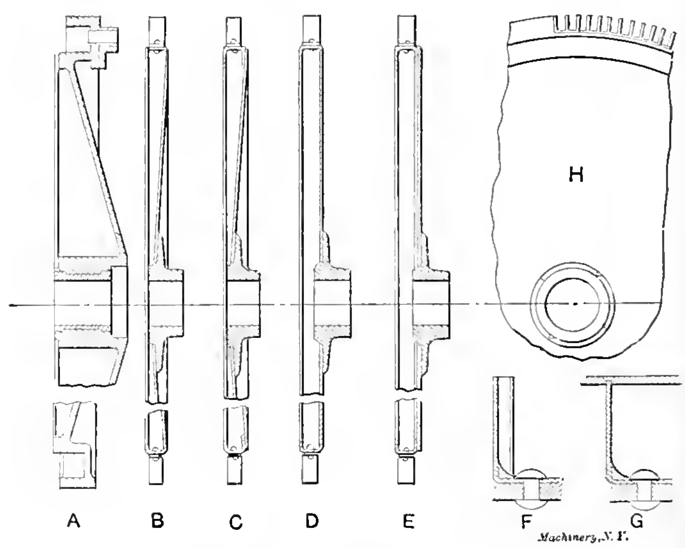

Fig. 62. Construction of Rateau Disks and Wheels.

The principle of this turbine as thus far outlined is in no way different from that of Moorhouse; but Rateau has introduced a principle in the arrangement of the vanes which is new and is covered by this patent. In Fig. 61 the first set of guide blades is shown at *A*. These are few in number and are arranged in, say, three groups about the periphery of the first disk. After passing through the wheel the next set of guide blades is reached at *B*, which consists of a greater number to accommodate the increasing volume of the steam, and these blades are arranged so as to extend by the first set in the direction in which the steam flows, as shown. When the steam reaches the first wheel it will be carried along a short distance by the rotation of the wheel before discharging into the wheel chamber, and a portion of the next set of guide blades should be located in advance of the previous set. At *C* the third set laps by still more, and finally a point will be reached where the blades will extend around the full periphery of the casing. The advantage of this arrangement over one in which steam is first admitted to the turbine around the whole periphery is that the steam at the admission point is comparatively small and the vanes would necessarily have but little radial depth at that point if they comprised a full circle, and there would be excessive friction of the steam when flowing through them. In the Rateau arrangement the steam passages are deeper and the volume of steam passing is large, in proportion to the rubbing surfaces of the vanes. The reference to this in the claims of the patent is as fol-

lows: "* * * distributors arranged in the membranes to direct the motive fluid directly upon the paddle blades, and said distributors increasing in width, and overlapping each other successively at one end and not at the other." Rateau also introduces features of construction on which claims are made, but which are in no way tied with the blade arrangement mentioned above. Some of these are shown in Fig. 62. At *A* is one of the diaphragms containing the guide vanes. At *B*, *C*, *D*, and *E* are typical wheels consisting of steel disks either flanged around their peripheries or else with annular channels riveted to their peripheries. In the first two instances, *B* and *C*, the disks are dished to add to their lateral strength and in the last two they are flat.

The vanes, which are curved suitably at the points where the steam strikes, are bent on an angle and riveted to the circumference of the disk. At *F* and *G* are enlarged details of the vanes, the second one showing a band or shroud riveted to the outer circumference.

Levin, 1904.

A type of wheel in which the steam is expanded completely in a nozzle before impinging against the buckets of the wheel and then is used several times in succession upon the blades of the same wheel. Steam is expanded in the nozzle, *N*, which projects it against one side of the semi-circular buckets, *B*, of the wheel. The steam passes around these buckets and is projected outward against the curved surface, *C*, of the casing twice in succession, which each time redirects the steam

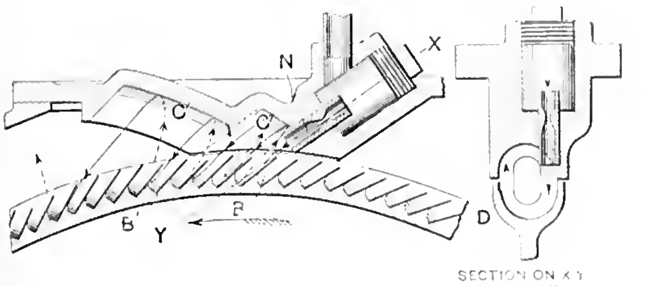

Fig. 63. Single-wheel Compound Turbine of Levin.

against the buckets of the wheel. The curved surface of the casing is stepped so that the portion at *C'* may be brought nearer to the wheel, and when the steam reaches the buckets located at *B'* it is returned against the surface at *C'*. As drawn, the arrangement is designed for a wheel having a peripheral speed of one-tenth the initial velocity of the steam since the steam is projected against the buckets five times in succession. The buckets are semi-circular in form.

At *D* in the right-hand sketch the sides of the buckets are cut away to allow the steam, which has become compressed in its impact against the wheel surfaces, to expand back to its original volume. The steam proceeds in a succession of helical whirls after leaving the nozzle, and it is necessary that the steam should be completely expanded in the nozzle so that it will be at constant pressure, but have a decreasing velocity after leaving the nozzle. The first claim for this wheel is for a "multiple impulse turbine, comprising a wheel having a row of buckets, an expansion nozzle delivering into said buckets, and a stationary reversing guide extending from said nozzle over a number of said buckets, to form a space open end to end within which the motive fluid proceeds in a helical whirl and is successively projected against the buckets of said wheel."

Hodgkinson, 1904.

It has been customary in the Parsons type of turbine to use by-pass valves to supply high-pressure steam to an intermediate point in the turbine where the pressure is normally lower than at the beginning, in order to temporarily increase the power of the turbine. The operation of the valves has usually been by hand, and the patent in question relates to an automatic valve for accomplishing the same end.

In Fig. 64, *A* is the steam inlet and *B* is a valve admitting high-pressure steam, when the valve is raised, to the space *C*, which connects with the intermediate part of the turbine. This is shown in Fig. 65, where steam enters at *A*; *B* is the valve, and *C* is the pipe leading to the turbine.

The valve, *B*, is hollow, allowing the steam to pass through it to the space, *D*, where it presses against the under side of the piston, *E*. *F* is a small passage leading from space *D* to the space, *H*, so that under ordinary conditions there will be balanced pressure on the piston, *E*, and the valve will be kept seated by the spring, *S*. Connecting with the space, *H*, in which the spring is located, is a pipe, *P*, leading to a by-pass

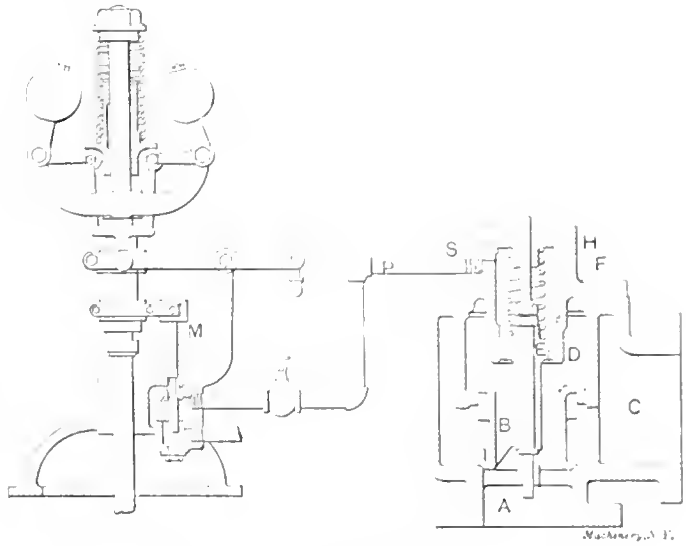

Fig. 64 Valve for Admitting High-pressure Steam to Low-pressure End of Turbine

in the base of the governor, shown at the left, which is opened or closed by a pilot valve, *M*, under control of the governor. Under normal conditions the pilot valve will be in the position shown, closing the by-pass and preventing the escape of steam from the chamber, *H*. Should the speed of the engine decrease beyond a fixed point, however, the governor balls would move inward, which would depress the governor yoke and the pilot valve, *M*, causing the by-pass to open and allow

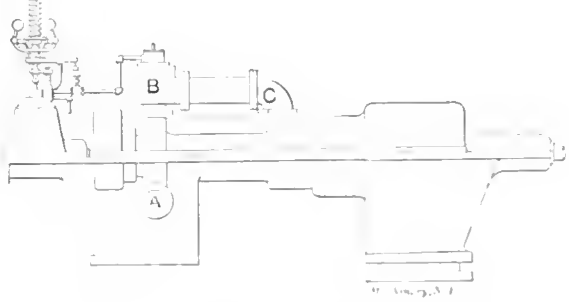

Fig. 65 Showing Connections for By-pass of Fig. 64

steam to escape from space, *H*, into the atmosphere or condenser. The result would be an unbalanced pressure on the piston, *E*, causing it to raise and compress the spring and open the valve, *B*, allowing the high-pressure steam to enter the low-pressure part of the turbine and increase the power

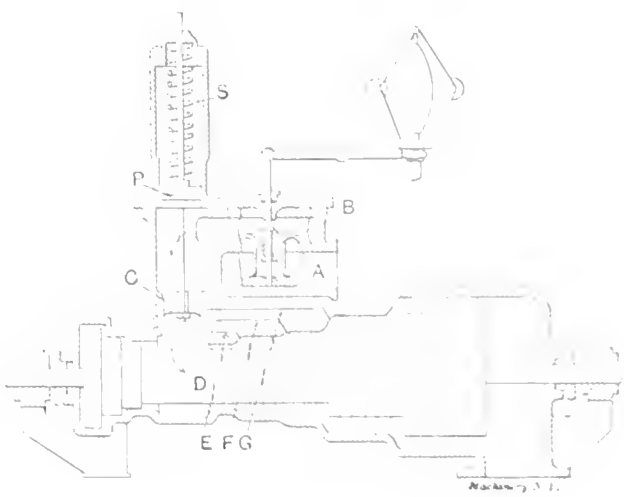

Fig. 66 Brown's Governing Arrangement

Brown, 1904.

Another patent for accomplishing the same result as with the Hodgkinson invention, in regulating the speed of a turbine by supplying high-pressure steam to the low-pressure passages under heavy loads, is that of C. E. L. Brown, of Brown, Boveri & Co., Switzerland. His invention consists in providing pipes from the steam chest to intermediate stages of the turbine and controlling the openings of these pipes by a valve operated by the governor.

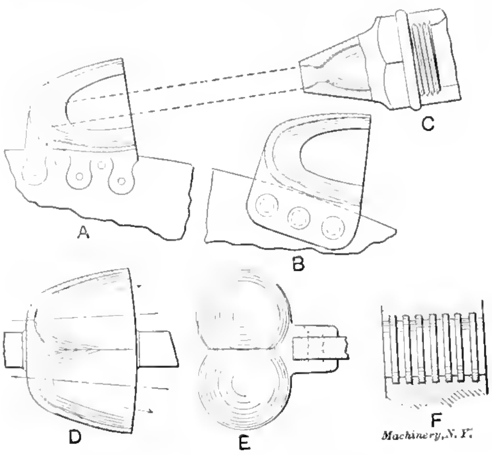

Fig. 67. Pelton Type of Buckets used by C. V. Kerr.

In Fig. 66, steam is admitted through the supply pipe, *A*, and when the throttle valve, *B*, is raised by the governor, steam will pass in the direction of the arrows through the valve, *C*, to the steam space, *D*, whence it will enter the high-pressure end of the turbine. The pipes, *E*, *F*, and *G*, leading to other points in the turbine, are opened to the steam space by movement of the valve, *C*, which uncovers the several ports in succession, when it is raised. Ordinarily, it is kept in its lowest position by the spring, *S*, thus closing all the ports. If, however, the speed of the turbine increases under a heavy load the governor will admit a greater quantity of steam through valve *D* to the steam space, increasing the pressure in the steam space and forcing the piston, *P*, upward against the pressure of the spring, by this means raising the valve, *C*, and admitting steam successively to the different stages of the turbine. Brown's patent also covers an arrangement, for a similar purpose, having the valve, *C*, controlled directly by the governor.

C. V. Kerr, 1904.

The compound impulse turbine, which is the subject of Mr. Kerr's patent, has buckets somewhat of the form of the Pelton water-wheel bucket. They are to be made of drop

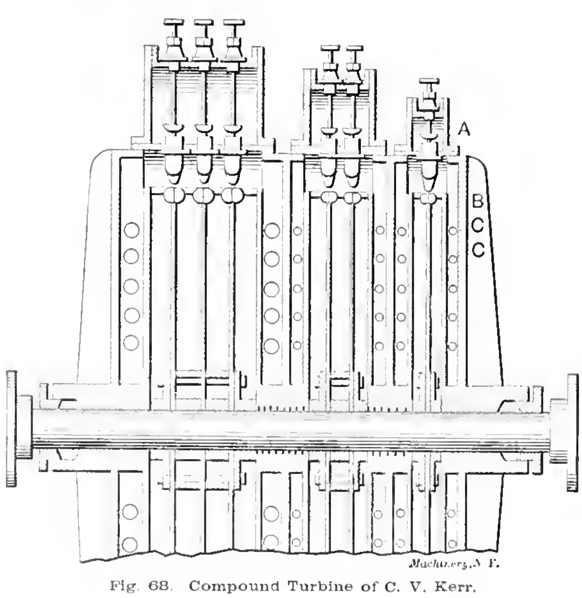

Fig. 68. Compound Turbine of C. V. Kerr.

forgings and of such a shape that they may be bored out perfectly smooth by means of a special reamer. Accordingly, each recess in the bucket on either side of the dividing wedge has a contour representing a surface of revolution. Sketches of the buckets appear in Fig. 67. The curves of the interior of the bucket in a transverse direction must obviously be circles in whole or in part, as shown at *E*, whereas the longitudinal section will show curves elliptical in shape.

The buckets are attached to steel disks, and in order to withstand the great strain he prefers to attach them, as shown at *A*, by dove-tailing and upsetting the interlocking parts, or else by electric welding. Another construction suggested is by riveting, as shown at *D*. Expansion nozzles are used, of the form indicated at *C*, Fig. 67, the tip of the nozzle being rather short inasmuch as the turbine is divided into stages and only a portion of the pressure of the steam has to be reduced at each stage. Each nozzle of the turbine is controlled by a hand valve.

In Fig. 68 is a partial longitudinal section of three stages, although ordinarily it would be constructed with six or more. As the steam progresses through the turbine an increasing nozzle area must be provided, and this the inventor prefers to accomplish partly by multiplying the number of disks in each space rather than by depending entirely on an increase of the areas of the individual nozzles. In the sketch *A* is one of the first series of nozzles, *B* is the first wheel, and *C C*, etc., are openings allowing the steam to pass from the first chamber to the next set of nozzles through a passage cored in the casing. The shaft is provided with a series of rings interlocking with a series of grooves in the partition between each chamber, as shown at *F* in Fig. 67. The object of these is to reduce leakage.

* * *

The U. S. consul at Birmingham, England, says that British industries are being rapidly rebuilt and reorganized on American lines. He complains that many British manufacturers or their representatives have visited America and, having been hospitably received by our manufacturers, have not hesitated to avail themselves of all possible information that would be helpful to them in putting their plants on a competing basis. He says that many young English graduates of the scientific classes of British universities and technical schools who are the sons of manufacturers, merchants, or professional men, are at work in American factories learning all they can about our methods. In this Consul Halstead sees a great national danger as in the movement he sees very little that is nationally reciprocal. Although American methods are condemned by the British technical press, and our products characterized as being "bad," "frail," "defective," "flimsy," etc., there are many Americans managing English factories and introducing the same systems which make American products formidable competitors in the marts of commerce. For instance, one American is now manager of a big British bridge company, and another is superintendent of the same works. With all the conservatism of the British manufacturers, it appears that some of them are outdoing American manufacturers in the matter of scrapping obsolete machines and of installing new and improved machinery in their stead. Hence the inference that the American manufacturer, who looks upon the markets of the world as his to exploit, must count upon an "Americanized" competition which hitherto has been unknown.

There is a whole lot of conceit and egotism in this view of foreign competition for American manufacturers who have no monopoly of new or original ideas, and it is wholly likely that British manufacturing concerns would have reorganized their plants without the stimulus of American ideas, if need be. It smacks somewhat of injustice to deny the right of foreign manufacturers to get new ideas wherever they can, for it is something that we have always done and are doing to-day. Industrial conditions change in all countries but more slowly in old than in newer sections, because of the inertia of investments. Perhaps one of the principal causes for our unexampled progress has been the absorption of foreign ideas unhampered by the fear of impairing the value of existing investments, which was and is now the case in older countries. We have taken whatever seemed good with no qualms as to its origin, but have not been imitators. If foreign concerns imitate us they will not be formidable—if they imitate and originate they will.

THE DESIGNING AND MAKING OF BELLS.

F. P. LOTZ.

F. P. Lotz.

The production of church bells is an art of uncommon interest. Few people understand it at all, and hence it excites the liveliest interest when attention is drawn to it even in an indirect way. How closely bells are united to the human feelings, the begrimed workmen who make them hardly appreciate. We laugh with their merry wedding peals, weep with their somber funeral toll, and, if we are night workers in a great city, we roundly abuse them when their clanging disturbs our Sunday morning slumbers. Everybody that has ears and is not deaf has been enthused and alarmed, has laughed or cried at the sound of the bells, but few persons have any idea of how they are manufactured.

Sometimes they are called brass bells and occasionally bronze bells, but strictly speaking, neither term is correct. Brass is a combination of various metals such as copper, tin, lead, and zinc; bronze, much used in art statuary, is composed of the same metals, but not in the same proportions. Bell metal is entirely different in composition for it consists of only two metals, namely, pure copper and pure tin Any addition of another kind of metal is an adulteration and always has an injurious tendency. The best tone effect in bell metal is, strangely enough, confined within very narrow limits, for any so-called bell metal having more than seventy-eight parts copper to twenty-two parts tin is too soft to produce the best quality of tone, while that having more tin than twenty-three parts in the 100 is too brittle and hence not safe. The old German bell founders used to make their bells of eighty parts copper to twenty parts tin, and bells are still made of that composition, but they lack brilliancy or "tone color."

The primary art of bell casting is in "drawing it" accurately as to shape so as to secure the best acoustic proportions. I believe each founder has his own rules for this work,

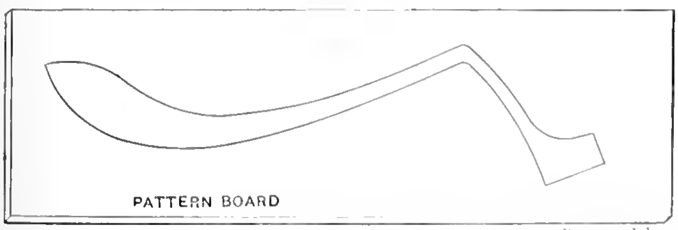

Fig. 1. Drawing of one-half of Bell.

but as they are in a large measure trade secrets, it is hardly expedient for me to discuss them here. The first step in making a bell sweep is to draw the pattern and for this purpose a good straight-grain white pine board of sufficient length and width is chosen and dressed down to about three-eighths of an inch in thickness. When the bell is drawn on this board it looks like Fig. 1. The rule for securing the peculiar empirical shape of the bell is in some respects quite complex, and there are different ways of obtaining the desired curves, since each founder has his own formula according to his own notion of accuracy. For the sake of convenience I will give an example of a process used in England a half century or more ago, for, of course, no one expects me to tell exactly my process for drawing the shape of the bell which I prefer, though I have my preference, of course, with reference to shape and acoustic properties involved. We must first determine upon the size of the bell, which must be mathematically calculated with reference to the note required, but I will not discuss this question because it involves technicalities which I do not think will much interest anyone outside the trade. We begin by drawing a horizontal line *SI*, representing the diameter (see diagram, Fig. 2), and a perpendicular line, *C*, representing the center of the bell, and we then lay off the outside diameter of the half section by drawing the perpendicular line, *OD*. Using the proportions of the drawing rule or formula, we now proceed to stick pins on the line *OD*, as shown by the figures 1, 1, and 3, and stretch a strong thread from the two pins 1 and 1 around the pin 3; when this is done and the string firmly tightened (see *AA*), pin 3 is withdrawn and a pencil is set at that point held firmly in a perpendicular position keeping the string taut. Carrying the pencil down as indicated by the dotted line, *aa*, it will form the quarter of an ellipse shown by the heavy dotted line, *AA*, which is the inner shape or curvature of the bell. To make the outside curvature or shape, the same process is followed shown by the lines *BB*, and in stretching the string with the pencil, as per the partly dotted line, *bb*, the outside curve, shown by the heavy black line ending at *K* is formed. This leaves only the outside curve of the sound-bow to be drawn, and this is done by following another part of the formula and forming the section of a circle, *HG*, by means of a compass. There now remains a small space, *W*, to be closed up, which is done by hand, in accordance with any convenient process, for the section is so small that no particular rule is necessary.

The crown or top of the bell, indicated by *Z* and *Y*, is then drawn according to any formula. The crown top *T*, has nothing to do with tone, but may be of any shape or device which

Fig. 2. Method for Laying out a Bell.

pleases the founder as long as it secures a good safe method of hanging and swinging the bell. Safety is the first consideration, and it is obvious that a bell suspended by only one bolt, no matter what the thickness of the bolt, is not entirely safe. In all continental and English bells there are numerous bolts, and none of the European founders think of hanging the bell on one bolt only I have often read of bells attached

F. P. Lotz was born in Baltimore, Md., in 1859. He took a course in business college and a correspondence course in literature, and his education outside of this was acquired by persistent study at home. He has been in the employ of the Henry McShane Mfg. Co., Baltimore, Md., the E. W. Van Duzen Co., Cincinnati, O., and Meneely & Co., West Troy, with whom he is at present. Mr. Lotz has contributed quite extensively to encyclopedias and to various New York, Boston and Cincinnati publications.

to the swinging yoke by but one bolt, which suddenly parted, and the bell dropped, making sad havoc in the tower. For this reason, if for no other, churches should select a bell held securely by two or more bolts.

The bell drawing or section is now complete, and the next step is to cut it out and make the two sweep patterns correspond with the inside and the outside shape respectively. This rule or process will make the bell at Y one-third of the thickness at X, which is the "soundbow" or thickest part of the bell, and is the point where the clapper strikes. The sweep

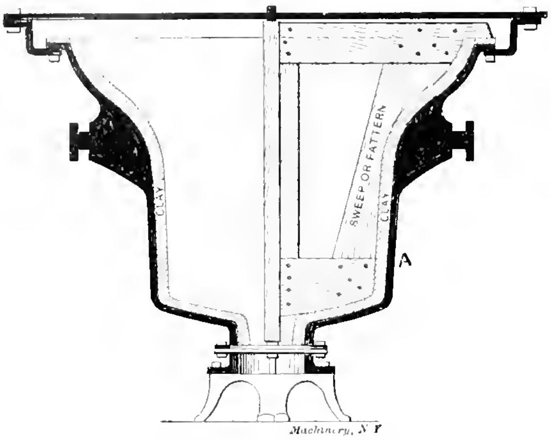

Fig. 3. Bell Sweep and Mold.

board or drawing which represents the outside shape of the bell will have little projections, which the founders call "beads"; these make little grooves in the molds and form the adorning lines on the surface of the bell, relieving what would otherwise be an unbroken smooth surface. These lines are seen in Fig. 4, which shows a finished bell. Fig. 3 shows a sectional view of a bell mold with the sweep or pattern inserted in working shape. The outer section, A, is an iron flask liberally perforated so as to give vent to the gas which is generated while pouring or casting the bell. This gas ignites and burns away, thus relieving internal pressure and obviating an otherwise possible explosion. Over the surface of the flask a layer of wet loam of equal and suitable thick-

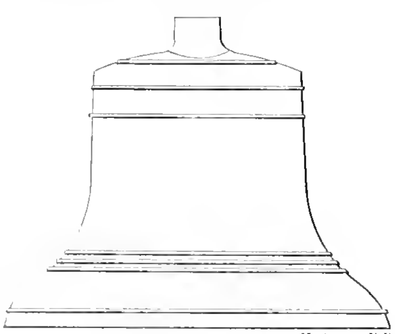

Fig. 4. Finished Bell.

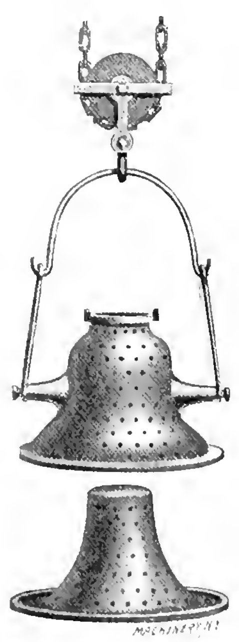

Fig. 5. Iron Flask consisting of "Case" and "Core."

ness is coated and baked, then another layer is coated on and baked, and so on, layer after layer, until the proper shape is secured. There are two such iron molding cases or flasks fitting one over the other, as shown in Fig. 5. The under one has its loam coating on the outer side, which has the inner shape of the proposed bell, while the upper iron molding flask has the loam on the inner surface, and forms the outside shape of the bell which is let down over the under mold and carefully adjusted all around, leaving a space inside between the two molds. The under flask is called the core, the upper or outer one the case; the space between these is filled up by the molten bell metal which, when cooled, is the bell. When the bell is taken out of the molds, it is polished and the hangings—tongue or clapper, etc.—fitted to it. It then receives several ringing tests to ascertain its tone and resonant quality and to observe its mechanical excellence and adjustment, after which, if it appears to be good in all points, the bell is shipped to the purchaser. The making and shipping of a bell usually require from ten to fifteen days in the smaller sizes, but the larger sizes—of 1,500 pounds and heavier—require more time. A peal of bells takes from forty to ninety days' time, while to make a chime of nine or more bells, from three to six months' time must be allowed.

* * *

NOTES ON LUTES AND CEMENTS.*

Luting and cementing materials for various purposes in the laboratory and shops may be classified as follows:

1. Water- and steam-proof.
2. Oil-proof.
3. Acid-proof.
4. Proof to hydrocarbon gases
5. Chlorine-proof.
6. Elastic.
7. General purposes.
8. Marine glue.
9. Gaskets.
10. Machinists'.
11. Leather (belting).
12. Crucible, iron, and stone
13. Core compounds.
14. Briquetting.

1. *Water-Proof Compositions.*—Of use to engineers are the asphalt fluid coatings for reservoir walls, concrete foundations, brick, wood, etc. Asphalt only partly dissolves in petroleum naphtha, but heated in a steam-jacketed kettle and not thinned out too much, a mixture of the two may be obtained in which the part of the asphalt not dissolved is held in suspension. Asphalt is entirely soluble in benzol or toluol, which are about the cheapest solvents for all the constituents of asphalt. Tar and pitch are sometimes used in this connection, but tar contains water, light oils, and free carbon, and does not wear as well as good refined asphalt; and pitch contains free carbon, which is sometimes objectionable when thinned out with a solvent. The asphalt alone is somewhat pervious to water, and this is improved by adding about one-fourth its weight of paraffin, and made better if in addition a little boiled linseed oil is added also. For thicker compositions, where body is required, asbestos, stone powder, cement, etc., may be added as fillers. Lutes of linseed oil thickened with clay, asbestos, red or white lead, etc., are water-proof if made thick enough. These are much used for steam joints. Flaxseed meal made into a paste with water is often serviceable, the oil contained serving as a binder as the water evaporates.

2. *Oil-Proof.*—The most useful lute for small leaks, etc., is the well-known "hektograph composition," as follows:

Good glue or gelatin	2 parts
Glycerin	1 part
Water	7 parts

This is applied warm and stiffens quickly on cooling. Another very useful composition is a stiff paste of molasses and flour. Another preparation, impervious to oil vapors, is the "flaxseed poultice," mentioned in Section 1, which is proof to oil vapors. One of the strongest cements, and one which is really oil-proof, water-proof, acid-proof, and proof to almost everything, is a stiff paste of glycerin and litharge. These form a chemical combination and set in a few minutes. If a little water is added, it sets more slowly, which is often an advantage. It is mixed when required for use. Plaster-of-paris wetted, by itself, or mixed with asbestos, straw, hair, etc., is useful. A solution of silicate of soda made into a stiff paste with carbonate of lime, gets hard in six to eight hours.

3. *Acid-Proof.*—The asphalt compositions already mentioned, compositions of melted sulphur with fillers of stone powder, cement, sand, etc.; also the following, which withstands hydrochloric acid vapors:

Rosin	1 part
Sulphur	1 part
Fire clay	2 parts

The lute composed of boiled linseed oil and fire-clay acts well with most acid vapors. The composition of glycerin and litharge referred to is useful in this connection, especially when made up according to the following formula:

Litharge	80 pounds
Red lead	8 pounds
"Flock" asbestos	10 pounds

fed into a mixer, a little at a time, with small quantities of

* Abstract of paper presented by Mr. S. S. Sadtler before the Engineers' Club, June 4, 1904.

boiled oil (about six quarts of oil being used). Sockets joined in 3-inch pipes carrying nitric acid were calked with this and showed no leaks in nine months. A particularly useful cement for withstanding acid vapors, being also tough and elastic, is:

Crude rubber, cut fine	1 part
Linseed oil, boiled	4 parts
Fire-clay	6 parts

The rubber is dissolved in carbon disulphide to the consistency of molasses and then mixed with the oil. Other examples of acid-proof cements, taken from "A Handbook of Chemical Engineering," by George E. Davis, and vouched for by the author, who has used them in chemical engineering work, are as follows:

"Black putty," made by intimately mixing equal portions of china-clay, gas-tar, and linseed oil. The china-clay must be well dried by putting over a boiler, etc. Barytes cement is composed of pure, finely ground sulphate of barium, and is made into a putty with a solution of silicate of soda. This sets very hard when moderately heated, and is then proof against acids. The gravity of the silicate of soda should be between 1.2 and 1.4, 24 deg. to 42 deg. Beaumé. If too thin, it does not hold; and when thicker than 1.4, it expands and breaks.

4. *Hydrocarbon gases.*—Compositions of plaster and cement, the former setting more quickly, are used. Also compositions of casein, such as:

Finely powdered casein	2 parts
Fresh slaked lime	50 parts
Fine sand	50 parts

Water is added, when used, to form a thick mush. Various mixtures of silicate of soda are employed in which the thick silicate is absorbed in some inert material, as clay, sand or asbestos.

5. *Chlorine.*—The best and only reliable compositions are a few made with Portland cement, and the following is much used for electrolytic and chemical plants:

Powdered glass	1 part
Portland cement	1 part
Silicate of soda	1 part

A small amount of powdered slate.

This lute is said to stand acid and alkali, as well as the influences of chlorine. Linseed oil made into a paste with fire-clay serves for a time.

6. *Elastic Cements.*—The various cements containing rubber are elastic, if it is in predominating amount; many containing boiled linseed oil and the hektograph composition already mentioned are quite elastic. The rubber-linseed oil cement, given under Section 3, is very tough and useful for nearly all purposes except when oil vapors are to be confined. The most useful single rubber lute is probably the so-called Hart's india-rubber cement. Equal parts of raw linseed oil and pure masticated rubber are digested together by heating and this mixture made into a stiff putty with fine "paper stock" asbestos. It is more convenient, however, to dissolve the rubber, first in carbon disulphide, and after mixing the oil with it, to let the solvent evaporate spontaneously.

7. *General Purposes.*—One of the most useful is plaster-of-paris, and especially when mixed with asbestos, straw, flush trimmings, hair, broken stone, etc., used according to temperature, strain, and other conditions. A putty of flour and molasses is a good composition to keep in a works ready for quick application when needed. It serves almost any purpose at moderate temperatures for a time. Casein compositions have great strength. White of egg made into a paste with slaked lime is strong and efficient, but must be used promptly on account of its quick setting qualities.

8. *Marine Glue.*—This can be purchased almost as cheaply as made. The rubber must first be dissolved in carbon disulphide or turpentine before mixing with the heated combination of the other two ingredients. Its uses are well known.

Crude rubber	1 part
Shellac	2 parts
Pitch	3 parts

9. *Gasket Compositions.*—Of course, almost any cementing substance may be used with rings of asbestos, etc., for gaskets, but some are specially adapted to the purpose. With regard to asphalt, tar, pitch and petroleum residuum, soft or hard pitch is recommended, as may be desired, because there are no light oils or water to go off at low heats, and the free carbon and compounds very high in carbon are good fillers to asbestos gaskets at high temperatures. Silicate of soda by itself is much used, but is sometimes advantageously mixed with casein, fine sand, clay, asbestos, carbonate of lime, caustic lime, magnesia, oxides of heavy metals, such as lead zinc, and iron, and powdered barytes. A few that might be selected are—silicate of soda and asbestos; silicate of soda asbestos and slaked lime; silicate of soda and fine sand; silicate of soda and fire-clay.

10. *Machinists' Cements.*—These are the well-known red and white leads. The red lead is often diluted with an equal bulk of silica or other inert substance so as to make it less powdery. The best way to do this, however, is to add rubber or gutta-percha to the oil as follows:

Linseed oil	6 parts by weight
Rubber or gutta-percha	1 part by weight

The rubber or gutta-percha is dissolved in sufficient carbon disulphide to give it the consistency of molasses, mixed with the oil, and left exposed to the air for about twenty-four hours. The red lead is then mixed to a putty. Oxide of iron makes a less brittle cement than red lead. Probably fish oils and red lead would make good lutes of the class for joining pipes, as the fish oils are not such strong drying oils as linseed and their use might be a case of permissible substitution rather than adulteration.

11. *Leather Cements.*—1. Equal parts of good hide glue and American isinglass, softened in water for ten hours and then boiled with pure tannin until the whole mass is sticky. The surface of the joint should be roughened and the cement applied hot. 2. One pound of finely shredded gutta-percha digested over a water-bath with 10 pounds of benzol, until dissolved, and 12 pounds of linseed oil varnish stirred in. 3. Seven and one-half pounds of finely shredded india-rubber are completely dissolved in 10 pounds of carbon disulphide by treating while hot, 1 pound of shellac and 1 pound of turpentine are added, and the hot solution heated until the two latter ingredients are also dissolved. Another leather cement is as follows:

Gutta percha	8 ounces
Pitch	1 ounce
Shellac	1 ounce
Sweet oil	1 ounce

These are melted together.

Still another is as follows: Fish glue is soaked in water twenty-four hours, allowed to drain for a like period, boiled well and a previously melted mixture of 2 ounces of rosin and ½ ounce of boiled oil is added to every 2 pounds of glue solution.

12. *Iron and stone cements.*—When iron in a fine state of divisions, as in fresh filings or cast-iron borings that have been powdered, is mixed with an oxidizing agent, such as manganese dioxide or a substance electro-negative to iron such as sulphur, in a good conducting solution like salt or sal-ammoniac galvanic action sets in very rapidly, and the iron swells, by forming iron oxide, and cements the mass together. It is best diluted with Portland cement:

Iron filings	10 parts
Manganese dioxide, or flowers of sulp'r	10 parts
Sal-ammoniac	1 part
Portland cement	20 to 40 parts
Water to form a paste.	

A hard stone-like composition is made as follows:

Zinc oxide	2 parts
Zinc chloride	1 part
Water to make a paste	

Magnesium oxide and chloride may also be used in like proportions. When used in considerable quantity this cement is mixed with powdered stone, for economical reasons, the proportions depending upon the character of the work

* * *

In the new *Times* building there will be few brass railings, signs, etc., requiring polishing. The management estimates that the labor wasted on one brass railing in the old *Times* building would have paid for it in solid silver.

TO MEASURE THE RADII OF DEEP-HOLE DRILLS.

OTTO ECKELT.

Deep-hole drills of the type shown in Fig. 4 should be made so that the cutting edge or lip *a* of the drill shall be a radial

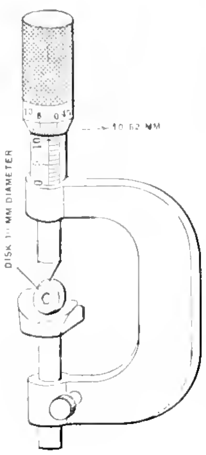

Fig. 1.

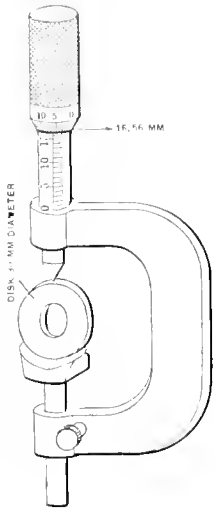

Fig. 2.

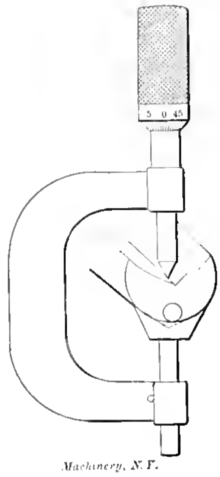

Fig. 3.

line, or in other words, shall go exactly through the center of the drill. It is clear that if a drill is made whose cutting edge lies under the center, a small core of the stock in the center

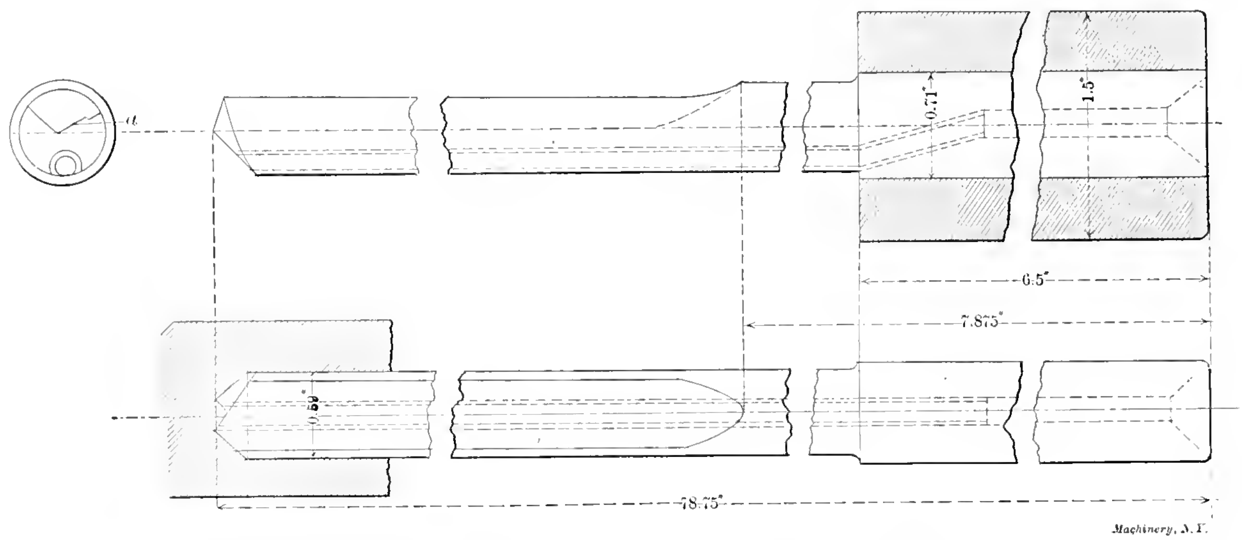

Fig. 4. Deep-hole Drill of the Type to which the Micrometer and its use Applies.

will not be cut off, and will instead tend to remain and form a slender column or thread remaining in the hole. On the other hand if the cutting edge lies over the center, the center portion cannot be cut out, but will be crushed together, the same as occurs with an ordinary twist drill. In deep-hole drilling this will not do as it will very soon cause inaccuracy of the hole or breaking of the drill. Hence it follows that the location of the center exactly in the cutting edge is very important. A glance at a cross section of the drill, Fig. 4, convinces us that a direct measuring of the drill center cannot be made with ordinary instruments. Hence Ludwig Loewe & Co., of Berlin, employ for this purpose a special micrometer with disks and V-shaped anvil block, the principle and use of which is described in the following:

Fig. 1 shows the special micrometer, which measures the radii of deep-hole drills up to 60 mm. (2.338 inches). Its construction is the same as that of an ordinary micrometer with a V-point for measuring screw threads, but in addition it has an adjustable V-block which is locked in position by a clamping screw; also two disks 10 and 30 mm. in diameter are provided. The smaller disk is used for setting the micrometer for drills up to 32 mm., as shown in Fig. 1, and the larger one for drills of 30 to 60 mm. diameter. For measuring drills of small diameter up to 32 mm. the scale of the micrometer is set to 10.52 mm. ($5 + 5 \times 1.1045$) and the disk of 10 mm. diameter is placed in the V-block, which latter is pushed against the measuring point and clamped fast in this position, whereupon the preliminary adjustment necessary is completed. For adjusting the micrometer for drills of 30 to 60 mm. diameter, the 30 mm. disk is used in the same manner, but the scale of the micrometer in this case is adjusted to 16.56 mm. (15×1.1045). After having found the preliminary adjustment of the V-block for drills up to 32 mm. diameter, as shown in Fig. 1, the radius or half the diameter of the drill to be measured is multiplied by the constant 1.1045, and the scale of the micrometer adjusted accordingly; or for greater convenience we may use the diagram, Fig. 9, in which we can read off the product of $r \times 1.1045$ without calculation. For example, suppose we wish to measure a drill whose radius is 7.45 mm. We must find the proper reading for the micrometer screw when the drill is laid in the angle block and the point adjusted, as indicated in Fig. 3. Turning to the diagram, Fig. 9, we find in the upper horizontal scale the figure corresponding to 7.45 and trace downward along the vertical line until we reach the diagonal, thence going horizontally from this point toward the right or left, whichever may be convenient, we find in the vertical scale the number 8.2 mm., or the product of 7.45×1.1045. Hence, if in measuring the drill of 7.45 mm. radius, we get a micrometer reading of 8.2 mm., it is known that the angle of the groove lies exactly in the center of the drill.

To adjust the micrometer for drills from 30 to 60 mm. diameter, the radius of the drill is multiplied by the constant 1.1045 and 15 mm. is subtracted from the product, or $r \times 1.1045 - 15$ mm. = micrometer setting. The diagram, Fig. 10, however, saves this calculation and is used in the same manner as Fig. 9. For example, to find the micrometer setting for a drill having a radius of 27.35 mm.: In the proper hori-

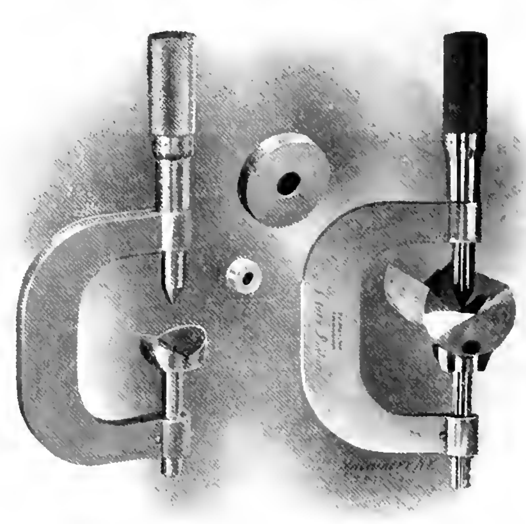

Fig. 5. Fig. 6.

zontal scale we find the point corresponding to 27.35 and follow the vertical line downward until it intersects the diagonal, thence to the right or left to the vertical where we read 15.2. With this datum any excess or deficiency of thickness

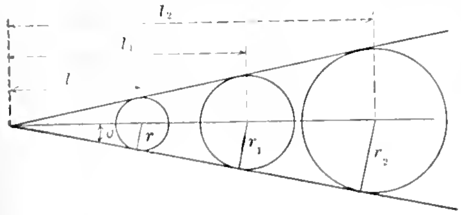

Fig. 7.

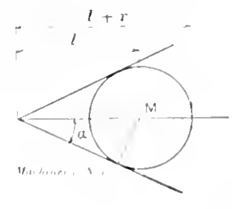

Fig. 8

of the drill over the center can be read off directly from the scale. Figs. 5 and 6 are from photographs showing substantially the same as Figs. 1, 2, and 3.

Principle of the Gage.

The principle of the gage depends upon the proposition that the homologous sides of similar triangles are in direct proportion. Hence in Fig. 7 we have $\frac{r}{l} = \frac{r_1}{l_1} = \frac{r_2}{l_2}$, etc. Therefore the values of l_1 and l_2 are easy to determine, since $l = \frac{r}{\sin \alpha}$

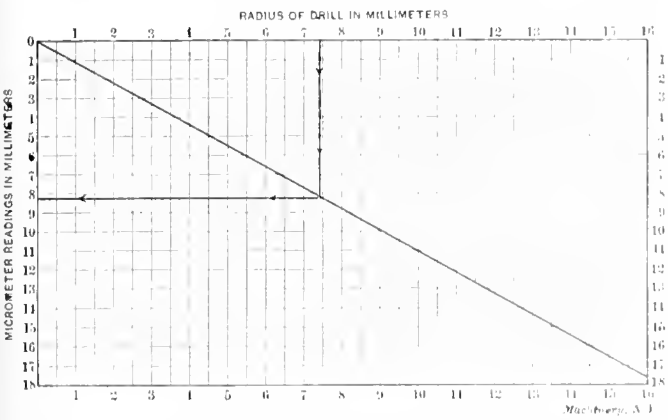

Fig. 9 About one-fourth size of Original.

in which r corresponds to the radius of the drill, and $\alpha = \frac{1}{2}$ the constant angle of the V-block of the micrometer, whence we derive the constant 1.1045.*

It will be observed that the product of the radius by the constant is used directly when setting for drills 32 mm. or less diameter, but that when measuring drills of 30 to 60 mm. the product is diminished by 15 mm. This comes about because in setting to the 30 mm. disk the micrometer screw is adjusted to 16.56 mm (instead of 31.56 mm.) in order to make the

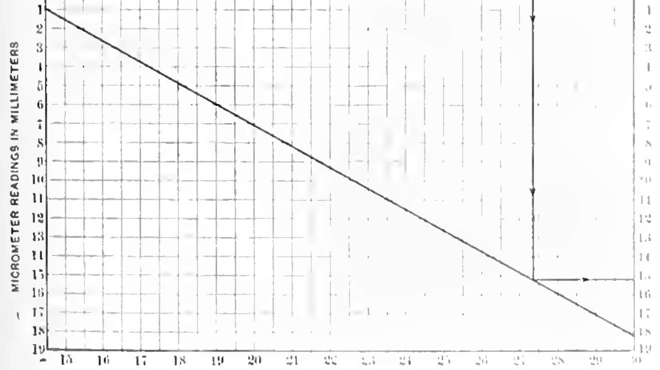

Fig. 10. About one-fourth size of Original

scope of the micrometer include the larger drills without the need of making a larger frame bow. The principle is illustrated in Fig. 8. For the disk M we reckon $l + r = \frac{r}{\sin \alpha} + r$.

* From the direction to use the constant 1.1045 it would appear that the included angle of the V-block must be 129 deg. 46 min.; the constant stamped on the frame of the micrometer shown in Figs. 5 and 6 is 1.103, but both give an odd figure for the included angle, the latter making it 129 deg. 50 min. In view of the fact that an odd angle was chosen it would have seemed more in the interest of convenience to have made it one that would have given a simpler constant. For instance angle 130 deg. 46 min. would give a constant almost exactly 1.1. —EDITOR.

Hence if one sets the screw of the micrometer to this measure and pushes the V-block with the disk M resting in it, until the disk is found to be in perceptible contact with the measuring point of the screw and there clamps it fast, the gage is adjusted. The proof of the correctness of the setting is that if we put back the micrometer screw equal to $l + r$ then will the point of the screw lie in the vertex of the angle α. In other words the lengths l, l_1 and l_2 should be exactly indicated without calculation.

* * *

GETTING THE FULL VALUE OUT OF JIGS.

J. F. MIRRIELEES

At the beginning of this article the writer finds it necessary to make three assumptions: First: That every shop manager recognizes the indispensability of jigs where rapid production at the lowest possible cost, and duplicate workmanship are the aims. Second: That his equipment of jigs be more or less complete. Third: That his jigs be in a somewhat satisfactory working condition.

Throughout this article the word "jig" will be meant to include all jigs, templets, fixtures, appliances, etc., which aid in the rapid and accurate machining of parts. With such assumptions allowed, the necessity for some systematic scheme of management for the use and care of the jigs should be apparent. However, it is not uncommon, even in these days, when the jig is admittedly one of the main factors instrumental in developing the shops of the past (where machinery was "built)," into the shops of the present (where it is "manufactured)," to find concerns where the jigs are given no consideration beyond designing them and keeping them in a questionable state of repair.

The whole tool or jig scheme is so interwoven with the entire shop that the success of a system cannot be dependent entirely upon any one person but upon the co-operation of all.

The tool foreman is the one, after the management, who contributes most to either success or failure, and therefore his selection should be made with care. This tool foreman, as we prefer to call him, is to the modern shop what the head toolmaker was to the old-time shop, and his increased duties and responsibilities entitle him to the new title. He should possess executive as well as mechanical ability, and be broad-minded and up-to-date, for to him should be intrusted the tooling of the machines, the manufacture and care of the jigs, the complete control of the tool room and the enforcement of any system the management may inaugurate. He will, however, be doomed to only partial success, if not absolute failure, without the support of some working system; and that is what this article proposes to outline.

The first thing we find it necessary to provide for is that the separate parts be produced in the most economical quantities. From the fact that the parts are produced rapidly by the use of jigs, in many instances the quantity production is overdone, and the money thus tied up in overstock more than offsets that saved by producing in large quantities. This is a point not appreciated by the average foreman, and, indeed, the superintendent himself may have only an indistinct idea of where that point lies beyond which, if he goes, he is putting an extra expense upon the firm. It is evident, therefore, that this is not a matter to be left to chance, but should be taken up and gone through with by some intelligent person who has a thorough knowledge of the shop conditions, and who has above all an accurate cost record of each piece to guide him. The product of his labor should be a list similar to the one shown in Fig. 1 and which is called a "Production Sheet." From this no deviation should be allowed in the number of parts to be produced at a time, until conditions change, necessitating an increase or decrease in the amounts.

Here I wish to make a point of the difference between "lot production" and "quantity production." In lot production, if twelve machines are to be gotten out, there will be made just twelve of the main parts, and perhaps twice that number of details. The only point taken into consideration is to have

MR. J. F. MIRRIELEES was born December 19, 1874, at Cincinnati, O. He received his technical education in the Technical School of Cincinnati, and the Ohio Mechanics Institute. His knowledge of the practical side of manufacturing was gained with the R. K. LeBlond Machine Tool Co. Besides this concern, he has worked for W. P. Callahan & Co., and has done special work for various concerns, with which he has held the positions of draftsman, designer, assistant superintendent, and superintendent.

Fig. 1.

enough and no more to complete the lot; while in quantity production there are four points: First, number used in any given period; second, total cost to produce; third, cost to carry, and fourth, proportion of actual machine time to total time. By considering these points we find that we arrive at entirely different results in the two methods.

Suitable methods should prevail in the tool room, or better, in the jig room, whereby a workman when delivered a jig gets all the necessary tools to perform all the operations upon the piece that the jig is designed to do. It should not be necessary for him to ask for the tools separately, but simply to ask for the jig and tools for such or such an operation, designated either by name or number—preferably by number—and have them delivered to him complete. By doing this, much time will be saved, and mistakes will often be avoided. This can be accomplished by giving each jig, all the loose pieces belonging to the jig and all the special tools, the same number as the piece they are used upon. They should be indexed under this number and kept in suitably grouped compartments and the compartments conspicuously numbered so that they can be easily located. In these compartments is also kept a list, Fig. 2, showing what constitutes a complete set. When a jig is called for, reference is made to the index, if necessary, the compartment found and the complete set of jig and tools delivered with reference to the list, Fig. 2.

Probably 50 per cent of all jigs are designed to perform two or more operations; and when such is the case, to economize in time and often to obtain the best results in machining, each jig should have its operation sheet, Fig. 3. To illustrate why it is necessary to perform the several operations in a prearranged order: Take for instance two holes intersecting at acute angles, such as a shaft hole and a locking rod hole, where the locking rod hole drills half out into the shaft hole. Ordinarily a workman would drill the larger or shaft hole first, and the locking rod hole afterward. This would be wrong, however, for the locking rod hole drill upon entering the shaft hole and meeting no resistance for half its diameter, would run out and the hole would not be straight.

Fig. 3.

A very handy arrangement is to have the tool sheet, Fig. 2, and the operation sheet, Fig. 3, mounted upon opposite sides of a cardboard. They should be of some convenient size, to be determined by the number of separate items it is necessary to put upon them.

It is regrettably too generally the custom to take for granted that a piece is right if it has been jigged, and in this way much work is often spoiled that could be avoided by the simple system of inspecting the first piece of every lot done in a jig and ascertaining its correctness. If the first piece is found to be correct it is reasonably safe to assume that the rest will be. It will be well to provide printed blanks upon which defects and possible improvements in jigs are reported to the tool foreman. These are made out in duplicate by the foreman under whom the defects, etc., are discovered, he keeping the copy and sending the original to the tool room. This method will be found to be superior to giving verbal instructions, as it is a check from one foreman to another. There is an adage which cannot be more appropriately applied than in the case of repairing jigs and keeping tools up, and that is, "don't put off until to-morrow what can be done to-day."

It seems hardly necessary to mention the matter of allowing repairs to be made upon jigs in any other place than the tool room, because it is so obviously wrong that every one must see the fallacy of such a course and what a demoralized state of affairs it will lead to; yet in some shops, where if one were to insinuate such a thing to the management they would throw up their hands in horror, I have seen a man "just taking off the wire edge," or "just easing it up a bit." In this matter there should be absolutely no margin, and it should be considered a misdemeanor, punishable with immediate dismissal, for a workman to assume any part of the tool room duties, however trivial.

If the first thing has been done toward improving the conditions and establishing a system, and that first thing is a competent tool foreman, such matters may safely be intrusted to him, for if he is held responsible for the jigs he will assuredly not tolerate such methods.

* * *

The recently-completed office building of the B. F. Sturtevant Co., Hyde Park, Mass., has four stories and a basement and is of handsome, yet simple design. The interior is finished in oak, while the decorations and fixtures are tasteful and appropriate. The building is heated and ventilated by the Sturtevant fan system, the heated fresh air being conveyed to the rooms through galvanized iron flues built into the walls. The heating and ventilating apparatus is in the basement, where are also the printing plant, and a lunch room for the office employees. The two lower floors are taken up by the business offices, the third floor by the drafting rooms, and the fourth floor is at present used only for the blueprint department. Eight large fireproof vaults give abundant room for the safe-keeping of drawings and other valuable data.

TOOL MAKING.—14.

MILLING MACHINE CUTTERS (Continued).

E. R. MARKHAM

Side Milling Cutters.

Side milling cutters, Fig. 19, are used for cutting the sides or ends of work, as shown in Fig. 20; also for cutting grooves, as, having teeth on the end, the friction is much less. When cutting the teeth on the end, the mill is held on a solid stud in the chuck on nose of spindle of centerhead; or on a plug which fits the tapered hole in the end of the spindle. The stud may be solid, or the end that enters in cutter hole may be made as in Fig. 21, which shows an expanding plug. The end of the mill being cut must not be set parallel with the milling machine table or the top of the tooth will not be of an equal width its entire length. The amount of angularity must be determined by experiment.

The angular cutter for producing the teeth on the end of the mill must be selected with reference to the use to which the cutter is to be put. For general use, a mill that will produce a tooth having an angle of about 60 degrees to the face of tooth answers nicely.

If greater strength is required a cutter that will form a tooth having an angle of 70 degrees may be used.

When cutters of unequal sizes are used together, as in Fig. 22, it is advisable to let the smaller into the larger as represented. If this is not done the teeth at the end of the smaller cutter, where it adjoins the larger, will break away leaving a fin on the work. When cutters of the same, or nearly the same diameter are used, various methods are employed to prevent this result. The more common method consists in making them with interlocking teeth or as it is sometimes

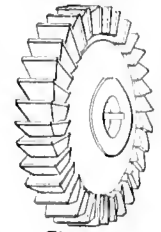

Fig. 19

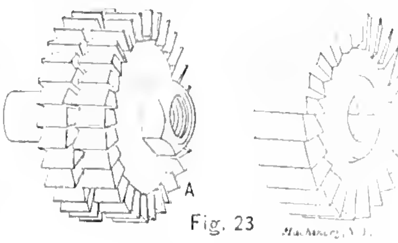

Fig. 23

termed, "dodged" teeth. In some shops every other tooth is cut away; the corresponding tooth on the other being left, projects into the recess. In other shops two, three, or even more teeth are cut away, and then a corresponding number left. These two forms are shown in Fig. 23 at *A* and *B*. For cutting these teeth away the cutter is placed on a solid or on an expanding plug, as when cutting the teeth on the end of a side milling cutter, and a mill of the proper width having a flat face is run through; or a narrow mill is used and the index head revolved to give the desired result. In this form of milling cutter the groove between the projecting teeth should be cut deep enough so that the teeth entering them will not bottom. The cutters should bear against each other on their hubs, as shown in Fig. 24.

A very satisfactory form of slotting cutter, where it is necessary to get adjustment as to width, may be made as in Fig. 25, and in many shops this form has superseded the cutter with interlocking teeth for the purpose mentioned. To make this form of cutter use an eccentric mandrel like that in Fig. 26. This mandrel has two sets of centers; the eccentric centers are located equidistant from the regular centers but on opposite sides, on the opposite ends, as shown. Half of the cutter is placed on the mandrel so the end that is to be cut at an angle shall be half-way between the ends of the mandrel, as shown in Fig. 27. After facing the end *a* by running the mandrel on the concentric centers, the eccentric centers are placed on the lathe centers and the end *b* is faced as shown. The two parts are then put together on a stud and the hole drilled and reamed for the dowel pin, *a*, Fig. 28. The cutter is then placed in the vise of the shaper or planer and the keyway cut, after which the teeth are milled. The necessary adjustment for width of the slot is obtained by blocking apart by means of collars of tin, thin sheet steel, or paper.

When a milling machine cutter is employed cutting a wide, flat surface the chip removed by each tooth is apt to have a length corresponding with the length of the portion of tooth cutting. Removing this long chip brings considerable strain on the cutter and requires a greater amount of power than taking a number of short chips aggregating in length that of the long chip. To accomplish this the surface of cutter teeth is sometimes broken by means of cuts, as in Fig. 29. This process is termed "nicking," and cutters so treated are termed cutters with nicked teeth. Such cutters are specially adapted for milling wide surfaces when heavy cuts are taken. It is

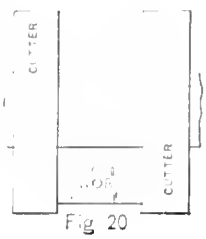

Fig. 20

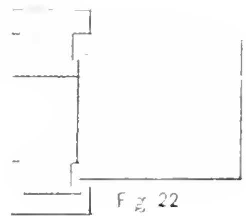

Fig. 22

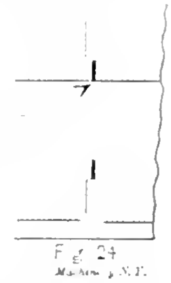

Fig. 24

apparent that the location of the nicks on one tooth must not be in line with those on the adjoining teeth. The nicking may be done as follows. An engine lathe may be geared to cut a thread of the desired pitch—two threads to the inch answers nicely—and a round-nose tool 1/8 inch in width, or a tool similar to a square-thread tool having its corners rounded, may be used to cut the thread. If the latter form of tool is used it must necessarily be thin as we do not wish to cut a wide groove, the desired object being to break the chip. The thickness given for the round nose would answer for the latter form.

The cut should be sufficiently deep to prevent its being ground out, before the tooth has been ground as much as possible before reworking. The thread should be cut before the teeth are milled.

Form Mills.

Cutters of irregular shape whose teeth are not backed off with a forming tool, and which are *not* ground on their faces when sharpening, are in many shops termed "form mills." Such a cutter is shown at *A* and *B*, Fig. 30. If but one mill is to be made the shape is generally produced by blocking out somewhere near to shape with the ordinary lathe tools, then finishing to shape with hand tools. If several cutters of the same design are required a forming tool will be needed. If the necessary facilities are at hand it is made of the form shown in Fig. 31. This is known as a *formed* mill and may be ground on the faces of the teeth without altering their shape. The teeth of cutters of this class should be very

Fig. 21

Fig. 28

Fig. 25

Fig. 26

Fig. 27

coarse; frequently, a 3-inch mill will not have more than seven teeth. These can be made more cheaply in shops provided with machinery adapted for this class of work but very few manufacturers make formed mills in quantities sufficient to warrant the purchase of a machine, which could be used for no other purpose. As a consequence some of the manufacturers of engine lathes make an attachment that can be applied to their lathes, and which answers the purpose nearly as well as a machine made purposely for this work,

unless extremely long mills are to be operated on, or those which subject the machine to great strains.

In the absence of a special machine, or of an attachment, an ordinary engine lathe may be rigged up for this purpose, provided there is one in the shop sufficiently heavy and rigid. It is a serious mistake to take some *old* lathe, so badly worn as to be of little use for any purpose and attempt to convert it into a backing-off lathe, as it will not give satisfactory results. It is cheaper, generally speaking, to get new machinery than to attempt to patch up worn-out machines, especially if they are not adapted to the work at hand.

If the cutters are comparatively short an inexpensive backing-off fixture known as Balzar's backing-off device may be

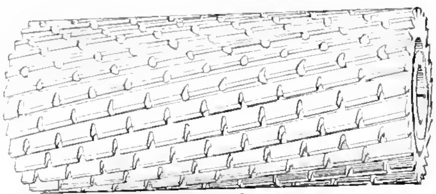

Fig. 29

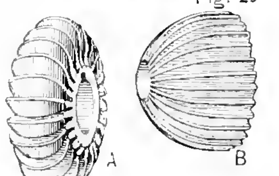

Fig. 30

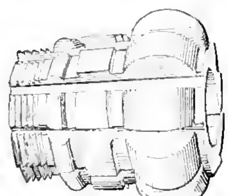

Fig. 31

procured, Fig. 32. This fixture is held between the lathe centers. The cutter being operated on is held on an arbor provided with a key which enters the keyway in the cutter. The keyway must be cut with special reference to the location of the teeth in order that the backing-off which is governed by an eccentric may work in reference to the cutting surface of the tooth. The fixture has a ratchet connected with the arbor. This is operated by a pawl. This ratchet wheel contains ordinarily 36 teeth, so it is apparent that cutters containing 6, 9, 12, 18 or 36 teeth may be backed off on it. Although this fixture has been on the market for a number of years it is not as generally known as it deserves to be. It is not only a useful device but it is an application of mechanical principles that is somewhat novel.

Backing Off Cutter Teeth On a Faceplate.—A method in use in some shops and formerly more commonly used than at

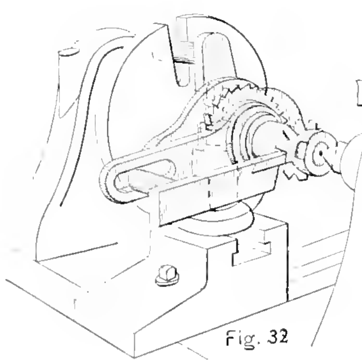

Fig. 32

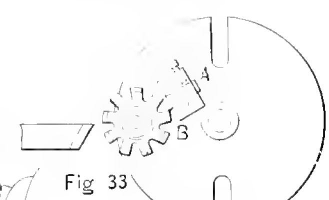

Fig 33

Fig. 34

present, consists in placing the cutter on a stud in the faceplate of a lathe, Fig. 33. It is necessary to provide a finger, one end of which fits into the gashes in the face of the cutter. And, by the way, it is also necessary to cut grooves somewhat narrower than the finish grooves are to be across the face of the cutter after it is formed to shape by means of the forming tool. These grooves are cut in formed mills before backing off the teeth. This cut should be made with an angular cutter of the form shown in Fig. 34.

The cutter is located on the faceplate by means of the finger shown but it must be held while being operated on by the nut on the end of the stud. The forming tool is fed in gradually by means of the cross-feed screw, the lathe spindle being revolved sufficiently to cause the tooth to pass the forming tool, when it may be turned back and the tool fed in for the next cut. Each tooth is operated on separately, being fed in until nearly the desired amount of cutting is done. When all the teeth have been cut in this manner the forming tool is sharpened and a light, finishing cut is taken on each tooth. When using this method cut the grooves somewhat wider than when almost any of the other methods are employed. In fact, they must be somewhat wider than the thickness of the teeth. After backing off it is necessary to mill the *faces* of the teeth about 1-32 inch, to remove the portion at the edge of the tooth that is cut a trifle deeper than the portion just back of it. This is caused by the forming tool drawing in when the cut commences.

Eccentric Backing-off Arbor.—A very simple fixture may be made for backing off cutter teeth. It consists of an eccentric arbor operated by a lever attached to one end. This arbor is shown with and without collars and nut, in Fig. 35. The amount of eccentricity must depend on the size of the cutter to be backed off; for those 4 inches diameter and under ¼ inch answers nicely. The spline cut extending nearly the whole length of the straight part of the arbor is to receive ends of the screws which extend through the collars, thus preventing their turning when pressure is applied to the nut used to fasten the cutter securely on the arbor. The screw to receive the nut on the end of the arbor should be of comparatively fine pitch; 12 threads per inch does very well. The cutter being operated on is not fastened by means of spline, or key, as it is necessary to turn the cutter on the arbor each time a tooth is brought into position.

The cutting is done by moving the lever the required amount, and should be set so as to strike the top of the lathe carriage

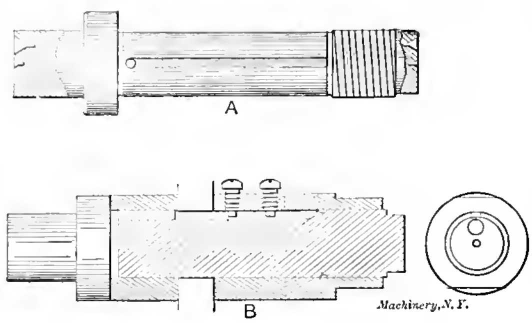

Fig. 35

when at the end of the stroke. To prevent its bruising the carriage of the lathe a strip of leather may be attached to the lower side where it comes in contact with the carriage. When a tooth is brought into position for backing off it should be so located that at the end of the stroke the tooth above it will not come in contact with the forming tool. This is done by lowering the lever so that it rests on the carriage, as shown in Fig. 36, then moving the cutter until the tooth above the one to be backed off rests on a strip of sheet metal placed on top of the forming tool, as shown at *a*. This strip is then removed, the tool withdrawn, the lever elevated, and the tool fed in right for the first cut. It is necessary to remove the tool each time the lever is elevated for return of tooth, and as a consequence a lathe is needed having a cross-feed stop, or a graduated dial on the cross-feed screw. The latter is the more satisfactory.

When using the eccentric arbor observe the same instructions given for using the stud on the faceplate; that is, take the necessary number of cuts on a tooth to bring it nearly to finish before turning to the next tooth.

It is advisable to grind formed mills after hardening and before using. Cutters of this description are ground on the faces of the teeth, and fixtures are used having a guide which properly locates the tooth to be ground by means of a locating finger that gages by the back of the tooth being ground, or against the cutting face of the next tooth, as shown in Fig. 37. Other forms of fixtures have a dial and pin.

Mills should be kept sharp; they dull rapidly when the keen cutting edge is gone, and as there is so broad a face to grind a vast amount of time is consumed if very much stock is to be removed. Then again, the life of the cutter is much shorter under these conditions than if ground when only slightly dull.

Milling Cutters with Inserted Teeth.

Milling cutters exceeding 6 or 8 inches diameter are usually made with inserted teeth; it is cheaper than making of a solid piece of steel, and danger of cracking when hardening is entirely eliminated. If the cutter is narrow, or is to be used for side milling, the grooves to hold the teeth may be straight—at right angles to the end; if the cutter is over 1 inch long make it with teeth that are spiral in form.

As it would not be practicable to make the blades of a shape to fit a spiral slot in the body of the cutter the slots are generally made at an angle to the ends. The blades are made straight, placed in the slots, turned to the required size and then the portion above the body is milled spiraling. If the cut taken with the mill is long or heavy the teeth are nicked as described in section under nicked teeth.

If the grooves that are to receive the blades are to be milled at an angle to the axis of the cutter they should be equidistant from a radial line at each end of the cut; they will of course be on opposite sides of a line drawn parallel to the axis.

Various methods are employed for holding the blades in place. The method used must be decided by those familiar with the character of the work in the individual shop. Fig. 38 shows that used by the Pratt & Whitney Co., Hartford, Conn. Between every second pair of teeth a hole is drilled. This is reamed with a taper reamer to receive a taper pin. After reaming, the slots are cut with a thin metal slitting saw. When the blades are in position the taper pins are driven into the taper holes, closing the stock onto the blades and securely holding them. To remove the blades drive the taper pins out, and the stock springing back to its normal position leaves the cutter free.

The method used by Brown & Sharpe Mfg. Co., Providence, R. I., is illustrated in Fig. 39, and consists of taper bushings and screws, as shown.

A third method is shown in Fig. 40, and is used by the Morse Twist Drill and Machine Co., New Bedford, Mass. To furnish a means of fastening the blades by this method the stock between every second pair of teeth is milled away yet not so deep as the grooves for the cutters. Wedge-shaped pieces of steel are fitted between the teeth, as shown. These binding pieces, however, must not reach the bottom of the cuts made for them. They are drawn to place by fillister-head screws.

It is possible when using inserted-blade cutters to have the blades of high speed steel, which makes it possible to use extremely high speeds and coarse feeds, and thus getting a greater amount of work.

While it is customary to use the circumference of the emery wheel when grinding milling machine cutter teeth for clearance, nevertheless this leaves the clearance edge of the tool somewhat concave in shape, and necessarily weak at the portion where the greatest amount of breaking strain comes. If the wheel used is the largest possible the amount of concavity is, of course, much less than when a small wheel is employed. To overcome this difficulty wheels are made of a shape that allows them to be used as shown in Fig. 41. The cutting is done with the end of the wheel and the cutter is held in a fixture that can be tipped to the desired angle when grinding teeth on the end of a side milling cutter, as shown.

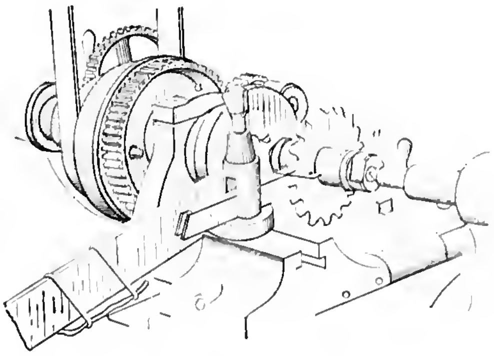

Fig. 36.

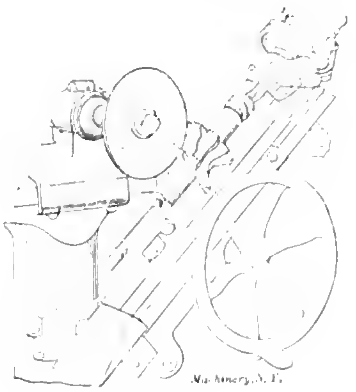

Fig. 37.

Fig. 38

While the cut shows the wheel grinding the teeth on the end of the mill, the teeth on the face may be ground by the use of the same form of wheel. This leaves the clearance at the desired angle and the surface straight rather than concave. To some mechanics this may appear to be straining a point, but the writer's experience convinces him that cutters ground so as to leave the clearance surface straight, rather than concave, will stand severe strains and heavy cuts, with less liability of chipping the cutting edges.

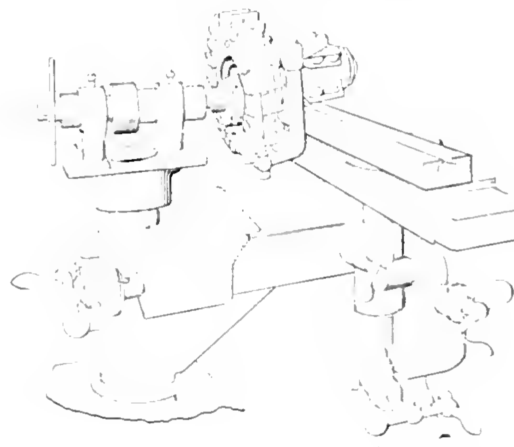

Fig. 41

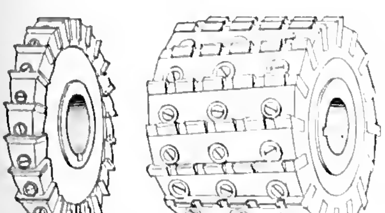

Fig. 39

Fig. 40

While a volume might be written on this subject, it is necessary to conclude, with a few words of caution: Do not make cutter teeth too fine; for many purposes they should be coarser than stated in table in previous article. Do not make them weak; strong teeth may be left much harder than weaker ones; do not overheat cutters when hardening; do not heat them unevenly; do not quench them unevenly in the bath, do not draw temper any more than is necessary; do not draw temper when grinding teeth for clearance; do not use the cutter on an arbor that does not fit the hole in milling machine spindle; do not use on an arbor that does not run true; do not use on an arbor that is smaller than hole in cutter, do not use collars on arbor, if any chips are bedded into their ends, as this would cause the arbor to spring, and the cutter run out

Do not use a nut on end of arbor, unless the end that bears against collars is true with threads on inside. Do not run the cutter at speeds that will cause it to heat and draw temper; on the other hand run at the maximum speed so as to produce the greatest amount of work possible. Do not fail to give the cutter all the feed it will stand. Do not fail to supply a suffi-

cient quantity of lubricant; this not only keeps the cutter cool, but it washes the chips from between the teeth, thus preventing friction. Do not use dull cutters; keep them sharp. Do not attempt to do a piece of milling on a machine, or in a fixture that is not heavy enough for the job. Lastly, do not fail to keep the milling machine well adjusted.

* * *

THE LINDMARK STEAM TURBINE.

It has been known for some time that the De Laval Steam Turbine Co., Stockholm, Sweden, were developing a compound steam turbine for use where greater power is desired than it has been found advisable to attempt to supply with the single-wheel De Laval turbine. This new turbine is made under the patents of T. G. E. Lindmark, the first of which was issued in this country in 1902. Along substantially the same lines as the Lindmark inventions are patents taken out by P. J. Hedlund and consigned to the same company. At present no information concerning the Lindmark turbine is available other than given in the patent records, but inasmuch as a new principle is involved in the operation of this invention, it will be of interest to explain the features of this turbine in so far as is now possible.

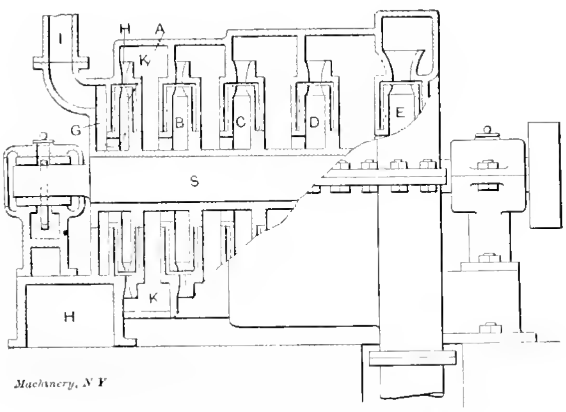

Fig. 1. Section of Lindmark Turbine.

Fig. 1 is a representation of a typical turbine containing the turbine wheels, *A*, *B*, *C*, *D*, and *E*, attached to the shaft, *S*, and rotating with it. Each wheel rotates in a separate compartment and is of the radial outflow type. The steam enters through an inlet pipe, *I*, to the steam space, *G*, whence it flows in the direction of the arrow into the first wheel, *A*. The two sides of the wheel converge at the periphery, forming a contracted outlet, and the steam discharges between curved vanes located in this contracted space, and flows through a diverging annular opening shown at *HH*, which guides the steam into a second compartment at *KK*. This process is repeated in connection with wheels *B*, *C*, *D*, and *E*.

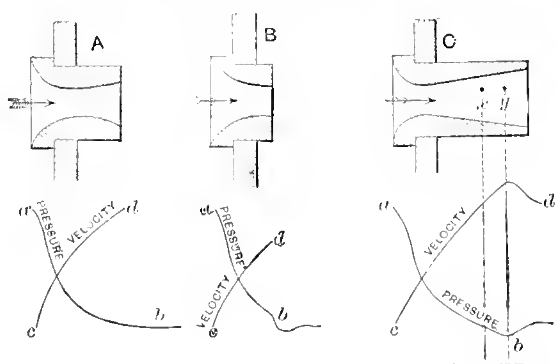

Fig. 2. Action of Steam Discharging from Nozzle under Different Conditions.

Purpose of the Turbine.

The peculiarity of the turbine lies in the pressure and velocity effect upon the steam of the converging and diverging passages as the steam progresses through the turbine. The purpose of the inventor is to transform the potential energy and pressure of the steam into kinetic energy and velocity as it flows through the converging passages of any given wheel, and then to transform the residual kinetic energy and velocity of the steam after it discharges from the wheel into potential energy and pressure during the passage through the annular space, *HH*.

Flow of Steam through Nozzles.

In order to explain the principle whereby this result is accomplished, it will be clearer to first refer to the action of steam in flowing through nozzles of different proportions. In Fig. 2 is shown a converging and diverging nozzle at *A*, through which steam flows from a higher to a lower pressure in the direction of the arrow. The nozzle is supposed to be proportioned so as to give complete expansion, and the pressure will accordingly drop from *a* to *b*, while the velocity will increase from *c* to *d* as indicated by the diagram below the nozzle.

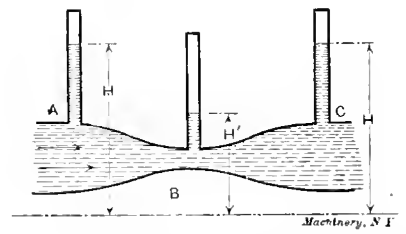

Fig. 3. Illustrating the Analogy of the flow of Water.

At *B* the diverging part of the nozzle is cut away so that the steam does not have the opportunity to fully expand until it has left the nozzle. The pressure, therefore, will gradually drop from *a* to *b*, at which latter point the steam leaves the nozzle and suddenly expands to the lower external pressure, producing a sudden change, *b*, in the curvature of the pressure line. Inasmuch as the expansion is not complete in the nozzle, the velocity line does not rise to as high a point as in the previous case.

At *C* the nozzle is shown lengthened out so as to produce over-expansion; that is to say, when the steam reaches point *x* in the nozzle it is expanded down to the external pressure of the medium into which the nozzle discharges, and beyond this point the steam will expand to a few pounds below the outside pressure until, say, point *y* is reached. After this the pressure will rapidly rise again until it reaches the external pressure at the mouth of the nozzle.

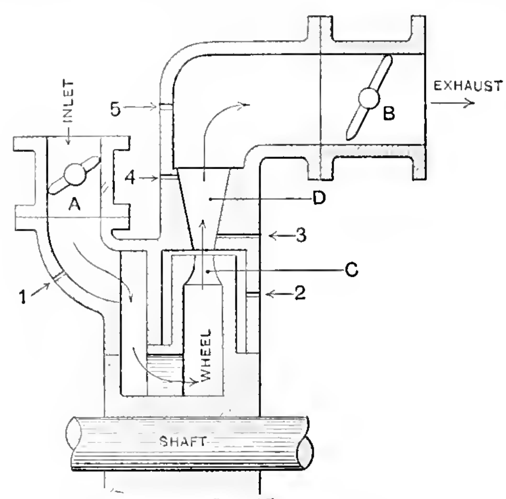

Fig. 4. Enlarged Detail of the Lindmark Turbine.

The Action in the Lindmark Turbine.

It is this latter action which takes place in the diverging passages of the Lindmark turbine. The steam having expanded to a very low pressure appears to follow laws somewhat similar to those governing an inelastic fluid like water, the static pressure and velocity of which change when flowing through a pipe with a varying cross section. Thus, in Fig. 3 is shown a pipe with a contracted section at *B*. Water is flowing in the direction of the arrow and the water rises in the first tube to a height *H* above the datum line. The water must here flow more rapidly in order that the same quantity shall pass through the pipe. This increases its kinetic energy, and consequently must reduce its potential energy, represented by its static pressure, and the water would

stand at a lower level, H', in the tube at this point. At C the flow has decreased again to the original velocity (neglecting friction), and the static pressure is again represented by H.

In like manner, when steam has been expanded to a low pressure and made to flow through a passage of varying section, an increase in the area of the passage will cause a retardation of the velocity of flow, and hence an increase in the pressure; whereas, if the expansion had not been carried to a low pressure, a passage with an increasing area of cross section would cause a decrease in the pressure and an increase in the velocity.

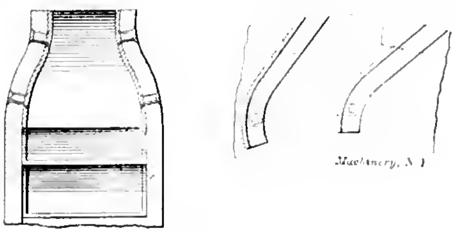

Fig. 5. Vanes of the Turbine.

The application of the principle can still further be explained by referring to the detail sectional sketch of the Lindmark turbine shown in Fig. 4, which represents half of one of the wheels and the connecting passages. Steam enters through the inlet and passes through the wheel in the direction of the arrow, and thence to the exhaust chamber, whence it escapes through the valve, B. Suppose first the turbine wheel to be blocked so that it will not turn, valves A and B to be wide open, and the steam to flow freely through the turbine. At points 1, 2, 3, 4, and 5, are openings to which gages may be attached for determining the pressure at the different points. The steam passages, C and D, will now act like a converging and diverging nozzle. At 1 the entering steam would be at boiler pressure; at 2 the pressure within the wheel casing would be substantially that at the throat of the nozzle, or about 6-10 of the boiler pressure,* at 3 it would be slightly lower; and at 4 nearly as low as the pressure in the exhaust space indicated by the gage at 5.

Action, Wheel Blocked, Exhaust Valve Partially Closed.

Now, suppose valve B to be closed as much as possible without increasing the pressure, 2, within the wheel chamber. The pressure at 1 will obviously remain as before, and the expansion in the passages, C, of the wheel will, as before, carry the pressure at the throat of the nozzle to six-tenths of the initial pressure. After the steam enters the diverging

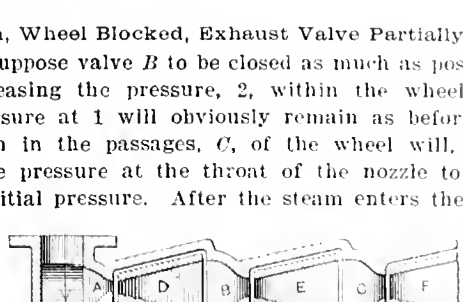

Fig. 6. Hedlund's Invention

space, D, however, over-expansion will occur just as in nozzle, C, Fig. 2. Probably the lowest pressure will be at or near the point where the gage is attached at 3, and from there on the velocity will decrease and the pressure will increase so that the gages at 4 and 5 will indicate a pressure considerably higher than that in the wheel chamber at 2, but lower than the initial pressure at 1.

* According to the well-known law that the pressure at the throat of a nozzle is 58% of the initial pressure, when the discharge takes place in a space the ambient pressure of which is at least 58% of the the initial pressure.

Action with the Wheel Rotating

Finally, if the wheel now be supposed to turn, instead of being blocked as before, and the exhaust valve still be partially closed, the principle of the steam's action will remain the same, the only change being due to the altered velocity of the steam owing to the fact that part of the velocity will be absorbed by the vanes of the rotating wheel. Under these conditions the velocity of flow when the steam reaches the entrance to the diverging portion will be less than before and this will produce an effect, which, according to the experiments of Lindmark, will reduce the pressures somewhat at points 4 and 5.

The Lindmark turbine is a reaction turbine, since the expansion of the steam and increase in velocity occur in the passages of the wheel vanes and the curvature given to them is similar to that employed for reaction wheels of other types. See Fig. 5.

Hedlund's Invention.

The Hedlund invention is the complement of the invention of Lindmark, and is designed to cover the same principle in turbine design, but with the converging passages located in the stationary part of the turbine and the diverging passages located in the rotating parts. In Fig. 6, A, B and C are the stationary converging passages, and D, E and F, the diverging passages in the rotating wheels attached to the shaft, S. In flowing through the turbine the passage of the steam fluctuates as shown in the diagram in the lower part of the figure, its general tendency from beginning to end being downward; while the velocity increases and decreases as indicated, but with an upward tendency.

GAS ENGINE ECONOMY.

GEORGE MILLER

The question of economy in the consumption of fuel is of great importance to the purchasers of gas or gasoline engines, and incidentally to the manufacturers of those engines, also; for, all things being equal, the firm that builds the most economical engine in the way of fuel consumption, or, in other words, that gives the best results for dollars expended, will get the largest amount of business, and as a corollary thereto, the greatest number of dollars. The question now arises, How shall we get the greatest amount of power out of a given sized engine with a given amount of fuel?

After having spent several years in studying this question and making experiments, and during that time having also built a large number of gas and gasoline engines, the writer of this article is firmly convinced that the position of the igniter in its relation to the charge of gas in the cylinder has far more to do with the economy of gas engines than is generally understood. It is a well-known fact that the charge of gas and air in the cylinder of an engine in operation is more or less stratified; that is, the air and gas are not thoroughly mixed, but portions of the charge are rich and others poor in gas. Someone might ask what difference this makes. When the explosion occurs the charge is entirely consumed and the piston receives its impulse from the expanding gases. The answer to this is: "All the difference between high and low economy in the consumption of fuel." If the charge is ignited at a point where it is rich in gas, the explosion is very sharp and strong and gives an injurious shock to the engine. The exhaust also is liable to be smoky, resulting in a loss of power. If the charge is ignited at a point where it is poor in gas the explosion is too weak, resulting also in a loss of power, to overcome which the engine is fed more gas or gasoline, with a consequent loss in economy. This argument is based on the assumption that the engine was at first fed the proper amount of gas and air to give the most efficient service. Now there are one or more parts of the indrawn charge where the air and gas are in exactly the right proportions. If the igniter can be brought in contact with the charge at this part the result is the greatest economy and efficiency.

It has been said by a prominent writer on gas engines that in designing a gas engine we can never be sure beforehand what the results will be. He says that an engine of given dimensions should develop a certain horse power, but when the engine is built and put in operation the result may be

very disappointing. In other words, the whole science of gas engine building, according to the writer, is a mere matter of guess work. Now I contend that this is wrong,—the science of gas engine building should be as exact as is the science of steam engine building. Imagine a man of to-day experimenting on steam engines in order to find out what size is required to run a certain plant! It is not for one instant claimed that the builders of gas engines have not advanced scientifically and intelligently in the direction of accurate knowledge as to the working of gas engines, nor do I claim that the placing of the Igniter in the proper position on the cylinder would put this industry among the exact sciences, but I do claim that it would make a great advance toward that end.
